8

9    **Abstract**

10

11    Atmospheric humidity plays an important role in climate analyses. Here we describe the production and key  
12    characteristics of a new quasi-global marine humidity product intended for climate monitoring,  
13    HadISDH.marine. It is an in-situ based multi-variable marine humidity product, gridded monthly at a 5° by 5°  
14    spatial resolution from January 1973 to December 2018 with annual updates planned. Currently, only reanalyses  
15    provide up to date estimates of marine surface humidity but there are concerns over their long-term stability. As  
16    a result, this new product makes a valuable addition to the climate record and will help address some of the  
17    uncertainties around recent changes (e.g. contrasting land and sea trends, relative humidity drying). Efforts have  
18    been made to quality control the data, ensure spatial and temporal homogeneity as far as possible, adjust for  
19    known biases in non-aspirated instruments and ship heights, and also estimate uncertainty in the data.  
20    Uncertainty estimates for whole-number reporting and for other measurement errors have not been quantified  
21    before for marine humidity. This is a companion product to HadISDH.land, which, when combined will provide  
22    methodologically consistent land and marine estimates of surface humidity.

23

24    The spatial coverage of HadISDH.marine is good over the Northern Hemisphere outside of the high latitudes but  
25    poor over the Southern Hemisphere, especially south of 20° S. The trends and variability shown are in line with  
26    overall signals of increasing moisture and warmth over oceans from theoretical expectations and other products.  
27    Uncertainty in the global average is larger over periods where digital ship metadata are fewer or unavailable but  
28    not large enough to cast doubt over trends in specific humidity or air temperature. Hence, we conclude that  
29    HadISDH.marine is a useful contribution to our understanding of climate change. However, we note that our

30 ability to monitor surface humidity with any degree of confidence depends on the continued availability of ship  
 31 data and provision of digitised metadata.

32

33 HadISDH.marine data, derived diagnostics and plots are available at  
 34 [www.metoffice.gov.uk/hadobs/hadisdh/indexMARINE.html](http://www.metoffice.gov.uk/hadobs/hadisdh/indexMARINE.html) (Willett et al., 2019).

35

## 36 1 Introduction

37

38 Water vapour plays a key role as a greenhouse gas, in the dynamical development of weather systems, and  
 39 impacts society through precipitation and heat stress. Over land, all these aspects are important and recent  
 40 changes have been assessed by Willett et al. (2014). Over the oceans, a major source of moisture over land, a  
 41 similar analysis is essential to enhance our understanding of the observed changes generally and as a basis for  
 42 worldwide evaluation of climate models. In recognition of its importance, the surface atmospheric humidity has  
 43 been recognised as one of the Global Climate Observing System (GCOS) Essential Climate Variables (ECVs).

44

45 Observational sources of humidity over the ocean are limited. The NOCSv2.0 (Berry and Kent, 2011) is the  
 46 only recently updated (January 1971 to December 2015) marine surface humidity monitoring product based on  
 47 in-situ observations, but it only includes specific humidity ( $q$ ). Satellite based humidity products exist (e.g.  
 48 HOAPS, Fennig et al., 2012) but these rely on the in-situ observations for calibration. Whilst quasi-global, the  
 49 uncertainties in the NOCSv2.0 product are large outside the northern, mid latitudes. In these regions the  
 50 NOCSv2.0 product shows a reasonably steadily rising trend over the period of record, similar to that seen over  
 51 land but with slightly different year-to-year variability. Most notably, 2010, a peak year over land in specific  
 52 humidity, does not stand out over ocean. Figure 1 and Willett et al. (2019) show global land and ocean specific  
 53 humidity and relative humidity (RH) series from available in-situ and reanalyses products. Older, static  
 54 products for the ocean (HadCRUH: Willett et al., 2008; Dai: Dai 2006) show increasing specific humidity to  
 55 2003 with similar variability to NOCSv2.0, and near-constant relative humidity. Both HadCRUH and Dai show  
 56 a positive relative humidity bias pre-1982 and slightly higher specific humidity over 1978-1984 compared to  
 57 NOCSv2.0. There is broad similarity between the reanalysis products and the in-situ products but with notable  
 58 differences for specific humidity in the scale of the 1998 peak and the overall trend magnitude. Differences are  
 59 to be expected given that the reanalyses are spatially complete in coverage, albeit derived only from their

60 underlying dynamical models over data sparse regions. The reanalyses exhibit near-constant to decreasing  
 61 relative humidity over oceans but with poorer agreement between both the reanalyses themselves and compared  
 62 to the in-situ products over land. This is to be expected given the larger sources of bias and error over ocean  
 63 (Sect. 2) and sparse data coverage. Importantly, land and marine specific humidity appear broadly similar  
 64 whereas for relative humidity, the distinct drying since 2000 over land is not apparent over ocean in reanalyses  
 65 and the previously available in-situ products finish too early to be informative. Note that the HadISDH.marine  
 66 described herein is shown here for comparison and will be discussed below.

67  
 68 A positive bias in global marine average relative humidity pre-1982 is apparent in Dai and HadCRUH, and has  
 69 previously been attributed to high frequencies of whole numbers in the dew point temperature observations prior  
 70 to January 1982 (Willett et al., 2008). This is less clear in the global average specific humidity timeseries.  
 71 ICOADS (International Comprehensive Ocean-Atmosphere Dataset) documentation  
 72 (<http://icoads.noaa.gov/corrections.html>) notes issues with the pre-1982 data especially mixed-precision  
 73 observations, where the air temperature has been recorded to decimal precision but the dew point temperature is  
 74 only available as a whole number. Such reporting was in accordance with the WMO Ship Code before 1982.  
 75 The documentation notes a truncation error in the dew point depression which would lead to a positive bias in  
 76 relative humidity. Alternatively, Berry (2009) show that patterns in the North Atlantic Oscillation coincide with  
 77 this time period and could have played a role. The NOCSv2.0 product is based on reported wet bulb temperature  
 78 rather than dew point temperature, where decimal precision is usually present. Hence, the NOCSv2.0 product is  
 79 expected to be unaffected by these rounding issues. Our analysis shows that changes to the code in January 1982  
 80 did not eliminate whole number reporting and high frequencies of whole numbers can be found throughout the  
 81 record in both air temperature and dew point temperature (Sect. 2.4 and Sect. 3.4).

82  
 83 Clearly, there is a need for more and up to date in-situ monitoring of humidity over ocean, especially for RH.  
 84 The structural uncertainty in estimates can only be explored if there are multiple available estimates so a new  
 85 product that explores different methodological choices, and extends the record, is complementary to the existing  
 86 NOCSv2.0 product and reanalyses estimates. Here we report the development of a multi-variable marine  
 87 humidity analysis HadISDH.marine.1.0.0.2018f (Met Office Hadley Centre; National Oceanography Centre,  
 88 2019 FINALISED AFTER REVIEW). This forms a companion product to the HadISDH.land monitoring  
 89 product, enabling the production of a blended global land and ocean product. We use existing methods where

possible from the systems used for building the long running HadSST dataset (Kennedy et al., 2011a, 2011b, 2019), and also use some of the bias adjustment methods employed for NOCSv2.0 (Berry and Kent 2011). We have explored the data to design new humidity specific processes where appropriate, particularly in terms of quality control and gridding.

HadISDH.marine is a climate-quality 5° by 5° gridded monthly mean product from 1973 to present (December 2018 at time of writing) with annual updates envisaged. Fields will be presented for surface (~10 m) specific humidity, relative humidity, vapour pressure, dew point temperature, wet bulb temperature and dew point depression. Air temperature will also be made available as a by-product but less attention has been given to addressing temperature specific biases. The product is intended for investigating long-term changes over large scales and so efforts have been made to quality control the data, ensure spatial and temporal homogeneity, adjust for known biases and also estimate remaining uncertainty in the data. In particular, we estimate uncertainties from whole-number reporting and other measurement errors that have not been quantified before for marine humidity.

Section 2 discusses known issues with marine humidity data. Section 3 describes the source data and all processing steps. Section 4 presents the gridded product and explores the different methodological choices and comparison with NOCSv2.0 specific humidity and ERA-Interim marine humidity. This section also includes a first look at the blended land and marine HadISDH product for each variable. Section 5 covers data availability and Section 6 concludes with a discussion of the strengths and weaknesses of the product.

## **2 Known issues affecting the marine humidity data**

### **2.1 Daytime solar-biases**

Marine air temperature measurements on board ships during the daytime are known to be affected by the heating of the ship or platform by the sun. This results in a positive bias during daylight and early night time hours. The bias varies with sunlight strength/cloudiness (and thus also latitude), relative wind speed, size and material of the ship. This solar heating bias affects both the wet bulb and dry bulb temperature measurements but, as noted by Kent and Taylor (1996), the ships do not act as a source of humidity or change the humidity content of the

120 air. As a result, biases in the specific humidity and dew point temperature due to the solar heating errors will be  
 121 negligible. However, care needs to be taken with relative humidity because estimates of the saturation vapour  
 122 pressure from the uncorrected dry bulb air temperature will be too high, leading to an underestimate in relative  
 123 humidity. Ideally, relative humidity should be estimated using the corrected dry-bulb temperature to calculate  
 124 the saturation vapour pressure and uncorrected wet and dry bulb temperature or dew point temperature to  
 125 calculate the vapour pressure.

126

127 Previously, efforts have been made to bias-adjust the air temperature observations for solar heating by  
 128 modelling the extra heating over the superstructure of the ship, taking account of the relative wind speed,  
 129 cloudiness, time of day, time of year and latitude (Kent et al, 1993; Berry et al., 2004; Berry and Kent, 2011).  
 130 These adjustments are complex and so we have decided not to attempt to implement them for our first version of  
 131 a marine humidity product given the wide variety of other issues we have accounted for. We have, however,  
 132 produced daytime, night time and combined products to investigate differences that may be caused by the solar  
 133 heating bias. Later versions of HadISDH.marine that apply bias corrections for solar heating may reduce the  
 134 amount of daytime data removed.

135

## 136 **2.2 Un-aspirated psychrometer bias**

137

138 Humidity measurements can be made in a variety of ways. Instruments can be housed in a screen with  
 139 ventilation slats, with or without additional artificial aspiration, or handheld in a sling or whirling psychrometer.  
 140 There is information on instrument ventilation provided up to 2014. Approximately 30 % of ship observations  
 141 have information in 1973, peaking at ~75 % by the mid-1990s, as summarised in Fig. 2. Initially, slings were  
 142 more common for the hygrometer and thermometer, but by 1982 a screen was more common. There is a  
 143 tendency for the screened instruments, in the absence of artificial aspiration, to give a wet bulb reading that is  
 144 higher relative to the slings/whirling instruments where airflow is ensured by the whirling motion. Bias  
 145 adjustments have been applied to un-aspirated humidity observations by Berry and Kent (2011), building on  
 146 previous bias adjustments of Josey et al. (1999) and Kent et al. (1993). They have also estimated the uncertainty  
 147 in the bias adjustments. We implement a modified version of their method of bias adjustment for the un-  
 148 aspirated observation types (Sect. 3.3.1) and uncertainty estimation. Uncertainties from instrument bias

adjustments will have some spatial and temporal correlation structure as the ships move around (Kennedy et al., 2011a).

151

### 2.3 Ship height inhomogeneity

153

Over time there has been a general trend for ship heights to increase. Kent et al. (2007; 2013) quantified the increase from an average of ~ 16m in 1973 to ~24m by the end of 2006. Instrument height information is available for some ships between the period of 1973 and 2014, providing heights for the barometer (HOB), thermometer (HOT), anemometer (HOA) and visual observing platform (HOP). Figure 3 shows the availability of height information and the mean and standard deviation of heights per year in each category for the ship observations selected here. Similar to the ventilation metadata, height information availability is low in 1973, peaking mid-1990s to 2000 and then declining slightly. Prior to 1994 only the platform height was available from WMO Publication 47. This was replaced in 1994 by the barometer height and augmented with the thermometer and visual observing heights from 2002 onwards (Kent et al., 2007). Anemometer heights have been available from WMO 47 since 1970. All four types of heights increase over time. We conclude that the mean height based on HOP/HOB/HOT increases from 17 m in 1973 to 23 m by 2014, which differs slightly to that in Kent et al., (2007). If uncorrected, this likely leads to a small artificial decreasing trend in air temperature and specific humidity, as, in general, these variables decrease with height away from the surface. The effect on relative humidity is less clear and depends on the relative effects on air temperature and specific humidity.

168

Prior studies (e.g. Berry and Kent, 2011; Berry 2009; Josey et al., 1999; Rayner et al., 2003; Kent et al., 2013) have applied height adjustments to the air temperature, specific humidity and wind speed measurements to adjust the measurements to a common reference height and minimise the impact of the changing observing heights on the climate record. These have been based on boundary layer theory and the bulk formulae, using the parameterisations of Smith (1980, 1988). In the absence of high-frequency observations of meteorological parameters for each observation location, allowing direct estimation of the surface fluxes, parameterisations have to be made and an iterative approach is necessary to estimate a height adjustment (Sect. 3.3.2). We have followed these previous approaches and estimated height adjustments for all observations and variables of interest. Where observing heights are unavailable we have made new estimates (Sect. 3.3.2). We have also provided an estimate of uncertainty on these height adjustments, which are larger where we have also estimated

179 the height of the observation. The uncertainties from height adjustments will have some spatial and temporal  
 180 correlation structure.

181

## 182 **2.4 Whole-number reporting biases**

183

184 Recording and reporting formats and practices have changed many times over the 20<sup>th</sup> century, affecting the  
 185 climate record. Some formats required the wet bulb temperature to be reported, others the dew point temperature  
 186 and some allowed either or both ([https://www.wmo.int/pages/prog/amp/mmop/documents/publications-](https://www.wmo.int/pages/prog/amp/mmop/documents/publications-history/history/SHIP.html)  
 187 [history/history/SHIP.html](https://www.wmo.int/pages/prog/amp/mmop/documents/publications-history/history/SHIP.html)). Some earlier formats restricted space to reporting temperature to whole numbers  
 188 only and this practice has continued with some ships continuing to report the dew point (or wet bulb)  
 189 temperature and sometimes even the dry bulb temperature to whole numbers. A practice of truncation of the  
 190 dew point depression has been noted for the pre-1982 data (<http://icoads.noaa.gov/corrections.html>) which  
 191 would result in spuriously high humidity (both in relative and actual terms). It is clear from the  
 192 ICOADS3.0.0/3.0.1 data that there has been a practice of reporting values to whole numbers rather than decimal  
 193 places, both for air temperature and dew point temperature. Rounding dew point temperature and air  
 194 temperature could result in a  $\pm 0.5^{\circ}\text{C}$  error individually or a just less than  $\pm 1^{\circ}\text{C}$  error in dew point  
 195 depression for a worst-case scenario combination.

196

197 Whole-number reporting is an issue throughout the record for both variables – a breakdown of air and dew point  
 198 temperature by decimal place over time is shown in Fig. S1. Air temperature also shows a disproportionate  
 199 frequency of half degrees (5s). The prevalence of whole numbers (0s) declines over time, dramatically in the  
 200 mid- to late 1990s for air temperature and from 2008 for both air and dew point temperature. This decline in the  
 201 1990s, and in part also the general decline, appears to be linked to an increase in numbers of moored buoys (see  
 202 Fig. 5), a similar analysis without the moored buoys (not shown) shows greater consistency over time. The dew  
 203 point temperature has two distinct peaks in whole number frequency in the 1970s and mid-1990 to early 2010s.  
 204 The latter peak is more pronounced when moored buoys are not included. The early peak is somewhat  
 205 consistent with the restriction in transmission space prior to January 1982. This was previously thought to have  
 206 been a possible cause of higher relative humidity over the period 1973-1981 compared to the rest of the record  
 207 in the HadCRUH marine relative humidity product (Willett et al., 2008). The pre-1982 moist bias was also  
 208 apparent in the global marine relative humidity product of Dai (2006). The NOCSv2.0 product preferentially

209 utilises the wet bulb temperatures from ICOADS which are not affected by whole number reporting to the same  
 210 extent. This could be part of the reason why NOCSv2.0 has a lower estimate of specific humidity anomalies  
 211 over the 1973-1981 period than HadCRUH or Dai, which use the dew point temperatures (Fig. 1).  
 212  
 213 Rounding of temperature alone should not affect the mean dew point temperature, specific humidity or vapour  
 214 pressure. However, as with the solar bias issue, it is sensitive to at what point the reported dew point  
 215 temperature was derived from the measured wet bulb temperature or relative humidity. Most likely, this would  
 216 be done prior to any rounding or truncating for reporting but during later conversion of various sources into  
 217 digital archives, or corrections, the dew point temperature may have been reconstructed  
 218 ([https://icoads.noaa.gov/e-doc/other/dupelem\\_1980](https://icoads.noaa.gov/e-doc/other/dupelem_1980)). The effect of rounding on a monthly mean gridbox average  
 219 should be small as these errors are random and should reduce with averaging. However, there is a risk of  
 220 removing very high humidity observations when a rounded dew point temperature then exceeds a non-rounded  
 221 air temperature. Such values are removed by our supersaturation check (Sect. 3.2). We do not feel able to  
 222 correct for this issue but instead include an uncertainty estimate for it. Overly frequent whole numbers are  
 223 identified both during quality control track analysis and deck analysis. This will be discussed in more detail in  
 224 Sect. 3.4. Clearly, there are various issues that can arise linked to the precision of measured and reported data in  
 225 addition to conversion between unit (e.g., Fahrenheit, Celsius and Kelvin, Fig. S1) and variable.

## 227 2.5 Measurement errors

228  
 229 All observations are subject to some level of measurement error and, outside of precision laboratory  
 230 experiments, the errors can be significant. The BIPM Guide to the Expression of Uncertainty in Measurement  
 231 (BIPM, 2008) describes two categories of measurement uncertainty evaluation. A Type A evaluation estimates  
 232 the uncertainty from repeated observations. A Type B evaluation of the uncertainty is based on prior knowledge  
 233 of the instrument and observing conditions. Within this study we use a Type B evaluation, adjusting for  
 234 systematic errors and inhomogeneities due to inadequate ventilation and changing observing heights (screen and  
 235 height adjustments) and estimate the residual uncertainty. For the random components, we make the conservative  
 236 assumption that all measurements were taken using a psychrometer (wet bulb and dry bulb thermometers),  
 237 which allows us to follow the HadISDH land methodology of Willett et al. (2013, 2014) as described in Sect.  
 238 3.4.. An assessment of the frequency of hygrometer types (TOH) within our selected ICOADS3.0.0/3.0.1 data

239 shows this to be a fair assumption as the vast majority of ships (where metadata is available: ~30 % increasing  
240 to ~70 % 1973 to 1995 then decreasing to 60 % by 2014) are listed as being from a psychrometer (Fig. 4).  
241 Electric sensors are becoming more common and made up ~30 % of observations by 2014 (the end of the  
242 metadata information). There are no instrument type metadata for ocean platforms or moored buoys. As it is  
243 likely that most buoy observations are made using RH sensors, we plan to develop an RH sensor specific  
244 measurement uncertainty in future versions.

245

## 246 **2.6 Other sources of error**

247

248 There are other issues specific to humidity measurements that may be further sources of error. Hygrometers that  
249 require a wetted wick (i.e., psychrometers), and thus a source of water, are vulnerable to the wick drying out or  
250 contamination, especially by salt in the marine environment. The wick drying results in erroneous readings of  
251 100 %rh where the wet bulb essentially behaves identically to the dry bulb thermometer. There can also be  
252 issues when the air temperature is close to freezing depending on whether the wet bulb has become an ice bulb  
253 or not and whether wet bulb or ice bulb calculations are used in any conversions. Humidity observing in low  
254 temperature can be generally problematic. For radiosondes, there has previously been a practice of recording a  
255 set low value when the humidity observation falls below a certain value (Wade 1994, Elliott et al. 1998). It is  
256 debateable how likely such low humidity values are over oceans and this practice has not been documented for  
257 ship observations. However, the set value issue is something to look out for. Wet bulb thermometers (and other  
258 instruments) can experience some hysteresis at high humidity where it takes some time to return to a lower  
259 reading. The wet bulb also requires adequate ventilation which has been discussed above.

260

261 These can be accounted for to a large extent through quality control but some error will inevitably remain. We  
262 can increase our confidence in the data by comparison with other available products and general expectation  
263 from theory.

264

## 265 **3 Processing the hourly data into a gridded product**

266

267 ICOADS Release 3.0 (Freeman et al., 2017) forms the base dataset for the HadISDH.marine humidity products.  
268 From January 1973 to December 2014 we use ICOADS.3.0.0 from <http://rda.ucar.edu/datasets/ds540.0/>. These

269 data include a unique identifier (UID) for each observation, a station identifier/ship callsign (ID), metadata on  
 270 instrument type, exposure and height in many cases. From January 2015 onwards we use ICOADS.3.0.1 from  
 271 the same source. These data include an ID and UID but no instrument metadata. Each observation is associated  
 272 with a deck number. These are identifiers for ICOADS national and trans-national sub-sets of data relating to  
 273 source e.g., deck 926 is the International Maritime Meteorological (IMM) data  
 274 (<https://icoads.noaa.gov/translation.html>). We utilise the reported air temperature ( $T$ ) and reported dew point  
 275 temperature ( $T_d$ ) as the source for our humidity products. Sea surface temperature (SST) and wind speed ( $u$ ) are  
 276 used for estimating height adjustments.

277

278 We calculate the specific humidity ( $q$ ), relative humidity (RH), vapour pressure ( $e$ ), wet bulb temperature ( $T_w$ ,  
 279 not the thermodynamic wet bulb but a close approximation to it) and dew point depression (DPD) for each point  
 280 observation. All humidity variables are derived from reported air and dew point temperature and ERA-Interim  
 281 climatological (from the nearest  $1^\circ$  by  $1^\circ$  pentad gridbox) surface pressure  $P_s$ , using the set of equations from  
 282 Willett et al., (2014) which can be found in Table S1. This provides consistency with HadISDH.land for later  
 283 merging. Note that for consistency we also use a fixed psychrometric coefficient that is identical for all  
 284 observations, minimising the impact of changing instrument types (e.g. whirling sling / ventilated measurement  
 285 vs screen) on the wet bulb temperature record. This is also consistent with what is done for HadISDH.land.

286

287 Additionally, we use ERA-Interim (Dee et al., 2011) reanalysis data to provide initial marine climatologies and  
 288 climatological standard deviations for all variables to complete a first iteration climatological outlier test. We  
 289 extract  $1^\circ$  by  $1^\circ$  gridded 6 hourly 2 m air and dew point temperature) and surface pressure to create 6 hourly  
 290 humidity variables and then pentad (5 day mean) climatologies and standard deviations over the 1981-2010  
 291 period. Note that several iterations are passed before finalising the product. Only the initial iteration uses ERA-  
 292 Interim climatologies, later iterations use climatologies built from the previous iteration's quality-controlled  
 293 observations (Sects. 3.2, 3.5, 4.1).

294

### 295 3.1 Data selection

296

297 We screen all ICOADS data to sub-select only those observations passing the following criteria:

- 298 - there must be a non-missing  $T$  and  $T_d$  value;

- 299 - the platform type (PT) must be in one of the following categories: a ship (a US Navy or unknown
- 300 vessel, a merchant ship or foreign military ship, an ocean station vessel off station /at an unknown
- 301 location, an ocean station vessel on station, a lightship, an unspecified ship - PT = 0, 1, 2, 3, 4, 5);
- 302 or a stationary buoy (moored or ice buoy - PT = 6, 8);
- 303 - the observation must have a climatology and standard deviation available for its closest 1° by 1°
- 304 pentad;
- 305 - the observation must pass the gross error checks: calculated RH must be between 0 and 150 %rh
- 306 (supersaturated values are flagged during quality control); both  $T$  and  $T_d$  must be between -80 and
- 307 65 °C; and calculated  $q$  must be greater than 0.0 g kg<sup>-1</sup>.

308

309 Other marine products (e.g., NOCSv2.0; Berry and Kent, 2011) solely use ship observations due to the lack of  
 310 buoy metadata available. In contrast, we include moored buoys for this version and to produce climatologies  
 311 because spatial coverage is of high importance. However, we provide ship-only and combined products. This  
 312 will be reassessed for future versions. Figure 5a shows the number of observations included in the initial  
 313 selection per year, broken down by platform type. The breakdown for day and night time observations  
 314 individually is near identical (not shown). Ship (PT = 5) observations make up almost the entire dataset until the  
 315 1990s. After this the number of moored buoys grows significantly to make up around ~50 % of observations  
 316 from 2000 onwards. The ship-only product (removal of moored buoys) significantly reduces the number of  
 317 observations in the recent period but gives a more consistent number of observations throughout the record. Our  
 318 use of climate anomalies should mitigate biasing due to uneven sampling to some extent. Note that the number  
 319 of gridboxes containing data may be a more relevant measure and that the vast increase in the number of buoys  
 320 has not actually resulted in the same level of increase in spatial coverage in terms of gridboxes (compare 2018  
 321 annual average maps for ship-only and combined HadISDH.marine in Fig. S2).

322

### 323 3.2 Quality control processing

324

325 We have not used any of the pre-set flags from ICOADS processing to ensure methodological independence of  
 326 HadISDH and a process that allows for exploration and analysis of different methodological choices. The  
 327 quality control processing employed here largely follows the methodology for HadSST4 (Kennedy et al., 2019)  
 328 with some changes to the climatology check and buddy check thresholds to increase regional sensitivity and

329 additional humidity specific checks. A flag for whole number prevalence has also been added but this is used for  
 330 uncertainty estimation and not to fail an observation. All observations have their nearest 1° by 1° pentad mean  
 331 climatology (source depends on iteration – Sect. 3.5) subtracted to create a climate anomaly.

332

333 Each observation is passed through a suite of basic quality control tests (base qc) which consist of:

- 334 - position check (failures removed): latitudes must be between -90° and 90° and longitudes must be  
 335 between -180° and 360° (later converted to -180° to 180°);
- 336 - date check (failures removed): hour, day, month and year must be valid quantities;
- 337 - blacklist check (failures removed): any observation from Deck 732 from a specified year and  
 338 region is blacklisted (Rayner et al., 2006, Kennedy et al, 2011a, Table S2);
- 339 - day check (daytimes are flagged): any value likely to be affected by the solar heating of a ship  
 340 where the sun was above the horizon an hour before the observation (based on the month, day,  
 341 hour, latitude and longitude; Kent et al. (2013)) is flagged;
- 342 - climatology check (failures flagged):  $T$  and  $T_d$  must be within a specified threshold of the nearest  
 343 1° by 1° pentad climatology;
- 344 - supersaturation check (failures flagged –  $T_d$  only):  $T_d$  must not be greater than  $T$ .

345

346 The climatology check differs from the static HadSST3 threshold of climatology  $\pm 10^\circ$  C. We have allowed for  
 347 a variable threshold depending on the nearest 1° by 1° pentad climatology standard deviation  $\sigma$ . This is set at 5.5  
 348  $\sigma$ . It accounts for the lower variability in the tropics and greater variability in the mid-latitudes. We have set  
 349 minimum and maximum  $\sigma$  values of 1° C and 4° C respectively resulting in a minimum range of  $\pm 5.5^\circ$  C and  
 350 a maximum range of  $\pm 22^\circ$  C. Several thresholds were tested with the selected threshold balancing avoiding  
 351 acute cut-offs in the data distribution while still removing obviously bad data (Figs. S3 to S6). Given that  
 352 outliers are assessed by comparing a point observation with a 1° by 1° pentad mean the thresholds have to be  
 353 relatively large.

354

355 Five additional checks are then applied at the ship track level where possible:

- 356 - track check (failures flagged): the distance and direction travelled by the ship must be plausible  
 357 and consistent;

- 358 - repeated value check (failures flagged): a  $T$  or  $T_d$  value must not appear in more than 70 % of a
- 359 ship track where there are at least 20 observations;
- 360 - repeated saturation check (failures flagged –  $T_d$  only): saturation ( $T_d = T$ ) must not persist for more
- 361 than 48 hours where there are at least 4 observations;
- 362 - buddy check (failures flagged – 3<sup>rd</sup> iteration only):  $T$  and  $T_d$  must be within a specified threshold of
- 363 the average of its nearest neighbours in space and time;
- 364 - whole number flag (whole numbers flagged): a  $T$  or  $T_d$  value must not appear as a whole number in
- 365 more than 50 % of a ship track where there are at least 20 observations.

366

367 The buddy check compares each observation's climate anomaly with the average of the climate anomalies of its  
 368 nearest neighbours in space and time, expanding the search area in space and time as necessary until at least one  
 369 neighbour observation is found. The permitted difference is set by the climatological standard deviation of the  
 370 candidate 1° by 1° pentad gridbox multiplied by an amount dependent on the number of neighbours present.

371 There are five levels of searches:

- 372 1.  $\pm 1^\circ$  latitude and longitude and  $\pm 2$  pentads: the climatological standard deviation is multiplied by
- 373 5.5, 5.0, 4.5 and 4.0 for 1-5, 6-15, 16-100 and >100 neighbouring observations respectively;
- 374 2.  $\pm 2^\circ$  latitude and longitude and  $\pm 2$  pentads: the climatological standard deviation is multiplied by
- 375 5.5 for >1 neighbouring observation;
- 376 3.  $\pm 1^\circ$  latitude and longitude and  $\pm 4$  pentads: the climatological standard deviation is multiplied by
- 377 5.5, 5.0, 4.5 and 4.0 for 1-5, 6-15, 16-100 and >100 neighbouring observations respectively;
- 378 4.  $\pm 2^\circ$  latitude and longitude and  $\pm 4$  pentads: the climatological standard deviation is multiplied by
- 379 5.5 for >1 neighbouring observation;
- 380 5. no neighbour  $\pm 2^\circ$  latitude and longitude and  $\pm 4$  pentads: the threshold is set at 500.

381 The thresholds used for the buddy check are wider than those previously used in HadSST3. This is to account  
 382 for the greater variability of air and dew point temperature, and sparser observation coverage. It is only applied  
 383 in the 3<sup>rd</sup> iteration of the quality control (Sect. 3.5).

384

385 Figure 5 shows the final number of observations passing through initial selection and then 3<sup>rd</sup> iteration quality  
 386 control by platform (PT) type. The quality control does not significantly affect one platform over another. The  
 387 performance of these tests is demonstrated for 4 example months in Figs. S3 to S6. These reveal a slight positive

388 bias in the removed air temperature observations and negative bias in removed dew point temperature.

389 Removals in terms of relative humidity and specific humidity similarly tend to have a negative bias. It is clear

390 that the majority of grossly erroneous observations are removed. The change in climatology between iterations

391 of the quality control process (Sect. 3.5) also makes a difference to removals. This is both because the

392 observation driven climatologies do not provide complete spatial coverage and because the ERA-Interim

393 climatologies are cooler and drier than the observations (Sect. 4.1). Removals are dense in the Northern

394 Hemisphere and especially sparse around the tropics. The addition of the buddy check in the 3<sup>rd</sup> iteration

395 considerably increases the removal rate, noticeably over the Southern Hemisphere and Tropics.

396

397 The quality-control flagging rate for the 3<sup>rd</sup> iteration reduces over time from ~25 % to ~18 %, as shown in Fig.

398 S7 This is driven by the buddy check and repeated saturation check. Proportionally more observations are

399 flagged during the daytime than night time but the interannual behaviour is very similar. The daytime increase is

400 driven by the larger number of air temperature buddy and climatology check failures. This could be due to the

401 issue of solar heating of the ship structure during the daytime. The main source of test fails by a large margin is

402 the buddy check, followed by the climatology check and repeated saturation check. There doesn't appear to be a

403 strong difference in the distribution of removals from each test between the 1973-1981 and 1982-1990 periods

404 that might explain the pre-1982 moist bias (Fig. S8, Sect. 4.2).

405

406 The whole number flags show very different behaviour to the other checks and to each other over time in Fig.

407 S7. These depend on the ability to assign each observation to a track/voyage and the frequency of whole number

408 observations on that voyage, hence, these flags are not a true reflection of the whole number frequency.

409 Compared to the actual proportion of whole numbers shown in Fig. S1, these tend to exaggerate the annual

410 patterns but the shape is broadly similar. This method of identifying problematic whole numbers appears to

411 under-sample the true distribution, especially for air temperature pre-1982. An additional deck-based check is

412 applied later for estimating uncertainty from whole numbers (Sect. 3.4).

413

414 Note that the NOCSv2.0 dataset, with which we compare our specific humidity data, includes an outlier check

415 that removes data greater than 4.5 standard deviations from the climatological mean. This test has already been

416 applied within the ICOADS format and so the NOCSv2.0 excludes any data with ICOADS trimming flags set

417 (Wolter 1997). They also apply a track check based on Kent and Challenor (2006).

418

### 419 3.3 Bias adjustments and associated uncertainties

420

421 Given the issues raised in Sect. 2, it is desirable to attempt to adjust the observations to improve the spatial and  
 422 temporal homogeneity and accuracy of the data. As discussed in Sect. 2.1, we have not attempted to adjust for  
 423 solar biases in this first version product. We have made adjustments for instrument and height biases and  
 424 estimated uncertainties in these adjustments.

425

#### 426 3.3.1 Application of adjustments for biases from un-aspirated instruments

427

428 We have shown that the majority of humidity observations have been made with a psychrometer (Fig. 4) and  
 429 that 30-70 % of instruments with metadata available have been housed within a non-aspirated screen (Fig. 2).  
 430 Berry and Kent (2011) found that applying a 3.4 % reduction to specific humidity observations from non-  
 431 aspirated screens was a reasonable adjustment to remove the bias relative to aspirated/well ventilated  
 432 observations (e.g., slings, whirled hygrometers or artificially aspirated instruments). Some uncertainty remains  
 433 after adjustment which they estimated to be  $\sim 0.2 \text{ g kg}^{-1}$ . We have used the hygrometer exposure metadata  
 434 (EOH) or the thermometer exposure (EOT) if EOH does not exist. We assume good ventilation for any  
 435 instruments that are aspirated (A), from a sling (SL) or ship's sling (SG) or from a whirling instrument (W). We  
 436 assume poorer ventilation for instruments that are from a screen (S), ship's screen (SN) or are unscreened (US)  
 437 and apply a bias adjustment. The reported exposure type of Ventilated Screens (VS) does not appear to mean  
 438 that the screen is artificially ventilated and so bias adjustments are also applied to these. We do not apply  
 439 adjustments to buoys and other non-ship data based on the assumption that these generally measure relative  
 440 humidity directly. For any ship observations with no exposure information we apply 55 % of the 3.4 %  
 441 adjustment based on the mean percentage of observations with EOH metadata that require an adjustment over  
 442 the 1973-2014 (metadata) period). This partial adjustment factor follows the method of Berry and Kent (2011)  
 443 and Josey et al. (1999) but differs in quantity. They assessed this over a shorter time period and found then that  
 444  $\sim 30$  % of observations were from poorly ventilated instruments.

445

446 To estimate the uncertainty in the non-aspirated instrument adjustment applied  $U_i$ , we use the Berry and Kent  
 447 (2011) and Josey et al. (1999) uncertainty estimate of  $0.2 \text{ g kg}^{-1}$  and apply this in all cases where an adjustment

or partial adjustment has been applied. This is treated as a standard uncertainty ( $1 \sigma$ ). In the case of partial adjustments for the ship observations with no metadata there is large uncertainty in both the adjustment and adjusted value. To account for this we use the amount of what would have been a full 3.4 % adjustment in addition to the  $0.2 \text{ g kg}^{-1}$  as the  $1 \sigma$  uncertainty.

To carry these adjustments to all other humidity variables we start with  $q$  and then propagate the adjustment and uncertainty amounts using the equations in Table S1. Using the original  $T$  (which does not need to be adjusted for poor ventilation) and ERA-Interim climatological surface pressure,  $e$  can be calculated from  $q$ .  $T_d$  and RH can be calculated from  $e$  and  $T$ . From these, the  $T_w$  and DPD can be calculated. The uncertainty is obtained by subtracting the new adjusted quantities from an adjusted quantity plus uncertainty, beginning again from the adjusted  $q$  plus the  $0.2 \text{ g kg}^{-1}$  uncertainty and full adjustment magnitude in the case of ships without metadata.

### 3.3.2 Application of adjustments for biases from ship heights

After bias adjustment for poor ventilation, all variables are adjusted to approximately 10 m elevation. This serves to account for the inhomogeneity from the systematic increase in ship height over time and for spatial inhomogeneity between observations made at different heights. In the absence of height adjustments, increasing ship heights likely lead to a small decrease in air temperature and specific humidity over time (Berry and Kent, 2011) because these quantities generally decrease with height. As Fig. 3 shows, the standard deviations in ships' instrument heights exceed 5 m in most cases. Also, we have included buoys in the processing so far and these can be very low (~4 m, e.g. Gilhousen, 1987) relative to ship observing heights.

The height of the hygrometer (HOH) must be estimated (HOHest) as no metadata is available. In the case of psychrometers, which are the most common instruments listed in the ship metadata, the wet and dry bulb thermometers are co-located. Figure 3 shows that the visual observation height (HOP) is the most commonly available information, followed by the barometer height (HOB) and then thermometer height (HOT). It also shows the mean and standard deviation of all observing heights including the anemometer (HOA). Hence, HOHest is obtained using the following methods in preference order:

1. HOP present and  $>2 \text{ m}$ : HOHest  $\mu = \text{HOP}$ ,  $\sigma = 1 \text{ m}$

2. HOB present and >2 m: HOHest  $\mu$  = HOB,  $\sigma$  = 1 m
3. HOT present and >2 m: HOHest  $\mu$  = HOT,  $\sigma$  = 1 m
4. HOA present and >12 m: HOHest  $\mu$  = HOA – 10,  $\sigma$  = 9 m
5. No height metadata: HOHest  $\mu$  =  $f$ (linear trend in mean HOP/HOB/HOT height, date),  $\sigma$  =  $f$ (linear trend in standard deviation HOP/HOB/HOT height, date)

The  $\mu$  and  $\sigma$  of the combined HOP, HOB and HOT increases from 16 m and 4.6 m respectively in January 1973 to 23 m and 11 m respectively in December 2014. Kent et al. (2007) and Berry and Kent (2011) used 16 m to 24 m between 1971 and 2007 so our estimate is very similar. The anemometer height is also required for the adjustments. We either use the provided HOA as long as it is greater than 2 m or set it to 10m above the HOHest. All buoys are assumed to be observing at 4 m, with anemometers at 5 m (<http://www.ndbc.noaa.gov/bht.shtml>).

Once HOHest has been obtained for each observation, the air temperature and specific humidity are adjusted to 10 m using bulk flux formulae. The methodology, assumptions and parameterisations largely follow that of Berry and Kent (2011), Berry (2009), Smith (1980, 1988) and Stull (1988). Essentially, the quantity of interest  $x$  can be adjusted to a reference height of 10 m as follows:

$$x_{10} = x - \frac{x_*}{\kappa} \left( \ln \left( \frac{z_x}{10} \right) - \psi_x + \psi_{x10} \right) \quad (1)$$

where  $x_*$  is the scaling parameter specific to that variable (e.g., friction velocity in the case of  $u$ , characteristic temperature or specific humidity in the case of  $T$  or  $q$  respectively),  $\kappa$  is the von Karman constant (0.41 used here),  $z_x$  is the observation height of the variable of interest,  $\psi_x$  is the stability correction for the variable of interest and is a function of  $f(z_x/L)$ ,  $\psi_{x10}$  is the stability correction for the variable of interest at a reference height of 10m and is a function of  $f(10/L)$  and  $L$  is the Monin-Obukov Length.

An iterative approach (as done for Berry and Kent 2011) is required to resolve Eq. (1) because we only have basic meteorological variables available at a single height for each observation. We start from  $T$ ,  $q$ ,  $u$ , sea surface temperature (SST), the co-located 1° by 1° gridbox pentad climatological surface pressure from ERA-Interim (climP), HOHest which becomes both  $z_q$  and  $z_r$  and our estimated anemometer height which becomes  $z_u$ .

For some observations the SST or  $u$  is missing. If SST is missing it is given the same value as  $T$  so in effect, no adjustment to  $T$  is applied. Either way, the SST is set to a minimum of  $-2^{\circ}\text{C}$  and a maximum of  $40^{\circ}\text{C}$ . If  $u$  is  $< 0.5\text{ m s}^{-1}$  it is given a light wind speed of  $0.5\text{ m s}^{-1}$ . If  $u$  is missing or  $>100\text{ m s}^{-1}$  it is assumed to be erroneous but given a moderate wind speed of  $6\text{ m s}^{-1}$ . We also approximate surface values  $T_0$ ,  $q_0$  and  $u_0$  where  $T_0 = \text{SST}$ ,  $q_0 = q_{\text{sat}}(\text{SST}) \times 0.98$  and  $u_0 = 0$ . Clearly, with so many necessary approximations there are many different plausible methodological choices, hence the need for multiple independent analyses that explore these different choices in order to quantify the structural uncertainty.

We begin the iteration by assuming a value for  $L$  depending on assumed stability:

- if  $(\text{SST} - T) > 0.2$ :  $L = -50$ , unstable conditions are assumed;
- if  $(\text{SST} - T) < -0.2$ :  $L = 50$ , stable conditions assumed;
- if  $(\text{SST} - T) \approx 0$ :  $L = 5000$ , neutral conditions assumed where  $L$  tends to  $\infty$ .

We also start with an assumption that the 10 m wind speed in neutral conditions  $u_{10n} = u$ . The iteration is continued until  $L$  converges to within 0.1, which it generally does. If after 100 iterations there is no convergence we either apply no adjustment or if absolute  $L$  is large ( $> 500$ ) we assume neutral conditions and take  $L$  (and all other parameters) as they are. In cases where  $u^*$  is very large (it should be  $< 0.5$  [Stull, 1988]) we also apply no adjustment. The iteration involves 21 steps as described in the Supplementary Material.

For most observations we arrive at a plausible  $L$ , friction velocity  $u^*$ ,  $\psi_s$  and  $\psi_{s10}$ . We then calculate the scaling parameters  $T^*$  and  $q^*$ :

$$T^* = \kappa \left( \ln \left( \frac{z_t}{z_{t0}} \right) - \psi_t \right)^{-1} (T - T_0) \quad (2a)$$

$$q^* = \kappa \left( \ln \left( \frac{z_q}{z_{q0}} \right) - \psi_q \right)^{-1} (q - q_0) \quad (2b)$$

where the neutral stability heat transfer coefficient  $z_{t0} = 0.001$  and the neutral stability moisture transfer coefficient  $z_{q0} = 0.0012$  (Smith 1988). The adjusted values for  $T_{10}$  and  $q_{10}$  can then be calculated from Eq. (1). From these we recalculate the other humidity variables using the equations in Table S1.

There is uncertainty in the obtained HOHest. Given that this is a best estimate we assume that the uncertainty in the height is normally distributed and use the standard deviation in the height estimate used to calculate an uncertainty range in the height adjusted value  $x$  of  $xH_{min}$  to  $xH_{max}$ . Following the BIPM Guide to the Expression of Uncertainty in Measurement (BIPM, 2008), the standard uncertainty ( $1 \sigma$ ) for the height adjusted value ( $U_h$ ) is then given by:

$$U_h = \frac{(xH_{max} - xH_{min})}{\sqrt{9}} \quad (3)$$

The range  $xH_{min}$  to  $xH_{max}$  depends on the source of HOHest and associated  $\sigma$ , as listed above. There are several scenarios where estimating the uncertainty in this way is not possible or calculation of an adjustment is not possible. Also,  $U_h$  for buoys is highly uncertain given the lack of height information available. These alternative scenarios are documented in Table 1.

### 3.4 Estimating residual uncertainty at the observation level

Three other sources of uncertainty affect the marine humidity data at the observation level. These are measurement uncertainty  $U_m$ , climatology uncertainty  $U_c$  and whole number uncertainty  $U_w$ . These are all assessed as  $1 \sigma$  standard uncertainties.

We have estimated  $U_m$  for each observation following the method used for HadISDH.land (Willett et al., 2013, 2014). This assumes that humidity was measured using a psychrometer which is a reasonable assumption for the marine ship data (Fig. 4). The HadISDH.land measurement uncertainty is based on an estimated standard ( $1 \sigma$ ) uncertainty in the wet bulb and dry bulb instruments of  $0.15^\circ \text{C}$  and  $0.2^\circ \text{C}$  respectively. As shown in Table 3, the equivalent uncertainty for the other variables depends on the temperature. The uncertainty is applied as a standard uncertainty in RH depending on which bin the air temperature falls in. This is then propagated through the other variables starting with vapour pressure, using the equations in Table S1.

Whole numbers of air and/or dew point temperature that have either been flagged as such during quality control (Sect. 3.2), or that belong to a source deck/year where whole numbers make up more than two times the frequency of other decimal places (Table S4), are given and uncertainty  $U_w$ . These decks and years where whole

566 numbers are very common differ for air and/or dew point temperature. Clearly with so many decks affected, the  
 567 removal of entire decks to remove any whole number biasing could easily reduce sampling to critically low  
 568 levels. We cannot distinguish between observations that have been rounded versus those that have been  
 569 truncated so we assume that all offending whole numbers have been rounded. This means that the value could  
 570 be anywhere between  $\pm 0.5^\circ \text{C}$ , with a uniform distribution. Hence, where only air or dew point temperature is  
 571 an offending whole number the standard  $1\sigma$  uncertainty expressed in air or dew point temperature ( $^\circ \text{C}$ ) is:

572

$$573 \quad U_w = \frac{0.5}{\sqrt{3}} \quad (4)$$

574

575 Where both air and dew point temperature are offending whole numbers the standard  $1\sigma$  uncertainty expressed  
 576 in air or dew point temperature ( $^\circ \text{C}$ ) for dew point depression, relative humidity and wet bulb temperature is:

577

$$578 \quad U_w = \frac{1}{\sqrt{3}} \quad (5)$$

579

580 There is uncertainty  $U_c$  in the climatological values used to calculate climate anomalies because of missing data  
 581 over time, uneven and sparse sampling in space and also the inevitable mismatch between a point observation  
 582 and a  $1^\circ$  by  $1^\circ$  gridded pentad climatology. This uncertainty reduces with the number of observations  
 583 contributing to the climatology  $N_{obs}$  and with the variability of the region  $\sigma_{clim}$ . The climatologies used to create  
 584 the anomalies have undergone spatial and temporal interpolation to move from  $5^\circ$  by  $5^\circ$  gridded monthly  
 585 climatologies and climatological standard deviations  $\sigma_{clim}$  to maximise coverage and so it is not straightforward  
 586 to assess the number of observations contributing to each  $1^\circ$  by  $1^\circ$  gridded pentad climatology and the true  $\sigma_{clim}$   
 587 is likely greater. Therefore, we assume a worst case scenario of  $N_{obs} = 10$ . Hence, for a standard  $1\sigma$  uncertainty:

588

$$589 \quad U_c = \frac{\sigma_{clim}}{\sqrt{N_{obs}}} \quad (6)$$

590

### 591 3.5 Gridding of actual and anomaly values and uncertainty

592

593 To create a quasi-global monitoring product the raw observations need to be gridded. The spatial density is too  
 594 low for high resolution grids and the intended purpose is for this marine product to be blended with the

595 HadISDH.land humidity product which is on a 5° by 5° grid at monthly resolution. Hence, the raw hourly  
 596 observations must be averaged to monthly mean gridded values.

597

598 The sparsity of the data means that there is a risk of bias due to poor sampling. A 5° by 5° gridbox covers an  
 599 area greater than 500 km<sup>2</sup> by 500 km<sup>2</sup> which, despite the large correlation decay distances of both temperature  
 600 and humidity, can include considerable variability. Furthermore, a monthly mean can be made up of a strong  
 601 diurnal cycle and considerable synoptic variability. This is minimised by the use of climate anomalies but  
 602 regardless, care should be taken to ensure sufficient sampling density while maximising coverage where  
 603 possible.

604

605 Several data-density criteria were trialled to balance spatial coverage and poor representativeness (high  
 606 variance) of the gridbox averages. Climate anomalies are created at the raw observation level by subtracting the  
 607 nearest 1° by 1° pentad climatology (1981-2010) and so we can grid both the actual values and the anomalies.  
 608 Gridding of the anomalies is safer than gridding actual values in terms of biasing through poor sampling density  
 609 because the correlation length scales of anomalies are higher than for actual temperatures. Initially, ERA-  
 610 Interim is used to provide a climatology. This then requires an iterative approach to produce an initial  
 611 observation-based climatology and improve the climatology through quality control. To reduce biasing further  
 612 we grid the data in six stages to create an average at each stage. The entire process including quality control,  
 613 bias adjustment, gridding and three iterations, is shown diagrammatically in Fig. 6 and each gridding stage  
 614 described below.

615

- 616 1. Create 1° by 1° 3-hourly gridded means from the hourly observations of actuals and anomalies;  
 617 there must be at least one observation.
- 618 2. Create separate 1° by 1° daytime and nighttime gridded means from the 1° by 1° 3-hourly gridded  
 619 mean actuals and anomalies; there must be at least one 1° by 1° 3-hourly grid.
- 620 3. Create 5° by 5° monthly daytime and nighttime gridded means from the 1° by 1° daytime and  
 621 nighttime gridded mean actuals and anomalies; there must be at least 0.3\*days in the month of 1°  
 622 by 1° daily grids.

- 623 4. Create combined 5° by 5° monthly gridded means from the 5° by 5° monthly daytime and  
 624 nighttime gridded mean actuals and anomalies; there must be at least 1 5° by 5° monthly daytime  
 625 or nighttime gridded mean.
- 626 5. Create 1981-2010 5° by 5° monthly mean climatologies and standard deviations from the 5° by 5°  
 627 monthly gridded means of actuals and anomalies; there must be at least 10 5° by 5° monthly  
 628 gridded means.
- 629 6. Renormalise the gridded anomalies by subtracting the monthly anomaly 1981-2010 climatology to  
 630 remove biases from use of the previous iteration climatology (Sect. 4.1).

631

632 At each iteration the gridded observation based climatologies are infilled linearly over small gaps in space and  
 633 time and then interpolated down to 1° by 1° pentad resolution. The observations are too sparse to create such  
 634 high-resolution grids directly.

635

636 The observation uncertainties also need to be gridded and the total observation uncertainty  $U_o$  calculated. Ships  
 637 move around, and so their uncertainties also track around the globe. This means that the uncertainty in any one  
 638 point / gridbox bears some relationship to nearby points / gridboxes over time and space and cannot be treated  
 639 independently. Correlation needs to be accounted for both in gridding and subsequently creating regional  
 640 averages from gridboxes to avoid underestimation. The five sources of observation uncertainty are summarised  
 641 in Table 1. The non-aspirated instrument adjustment uncertainty  $U_i$ , height adjustment uncertainty  $U_h$  and  
 642 climatology uncertainty  $U_c$  persist over time and space as ships move around. These are accordingly treated as  
 643 correlating completely within one gridbox month. The measurement uncertainty  $U_m$ , and whole number  
 644 uncertainty  $U_w$  are likely to differ observation to observation and so treated as having no correlation within one  
 645 gridbox month. Hence, observation uncertainty sources are first gridded individually, following the first four  
 646 steps outlined above and taking into account correlation where necessary. The gridded uncertainty sources are  
 647 then combined to give a total observation uncertainty for each gridbox. For those that do not correlate ( $U_m$  and  
 648  $U_w$ ) the gridbox mean uncertainties  $U_{gb}$  are combined over  $N$  points in time and space as follows:

649

$$650 \quad U_{gb} = \frac{\sqrt{a^2 + b^2 + \dots + n^2}}{N} \quad (7)$$

651

For those sources that do correlate ( $U_c$ ,  $U_i$  and  $U_h$ ), assuming  $r = 1$ , the gridbox mean uncertainties  $U_{gb}$  are combined over  $N$  points in time and space as follows:

$$U_{gb} = \frac{a+b \dots + n}{N} \quad (8)$$

To create the total observational uncertainty the gridbox quantities of the five uncertainty sources can then be combined in quadrature:

$$U_o = \sqrt{U_c^2 + U_m^2 + U_w^2 + U_h^2 + U_i^2} \quad (9)$$

Given the general sparsity of observations across each gridbox month and the uneven distribution of observations across each gridbox and over time there is also a gridbox sampling uncertainty component,  $U_s$ . This is estimated directly at the  $5^\circ$  by  $5^\circ$  monthly gridbox level and follows the methodology applied for HadISDH.land (Willett et al., 2013, 2014), denoted  $SE^2$ , which is based on station-based observations from Jones et al (1997):

$$U_s = \frac{(\bar{s}_i^2 \bar{r}(1-\bar{r}))}{(1+(N_s-1)\bar{r})} \quad (10)$$

where  $\bar{s}_i^2$  is the mean variance of individual stations within gridbox,  $\bar{r}$  is the mean inter-site correlation and  $N_s$  is the number of stations contributing to the gridbox mean in each month. The mean variance of individual stations within the gridbox is estimated as:

$$\bar{s}_i^2 = \frac{(\hat{S}^2 N_{SC})}{(1+(N_{SC}-1)\bar{r})} \quad (11)$$

where  $\hat{S}^2$  is the variance of the gridbox monthly anomalies over the 1982-2010 climatology period and  $N_{SC}$  is the mean number of stations contributing to the gridbox over the climatology period. The mean inter-site correlation is estimated by:

$$\bar{r} = \frac{x_0}{X} \left( 1 - \exp\left(-\frac{x_0}{X}\right) \right) \quad (12)$$

681  
 682 where  $X$  is the diagonal distance across the gridbox and  $x_0$  is the correlation decay length between gridbox  
 683 means. We calculate  $x_0$  as the distance (gridbox midpoint to midpoint) at which correlation reduces to  $1/e$ . To  
 684 account for the fact that marine observations generally move around at each time point we use the concept of  
 685 pseudo-stations to modify this methodology. For any one day there could be  $25\ 1^\circ$  by  $1^\circ$  gridboxes and so we  
 686 assume that the maximum number of pseudo-stations per gridbox is 25 which is broadly consistent with the  
 687 number of stations per gridbox in HadISDH.land. Over a month then, there could be a maximum of  $775\ 1^\circ$  by  $1^\circ$   
 688 daily gridboxes contributing to each  $5^\circ$  by  $5^\circ$  monthly gridbox. Given ubiquitous missing data and sparse  
 689 sampling the maximum in practice is closer to 600. Using these values we then scale the actual number of  $1^\circ$  by  
 690  $1^\circ$  daily gridboxes contributing to each  $5^\circ$  by  $5^\circ$  monthly gridbox to provide a pseudo-station number between 1  
 691 and 25 for each month ( $N_s$ ) and then the average over the climatology period ( $N_{sc}$ ).

692

693 The gridbox  $U_o$  and  $U_s$  uncertainties are then combined in quadrature, assuming no correlation between the two  
 694 sources. This gives the full gridbox uncertainty  $U_f$ . Calculation of regional average uncertainty and spatial  
 695 coverage uncertainty is covered in Sect. 4.

696

#### 697 **4 Analysis and validity of the gridded product**

698

699 The final gridded marine humidity monitoring product presented as HadISDH.marine.1.0.0.2018f is the result of  
 700 the 3<sup>rd</sup> iteration quality-control and bias-adjustment of ship-only observations average into  $5^\circ$  by  $5^\circ$  gridded  
 701 monthly means (Fig. 6). There are four reasons for only using the ship observations. Firstly, the increase in  
 702 spatial coverage in the combined ship and buoy product is actually fairly small (Fig. S2) and only during the  
 703 latter part of the record. Secondly, a dataset intended for detecting long-term changes in climate should have  
 704 reasonably consistent input data and coverage over time. Thirdly, we believe that the buoy data are less reliable  
 705 given their proximity to the sea surface and exposure to sea spray contamination in addition to the lower  
 706 maintenance frequency compared to ship data. Fourthly, there are no metadata available for buoy observations  
 707 which makes it difficult to apply necessary bias adjustments or estimate uncertainties. Actual monthly means,  
 708 anomalies from the 1981-2010 climatology (not standardised by division with the standard deviation), the  
 709 climatological means and standard deviation of the climatologies, uncertainty components and number of  
 710 observations for both products are all made available as netCDF from [www.metoffice.gov.uk/hadobs/hadisdh/](http://www.metoffice.gov.uk/hadobs/hadisdh/).

711

#### 712 4.1 Comparison of climatologies between HadISDH.marine and ERA-Interim

713

714 At the end of each iteration (Fig. 6), observation-based climatology fields are created at both the monthly 5° by  
 715 5° grid and, by interpolation, pentad 1° by 1° grid (Sect. 3.5). These are then used to quality control and create  
 716 anomaly values for the next iteration. Hence, the 2<sup>nd</sup> iteration quality-controlled data are used to build the final  
 717 3<sup>rd</sup> iteration and therefore, there should be no lasting effect from having used the ERA-Interim fields initially.  
 718 The quality-controlled, buddy-checked and bias-adjusted 3<sup>rd</sup> iteration is used to create the final climatology  
 719 provided to users.

720

721 Specific humidity, relative humidity and air temperature difference maps of the 2<sup>nd</sup> iteration minus ERA-Interim  
 722 pentad 1° by 1° grid climatologies and climatological standard deviations are shown in Figs. S9 to S14 for a  
 723 selection of pentads. Note that ERA-Interim fields are for 2 m above the ocean surface whereas the raw  
 724 observations range between approximately 10 m to 30 m above the surface. In normal conditions we may  
 725 therefore expect ERA-Interim to provide climatologies that are warmer and moister than the observations.  
 726 However, overall, ERA-Interim appears drier (both in absolute and relative terms) and cooler than the  
 727 observation based climatologies. For humidity this is consistent with the results of Kent et al. (2014). For the  
 728 majority of gridboxes these differences are within  $\pm 2 \text{ g kg}^{-1}$ , %rh and °C. However, differences are especially  
 729 strong around coastlines with magnitudes exceeding  $\pm 10 \text{ g kg}^{-1}$ , %rh and °C. This is to be expected given that  
 730 ERA-Interim coastal gridboxes will include effects from land, especially at the relatively coarse 1° by 1° grid  
 731 resolution. For relative humidity there are more regions where ERA-Interim is more saturated and there is more  
 732 seasonality in the differences. Relative humidity is less stable spatially and on synoptic time scales and also  
 733 more susceptible to biases and errors than specific humidity and air temperature, largely because it is affected by  
 734 errors in both air temperature and dew point temperature. For temperature, the coastal difference can be positive  
 735 or negative depending on the season.

736

737 The climatological standard deviations are generally lower in the 2<sup>nd</sup> iteration observations compared to ERA-  
 738 Interim. Differences are generally between  $\pm 2 \text{ g kg}^{-1}$ , %rh and °C but for relative humidity there are expansive  
 739 regions in the extratropics to mid-latitudes, especially in the Northern Hemisphere where climatological  
 740 standard deviations are up to 5 %rh lower in the observations. The generally lower variability in the

741 observation-based climatology is to be expected given the interpolation from monthly mean resolution and  
 742 interpolation over neighbouring gridboxes where data coverage is limited. However, much of the tropics,  
 743 particularly in the Southern Hemisphere tends to show more variability in the observations. Similarly, many of  
 744 the peripheral gridboxes (those at the edge of the spatial coverage and therefore more likely to be interpolated  
 745 from nearby gridboxes rather than based on actual data) show higher variability for specific and relative  
 746 humidity and lower variability for air temperature. All of these gridboxes are in data sparse regions which likely  
 747 contributes to the higher variability. Ideally, observation based climatologies would be created directly at the  
 748 pentad  $1^\circ$  by  $1^\circ$  grid but this severely reduces spatial coverage of the climatology fields and any product based  
 749 on them. A balance has to be made between coverage and quality.

750

751 Annual mean  $5^\circ$  by  $5^\circ$  climatologies (no interpolation) from the 3<sup>rd</sup> iteration quality-controlled, bias-adjusted  
 752 ship-only product are shown in Fig. 7 for specific humidity, relative humidity, air temperature and dew point  
 753 temperature. These have a minimum data presence threshold of 10 years for each month over the climatology  
 754 period and at least 9 climatological months present for the annual climatology. Data coverage is virtually non-  
 755 existent in the Southern Hemisphere below  $40^\circ$  S and Northern Hemisphere coverage diminishes drastically  
 756 above  $60^\circ$  N. These climatologies are as expected for these variables and compare well in terms of broad spatial  
 757 patterns with ERA-Interim (not shown). There is good spatial consistency considering that no interpolation has  
 758 been conducted meaning that any erroneous gridboxes should stand out. We conclude that as a first version  
 759 product, these climatologies look reasonable.

760

#### 761 **4.2 Analyses of global average for various processing stages and with other products**

762

763 Global average quantities are key measures of climate change and so we focus here on the differences arising  
 764 from the various processing steps of HadISDH.marine along with the NOCSv2.0 specific humidity and ERA-  
 765 Interim reanalysis products. Global averages ( $70^\circ$  S to  $70^\circ$  N) have been created by weighting each gridbox by  
 766 the cosine of its latitude at gridbox centre. All timeseries shown are the renormalised anomalies with a zero-  
 767 mean over the 1981-2010 period. Figs. 8 to 11 show timeseries for specific humidity, relative humidity, dew  
 768 point temperature and air temperature respectively. Decadal linear trends (shown) are computed using the  
 769 median of pairwise slopes with ranges representing the 90<sup>th</sup> percentile confidence interval.

770

771 For all variables, there are only small differences in the global average timeseries between the various  
 772 processing steps – from the raw data (noQC) to the 3<sup>rd</sup> iteration quality-controlled (NBC) and then the bias-  
 773 adjusted data (BClocal). They are smallest for air temperature and largest for relative humidity. Both the  
 774 interannual variability and long-term linear trends are very similar, and the trends in the global average are  
 775 positive over the 1973-2018 period for specific humidity, dew point temperature and air temperature, and  
 776 negative for relative humidity. We consider these trends to be significant because the 90<sup>th</sup> percentile confidence  
 777 intervals around the trend are not large enough to bring the direction of the trends into question. The linear  
 778 trends for the final HadISDH.marine.1.0.0.2018f version are  $0.07 \pm 0.01 \text{ g kg}^{-1} \text{ decade}^{-1}$ ,  $-0.09 \pm 0.02 \text{ \%rh}$   
 779  $\text{decade}^{-1}$ ,  $0.08 \pm 0.01^\circ \text{ C decade}^{-1}$  and  $0.11 \pm 0.01^\circ \text{ C decade}^{-1}$  for specific humidity, relative humidity, dew  
 780 point temperature and air temperature respectively. Hence, we conclude that HadISDH.marine shows  
 781 moistening and warming since the 1970s globally in actual terms but that the air above the oceans has become  
 782 less saturated and drier in relative terms. This differs from theoretical and model-based expectations of a small  
 783 positive or no change in relative humidity over ocean (Byrne and O’Gorman, 2013, 2018).

784

785 Since there are considerable known issues affecting the marine humidity data, and because there are large  
 786 outliers (Figs. S3 to S6), the effect of quality (noQC compared to NBC), might be expected to be large.  
 787 Furthermore, approximately 25 %, dropping steadily over time to 18 % of the initial selection of data have been  
 788 removed by the quality control (Fig. 6), so there is a considerable difference in the amount of data contributing  
 789 to the quality-controlled version compared to the raw version. Despite all of this, differences are relatively  
 790 small. Overall, the quality control makes the positive trends smaller (specific humidity, dew point temperature  
 791 and air temperature) and negative trends larger (relative humidity). The effect of quality control, including  
 792 buddy checking, is largest in the 1970s to early 1980s, when the largest amount of data was removed by quality  
 793 control. This is especially noticeable for relative humidity and dew point temperature, and the same period as  
 794 the previously noted moist relative humidity bias, suggesting that the pre-1982 bias could be an artefact of the  
 795 quality control. This could be due to erroneous removal of good data but investigation (Figs. S3 to S8) suggests  
 796 that much of the data removal was appropriate – many very low relative humidity values were removed. It could  
 797 also be an artefact of the reduced number of observations after quality control, reducing the chance of averaging  
 798 out random error. Either way, the pre-1982 moist bias is apparent in HadISDH.marine and quality control of the  
 799 pre-1982 data is an area for more research in future versions.

800

801 The bias adjustment (BClocal, BClocalHGT, BClocalINST) reduces the negative trends in relative humidity  
 802 both compared to the raw (noQC) and quality-controlled (NBC) data. It increases the positive trends in specific  
 803 humidity and dew point temperature relative to the quality-controlled data but reduces the trends compared to  
 804 the raw data. The effect of bias adjustment is negligible for air temperature, which only has adjustment for ship  
 805 height applied. For the humidity variables the height adjustment has a far larger effect than the non-aspirated  
 806 instrument adjustment. The non-aspirated instrument adjustment makes the positive trends in specific humidity  
 807 and dew point temperature slightly smaller and the negative trends in relative humidity slightly larger. The  
 808 height adjustment has the opposite effect. For relative humidity, the bias adjustments appear to have introduced  
 809 greater intra-decadal scale variability but retained the interannual patterns, again highlighting the sensitivity of  
 810 relative humidity compared to the other variables. Given that these biases exist we do have to try and mitigate  
 811 their impact. However, this is a focus area for investigation and improvements in future versions of  
 812 HadISDH.marine.

813  
 814 The timeseries that include data from moored buoys compared to those from ships only ('all' versus 'ship')  
 815 show smaller positive trends for specific humidity, dew point temperature and air temperature and larger  
 816 negative trends for relative humidity. Moored buoys begin to play a role from the late 1980s, increasing in  
 817 number dramatically to make up over 50 % of the observations by 2015. The 'all' timeseries can be seen to  
 818 diverge slightly from the 'ship' timeseries in the latter part of the record. Therefore, it is more consistent to  
 819 produce the final HadISDH.marine version without inclusion of moored buoy data.

820  
 821 Before quality control there are more daytime ship observations than night time ship observations in the early  
 822 record (~1000000 compared to ~800000 per year) but this evens out by the end of the record to ~900000 per  
 823 year. However, the quality control removes more daytime observations than night time observations, especially  
 824 in the 1970s and 1980s such that both contribute ~700000 observations per year, dipping in the middle of the  
 825 record. There has been no bias adjustment for solar heating of ships applied in this version of HadISDH.marine  
 826 so the daytime data may contain some artefacts of solar heating. If this is a problem it should affect the air  
 827 temperature and relative humidity but not the dew point temperature or specific humidity (Sect. 2.1). While the  
 828 full dataset (both) combines both daytime and night time data, for various gridboxes and seasons there is only  
 829 either a daytime or night time value present. As such, the 'both' timeseries and its linear trend may not be a  
 830 straightforward average of the 'day' and 'night' timeseries and trends. In the case of specific humidity, the

831 daytime and night time global average timeseries have slightly larger positive trends than the combined  
 832 timeseries and for relative humidity they have smaller negative trends than the combined series. For specific  
 833 humidity, dew point temperature and air temperature the ‘day’ and ‘night’ trend differences are essentially  
 834 negligible, with linear trend differences within  $0.01 \text{ g kg}^{-1} \text{ decade}^{-1}$  or  $0.01^\circ \text{ C decade}^{-1}$ . Even for relative  
 835 humidity the differences are small. The ‘day’ timeseries gives the largest negative trend followed by ‘both’  
 836 which is  $0.01 \text{ \%rh decade}^{-1}$  smaller and then ‘night’ which is  $0.02 \text{ \%rh decade}^{-1}$  smaller again. The negligible  
 837 differences in air temperature suggest that solar heating is not a significant concern at least at the global average  
 838 scale. Relative humidity is very sensitive to any differences in the data but even these differences are fairly  
 839 small and do not change the overall conclusion of decreasing long-term trends. ‘Night’ trends are often thought  
 840 to provide a better signal of change because they are generally free from convective and shortwave radiative  
 841 processes and more a measure of outgoing longwave radiation. The main conclusion here is that trends and  
 842 variability are very similar in the daytime, nighttime and combined timeseries which adds confidence in their  
 843 representativeness of real-world trends and variability.

844

845 Overall, at least in terms of linear trend direction, HadISDH.marine compares well with other monitoring  
 846 estimates from NOCSv2.0 and ERA-Interim and to other reanalyses and older products (Fig. 1). ERA-Interim  
 847 has been masked to ocean coverage using a  $1^\circ$  by  $1^\circ$  land-sea mask and also to HadISDH.marine coverage for  
 848 comparison. Note that the ERA-Interim timeseries shown in Figs. 8 to 11 are from analysis fields of 2 m air  
 849 temperature and dew point temperature, whereas the timeseries shown in Fig. 1 are from background forecast  
 850 values to avoid biases introduced from ship data and ocean-only points over open sea. They are very similar at  
 851 least in terms of the global average. Both NOCSv2.0 and HadISDH.marine are estimates of 10 m quantities and  
 852 the NOCSv2.0 coverage is similar to that of HadISDH.marine but it only extends to 2015. NOCSv2.0 shows the  
 853 largest trends in specific humidity over the 1979-2015 common period,  $0.03 \text{ g kg}^{-1} \text{ decade}^{-1}$  greater than  
 854 HadISDH.marine. The interannual patterns are broadly similar but with some differences showing that  
 855 methodological choices do make a difference, given that the underlying observations are from the same source.  
 856 ERA-Interim shows very weak moistening compared to HadISDH.marine for specific humidity and dew point  
 857 temperature and slightly weaker warming for air temperature. Over the longer 1979-2018 period ERA-Interim  
 858 trends are slightly larger for specific humidity but still weaker than in HadISDH.marine. The decreasing  
 859 saturation in relative humidity is very strong in ERA-Interim at more than 3 times the HadISDH.marine trend  
 860 over the common period. The masking to HadISDH.marine coverage surprisingly makes very little difference in

861 the linear trends and only small year-to-year differences. Interannual behaviour does differ, especially for  
 862 relative humidity and especially in the period up to the early 1990s where ERA-Interim is warmer and wetter  
 863 generally, thus moderating the long-term trends in specific humidity, dew point temperature and air temperature.  
 864 Note that the ERA-Interim background field relative humidity shown in Fig. 1 also shows a decrease but to a  
 865 lesser extent than the analysis fields (Fig. 9) which include ship data. Agreement is closest for air temperature in  
 866 both trends and variability.

867

868 The decreasing relative humidity trends over ocean are consistent with the drying seen in HadISDH.land and  
 869 ERA-Interim land relative humidity (Fig. 1). The timeseries pattern is quite different though with marine  
 870 relative humidity decreasing throughout the period around large variability and land relative humidity clearly  
 871 decreasing from 2000. The greater sensitivity of relative humidity to observation errors, biases and sampling  
 872 issues makes the conclusion of long-term drying an uncertain one but agreement with ERA-Interim adds weight  
 873 to this conclusion.

874

875 For the final HadISDH.marine.1.0.0.2018f product the regional average uncertainty is also computed and shown  
 876 for the global average in Fig. 12. This includes the total observation uncertainty, sampling uncertainty and also a  
 877 spatial coverage uncertainty, following the method applied for HadISDH.land (Willett et al., 2014). The  
 878 coverage uncertainty essentially uses the variability between ERA-Interim full coverage compared to ERA-  
 879 Interim with HadISDH.marine coverage to estimate uncertainty. To obtain uncertainty in the global average  
 880 from the gridbox uncertainties correlation in time and space should be taken into account. It is not trivial to  
 881 assess the true spatial and temporal correlation of the various uncertainty sources. In reality, although ships  
 882 move around over space and time, implying some correlation, the contributing sources to each  $\sim 500 \text{ km}^2$   
 883 gridbox monthly mean differ widely. Therefore, for this first version product we assume no correlation between  
 884 gridboxes in time or space and take the simple approach of the quadrature combination of uncertainty sources,  
 885 noting that this is a lower limit on uncertainties.

886

887 The uncertainty in the global averages (Fig. 12) are larger than the equivalent time series for land (see Fig. 12 in  
 888 Willett et al., 2014). The coverage uncertainty (accounting for observation gaps in space and time) is generally  
 889 the largest source of uncertainty with the exception of relative humidity and dew point depression. For the latter  
 890 two, the total observation uncertainty makes up the greatest contribution. In all cases the total observation

uncertainty is larger at the beginning and especially the end of the records, where there are fewer/no metadata with which to apply bias adjustments. The contribution from sampling uncertainty (gridbox spatial and temporal coverage) is generally very small except for relative humidity. This is as expected given that the correlation decay distance of humidity should generally be larger over ocean than over land given the homogeneous surface altitude and composition. Overall, the magnitudes of the uncertainties are small relative to the magnitudes of long-term trends and variability in all variables except for relative humidity and dew point depression. This suggests that there is good confidence in changes in absolute measures of humidity over ocean (e.g., specific humidity), and also air temperature, but lower confidence in changes in the relative humidity. The warming and moistening are further corroborated by strong theoretical reasoning based on laws of physics governing the expectation that specific humidity should have increased over the period of record given the warming of the oceans and atmosphere that has occurred (Hartmann et al., 2013). The uncertainty model makes many assumptions over correlation of uncertainty in space and time. It is likely that we have overestimated the uncertainty at the gridbox scale by assuming complete correlation for height adjustment uncertainty, instrument adjustment uncertainty and climatological uncertainty. Conversely, we have likely underestimated the uncertainty at the regional average level by assuming no correlation. This is certainly an area for improvement in future versions.

### 4.3 Decadal trends across the globe presented by HadISDH.marine

Figure 13 shows the decadal linear trends for specific humidity, relative humidity, dew point temperature and air temperature for HadISDH.marine.1.0.0.2018f. The completeness criteria for trend fitting is 70 %, more strict than for the climatologies (Fig. 7). This results in poorer spatial coverage especially in the Southern Hemisphere. Clearly, there are no data points outside 70° S to 70° N, hence the restriction of the global average timeseries to this region is sensible. The tropical and Southern Hemisphere Pacific Ocean, and Southern Hemisphere Atlantic Ocean have virtually no data coverage. Overall, the appearance of the trends shows good spatial consistency, with few gridboxes standing out as obviously erroneous. There has been no interpolation across gridboxes that would have smoothed out any outliers, and so the lack of these outlying gridboxes suggests that the data are of reasonable quality for this long-term analysis at least. Trends are as expected from the global average timeseries – generally moistening and warming but becoming less saturated. The same is true over land (Willett et al., 2014).

921 The moistening shown in specific humidity and dew point temperature (Fig. 13 panels a, b and e, f) is  
 922 widespread. The majority of gridboxes are considered to be statistically significant in that the 90<sup>th</sup> percentile  
 923 confidence interval around the trend magnitude is the same sign as the trend and does not encompass zero. The  
 924 largest increases in specific humidity are in the lower latitudes where as the largest increases in dew point  
 925 temperature are more spread out with a tendency towards the extratropics and mid-latitudes. There are a few  
 926 regions where there are clusters of gridboxes with drying trends. These are generally consistent between the  
 927 specific humidity and dew point temperature, especially in the few cases where these negative trends are  
 928 significant such as the central Pacific, the east coast of Brazil, the southern coast of Australia and around New  
 929 Zealand.

930

931 Marine air temperature shows widespread and significant warming, in agreement with HadNMAT (Kent et al.,  
 932 2013). Very few of the gridboxes with a negative trend are significant. In some cases they are in similar  
 933 locations to the drying trends seen in specific humidity and/or dew point temperature e.g., the coast south of  
 934 Australia around Tasmania, the east coast of Brazil. The warming is stronger in the northern mid latitudes with  
 935 the Baltic, Mediterranean and Red Seas showing particularly strong warming consistent with strongly increasing  
 936 dew point temperature and specific humidity.

937

938 Whilst relative humidity is more sensitive to methodological choices and observational errors, the broad  
 939 spatially coherent structures to the regions of increasing and decreasing saturation, with broadscale significance,  
 940 are very encouraging in terms of data quality. Furthermore, the drying trends tend to be around the mid-latitudes  
 941 while the increasing saturation trends are more around the tropics, as seen over land. We still urge caution in the  
 942 use of marine relative humidity but these results collectively suggest that decreasing saturation might be a real  
 943 feature.

944

## 945 **5 Code and data availability**

946

947 HadISDH.marine is available as 5° by 5° gridded fields of monthly means and anomalies along with a 1981-  
 948 2010 climatology and uncertainty estimates at the gridbox scale. The data begin in January 1973 and continue to  
 949 December 2018 (at time of print) and will be updated annually. HadISDH.marine is publicly available from  
 950 [www.metoffice.gov.uk/hadobs/hadisdh/](http://www.metoffice.gov.uk/hadobs/hadisdh/) under an Open Government license

951 (<http://www.nationalarchives.gov.uk/doc/open-government-licence/version/3/>) as netCDF and text files.  
 952 Processing code (Python) can also be made available on request. HadISDH.marine data, derived diagnostics and  
 953 plots can be found at [www.metoffice.gov.uk/hadobs/hadisdh/indexMARINE.html](http://www.metoffice.gov.uk/hadobs/hadisdh/indexMARINE.html) (Willett et al., 2019). It  
 954 should be cited using this paper and the following: Willett, K., Dunn, R., Kennedy, J. and Berry, D.:  
 955 HadISDH.marine: gridded global monthly marine surface humidity data (version 1.0.0.2018f) [Data set]. Met  
 956 Office Hadley Centre HadOBS Datasets, [www.metoffice.gov.uk/hadobs/hadisdh/indexMARINE.html](http://www.metoffice.gov.uk/hadobs/hadisdh/indexMARINE.html), 2019.  
 957  
 958 This product forms one of the HadOBS ([www.metoffice.gov.uk/hadobs](http://www.metoffice.gov.uk/hadobs)) climate monitoring products and will  
 959 be blended with the HadISDH.land product to create a global land and marine humidity monitoring product.  
 960 Updates and exploratory analyses are documented at <http://hadisdh.blogspot.co.uk> and through the Met Office  
 961 HadOBS twitter account @metofficeHadOBS.

962

## 963 **6 Discussion and conclusions**

964

965 Marine humidity data are susceptible to a considerable number of biases and sources of error that can be large in  
 966 magnitude. We have cleaned the data where possible by applying quality control for outliers, supersaturation,  
 967 repeated values and neighbour inconsistency which has removed up to 25 % of our initial selection in some  
 968 years. We have also applied adjustments to account for biases arising from un-aspirated instrument types and  
 969 differing observation heights over space and time. Care has also been taken to avoid diurnal and seasonal  
 970 sampling biases as far as possible when building the gridded fields and the use of gridbox mean climate  
 971 anomalies reduces remaining random error through averaging

972

973 Spatial coverage of HadISDH.marine differs year to year. The coverage is generally poorer than seen for  
 974 variables such as SST which benefit significantly from drifting buoy observations. Any further decline in  
 975 observation and transmission of humidity from ships is of concern to our ability to robustly monitor surface  
 976 humidity over oceans. Future versions may be able to make more use of humidity data from buoys but their  
 977 proximity to the sea surface and difficulty of regular maintenance can lead to poor quality observations. The  
 978 provision of digital metadata significantly improves our ability to quantify and account for biases in the data.  
 979 Hence, the continuity of this metadata beyond 2014, and ideally an increase in quantity, also strongly affects our  
 980 ability to robustly monitor ocean surface humidity. Given the current availability of ship data and metadata, and

981 necessarily strict selection criteria and quality control, the resulting spatial coverage is good over the Northern  
 982 Hemisphere outside of the high latitudes. There is very poor coverage over the Southern Hemisphere, especially  
 983 south of 20° S. This means that our ‘global’ analyses are biased to the Northern Hemisphere. Care should be  
 984 taken to account for different spatial coverage when comparing products. However, when comparing HadISDH  
 985 to masked and unmasked ERA-Interim fields differences were surprisingly small.  
 986  
 987 We have shown that the observations are warm and moist relative to ERA-Interim reanalysis for the majority of  
 988 the observed globe apart from the northwestern Pacific. This is despite ERA-Interim fields representing 2 m  
 989 above the surface compared to the general observation heights of 10-30 m above the surface. Differences are  
 990 largest around coastlines, particularly in the Red Sea and Persian Gulf. There is insufficient spatial coverage to  
 991 produce a high resolution climatology from the data themselves, hence our use of ERA-Interim initially and then  
 992 interpolated observation based fields. However, the lower resolution (5° by 5°) monthly mean climatologies  
 993 from the final HadISDH.marine.1.0.0.2018f version show expected spatial patterns and have good spatial  
 994 consistency, providing evidence that our data selection methods have resulted in reasonably high quality data.  
 995  
 996 The quality control and bias adjustment procedures have made small differences to the global average anomaly  
 997 timeseries for specific humidity, dew point temperature and air temperature. This overall agreement in the  
 998 global average timeseries between versions, and also between the daytime, night time and combined versions,  
 999 increases confidence in the overall signal of increased moisture and warmth over oceans. These features show  
 1000 widespread spatial consistency in the HadISDH.marine.1.0.0.2018f gridbox decadal trends which also adds  
 1001 confidence. Hence, we can conclude that the ICOADS data are a useful source of humidity data for climate  
 1002 monitoring. However, we expect differences to be larger on smaller spatial scale analyses. HadISDH.marine  
 1003 shows consistency with other products in terms of long-term linear trends in the global averages. There are some  
 1004 differences year to year, with ERA-Interim showing warmer and moister anomalies prior to the early 1990s, and  
 1005 hence, smaller trends overall. For relative humidity, differences between the versions can be large for any one  
 1006 year but the overall decreasing saturation trend appears to be robust. We conclude this because the trend is  
 1007 consistent across all processing steps, apparent in ERA-Interim fields and also has spatial consistency across the  
 1008 extratropics and mid-latitudes. This is a somewhat surprising result and one that should be treated cautiously.  
 1009 Model based analysis of changes in relative humidity over ocean under a warming climate suggest negligible or  
 1010 small positive changes (Byrne and O’Gorman, 2013, 2018). The temporal patterns in global average relative

1011 humidity are quite different to those over land whereas specific humidity shows similarity with the  
 1012 HadISDH.land timeseries, largely driven by the El Niño related peaks. Further work to assess the physical  
 1013 mechanisms that might lead to such trends is needed.  
 1014  
 1015 There are known issues with ERA-Interim in terms of its stability. For example, sea surface temperatures cooled  
 1016 around mid-2001 due to a change in the SST analysis product used (Simmons et al., 2014). This is very likely to  
 1017 affect humidity over the ocean surface in ERA-Interim. Similarly, changes in satellite streams over time can also  
 1018 affect the long-term stability of ERA-Interim, even in the surface fields. Also, the assimilated ship data are not  
 1019 adjusted for biases in the ERA-Interim assimilation. Clearly, there are various issues affecting both in-situ based  
 1020 monitoring products and reanalysis products such that neither one can be easily identified as the more accurate  
 1021 estimate. Analyses should take into account all available estimates and their strengths and weaknesses.  
 1022 Comparison of HadISDH.marine with satellite-based estimates of humidity over ocean will be an important next  
 1023 step.  
 1024  
 1025 We have attempted to quantify uncertainty in HadISDH.marine. The uncertainty analysis comprises observation  
 1026 uncertainty at the point of measurement which is then propagated through to gridbox averages taking correlation  
 1027 in space and time into account where relevant. Sampling uncertainty at the gridbox level due to uneven  
 1028 sampling across the gridbox in space and time is assessed. We have also provided uncertainty estimates in  
 1029 regional and global averages including coverage uncertainty. The propagation of gridbox observation and  
 1030 sampling uncertainty to large scale averages does not explicitly take into account correlation in these uncertainty  
 1031 quantities in space and time. As this is a first version monitoring product this simple method is seen as an  
 1032 appropriate first attempt to assess uncertainty. The ranges presented should be seen as a lower limit on the  
 1033 uncertainty. Overall, uncertainty in the global average is dominated by the coverage uncertainty for all variables  
 1034 except relative humidity and dew point depression. The total observation uncertainty is larger at the beginning,  
 1035 and especially the end of the record, where digital metadata are fewer or non-existent (post-2014). Overall, the  
 1036 uncertainty is small relative to the magnitude of long-term trends with the exception of relative humidity. We  
 1037 suspect that this is an over estimate at the gridbox level owing to assumptions of complete correlation in the  
 1038 height adjustment, instrument adjustment and climatology uncertainty components, and an underestimate at the  
 1039 regional average level given assumptions of no correlation. This is a first attempt to comprehensively quantify  
 1040 marine humidity uncertainty and future methodological improvements are envisaged.

1041

1042 We conclude that this first version marine humidity monitoring product is a reasonable estimate of large-scale  
 1043 trends and variability and contributes to our understanding of climate changes as a new and methodologically-  
 1044 independent analysis. The trends and variability shown are mostly in concert with expectation; widespread  
 1045 moistening and warming is observed over the oceans (excluding the mostly data-free Southern Hemisphere)  
 1046 from 1973 to present. These are also large relative to the magnitude of our uncertainty estimates. Our key  
 1047 finding is that the marine relative humidity appears to be decreasing (the air is becoming less saturated). We  
 1048 have explored various processes for ensuring high quality data and shown that these do not make large  
 1049 differences for large scale analyses of specific humidity, dew point temperature and air temperature but that  
 1050 there is greater sensitivity to methodological choices for relative humidity.

1051

1052 The spatial coverage of surface humidity data is very low outside of the Northern Hemisphere. If only those data  
 1053 with digitised metadata are included then this coverage deteriorates further. Although moored buoy numbers  
 1054 have increased dramatically since the 1990s, their measurements are more prone to error through proximity to  
 1055 the water, and hence, contamination, in addition to less frequent manual checking and maintenance. Hence, our  
 1056 ability to monitor surface humidity with any degree of confidence depends on the continued availability of ship  
 1057 data and provision of digitised metadata.

1058

#### 1059 **Author Contributions**

1060

1061 Kate Willett undertook the majority of the methodology, coding, writing and plotting. John Kennedy designed  
 1062 and coded the quality control methodology and software with some contribution from Kate Willett. Robert  
 1063 Dunn designed and coded the gridding methodology and software with some contribution from Kate Willett.  
 1064 David Berry designed and reviewed the height adjustment methodology and provided guidance on marine  
 1065 humidity data biases, inhomogeneities and issues. All authors have contributed text and edits to the main paper.

1066

#### 1067 **Competing Interests**

1068

1069 The authors declare that they have no conflict of interest.

1070

#### 1071 **Acknowledgements**

1072

1073 Kate Willett, Robert Dunn and John Kennedy were supported by the Met Office Hadley Centre Climate  
 1074 Programme funded by BEIS and Defra. (GA01101).

**Tables**

Table 1. Description of the uncertainty elements affecting marine humidity. All uncertainties are assessed as  $1\sigma$  uncertainty.

Uncertainty Source	Description	Type	Formula	Correlation
--------------------	-------------	------	---------	-------------

$U_i$	Non-aspirated instrument adjustment uncertainty. Expressed as $q$ ( $\text{g kg}^{-1}$ ) and then propagated to other humidity variables	Adjusted poorly aspirated instrument: $0.2 \text{ g kg}^{-1}$ in terms of $q$ (following Berry and Kent, 2011 standard uncertainty assessment).	Standard	0.2	Space and time, $r = 1$
		Partially adjusted unknown instrument: $0.2 \text{ g kg}^{-1}$ + the full adjustment amount in terms of $q$ .		$0.2 + 100 \left( \frac{q_{adj} - q}{55} \right)$	
$U_h$	Observation height adjustment uncertainty. Expressed as $T$ ( $^{\circ}\text{C}$ ) and $q$ ( $\text{g kg}^{-1}$ ) and then propagated to other humidity variables	Height adjusted ship and valid SST: assessed using the range of adjustments from a $1\sigma$ uncertainty in the height estimate.	Normally distributed	$\frac{\left( \frac{xH_{max} - xH_{min}}{2} \right)}{\sqrt{9}}$	Space and time, $r = 1$
		Height adjusted ship and invalid SST or height adjusted buoy: the larger of the adjustment value or $0.1^{\circ}\text{C}$ in terms of $T$ and $0.007q$ .		$\frac{x_{adj}}{\sqrt{9}}$ Or $0.1^{\circ}\text{C}$ in terms of $T$ $0.007q_{adj}$	
		Height adjustment or uncertainty range not resolved, valid SST: half of the difference between the observation value and the surface value (SST or $q_{sf}$ ).		$\frac{T_{(adj)} - SST}{2}$ $\frac{q_{(adj)} - q_{sf}}{2}$ $q_{sf} = 0.98q_{sat}(SST)$	
		Height adjustment or uncertainty range not resolved, no valid SST: $0.1^{\circ}\text{C}$ in terms of $T$ and $0.007q$ .		$0.1^{\circ}\text{C}$ in terms of $T$ $0.007q_{adj}$	

$U_m$	Measurement uncertainty. Expressed as $T$ ( $^{\circ}\text{C}$ ), $T_w$ ( $^{\circ}\text{C}$ ) and RH (%rh) and then propagated to other humidity variables.	Standard uncertainty in the thermometer ( $T$ ) and psychrometer ( $T_w$ ) is $0.2^{\circ}\text{C}$ and $0.15^{\circ}\text{C}$ respectively. This equates in an uncertainty in RH dependent on $T$ .	Standard	$0.2^{\circ}\text{C}$ in terms of $T$ $0.15^{\circ}\text{C}$ in terms of $T_w$ $x$ %rh depending on the temperature and RH bins in Table S3	None, $r = 0$
$U_w$	Whole number uncertainty. Expressed as $T$ ( $^{\circ}\text{C}$ ) and $T_d$ ( $^{\circ}\text{C}$ ) and then propagated to other humidity variables.	Observation either has the Whole Number flag set or is a whole number and from a red listed source deck in Table S4. If both $T$ and $T_d$ are offending whole numbers then RH, $T_w$ and DPD have a combined uncertainty.	Uniformly distributed	$\frac{0.5}{\sqrt{3}}$ $\frac{1}{\sqrt{3}}$	None, $r = 0$
$U_c$	Climatology uncertainty. Assessed for each variable independently.	The $1^{\circ}$ by $1^{\circ}$ pentad gridbox climatological standard deviation for the variable is divided by the square root of the number of observations used to create it.	Standard	$\frac{\sigma_{clim}}{\sqrt{N_{obs}}}$	Space and time, $r = 1$
$U_{og}$	Total observation uncertainty of the gridbox	All gridbox observation uncertainty sources are combined, assuming no correlation between sources.	Standard	$\sqrt{U_i^2 + U_h^2 + U_m^2 + U_w^2 + U_c^2}$	Space and time to some extent, decreasing with space and time
$U_{sg}$	Temporal and spatial sampling uncertainty of the gridbox	Sampling uncertainty follows Jones et al., (1997) depending on the mean	Standard	$\frac{(\bar{s}_i^2 \bar{r}(1 - \bar{r}))}{(1 + (N_s - 1)\bar{r})}$	Space and time to some extent, decreasing

		'station' variance, the mean inter-site correlation and the number of 'stations' contributing to the gridbox.			with space and time
$U_{fg}$	Full uncertainty of the gridbox	All gridbox uncertainty sources are combined, assuming no correlation between sources.	Standard	$\sqrt{U_{og}^2 + U_{sg}^2}$	Space and time to some extent, decreasing with space and time

Figures

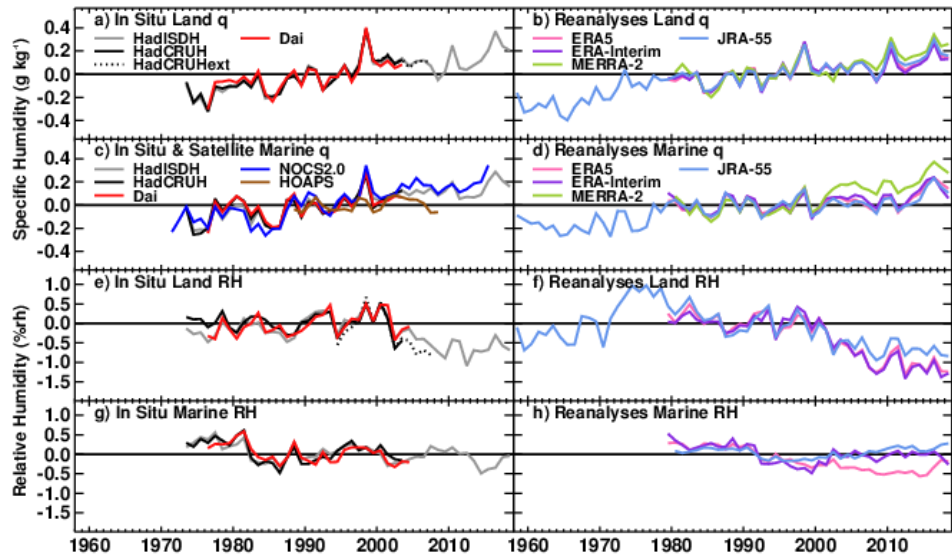

Figure 1 Global average surface humidity annual anomalies (base period: 1979–2003). For in-situ datasets, 2-m surface humidity is used over land and ~10-m over the oceans. For the reanalysis, 2-m humidity is used across the globe. For ERA-Interim and ERA5, ocean-only points over open sea are selected and background forecast values are used as opposed to analysis values to avoid incorporating biases from unadjusted ship data. All data have been given a mean of zero over the common period 1979–2003 to allow direct comparison, with HOAPS given a zero mean over the 1988–2003 period. [Sources: HadISDH (Willett et al., 2013, 2014); HadCRUH (Willett et al., 2008); Dai (Dai 2006); HadCRUHext (Simmons et al. 2010); NOCSv2.0 (Berry and Kent, 2009, 2011); HOAPS (Fennig et al. 2012), ERA-Interim (Dee et al., 2011), ERA5 (C3S 2017, Hersbach et al., 2018), MERRA-2 (Gelaro et al. 2017; Bosilovich et al. 2015) and JRA-55 (Ebata et al. 2011). Adapted from Willett et al., 2019.

Figure 2 Availability of instrument exposure information (black) for ships (platform (PT) = 0, 1, 2, 3, 4, 5) for the hygrometer (EOH, SOLID) and thermometer (EOT, DASHED) for each year. All ICOADS 3.0.0/3.0.1 observations passing 3<sup>rd</sup> iteration quality control are included. The percentage of EOHs/EOTs in each exposure category is also shown. Aspirated (A) screens are shown in red. Handheld instruments (ship's sling [SG], sling [SL], whirling [W]) are shown in orange. Unaspirated/unventilated screens (S) and ship's screens (SN) are shown in blue. Additionally, ventilated screens (VS) are also shown in blue as these are generally not artificially aspirated. Unscreened (US observations are shown in violet.

Figure 3 a) Availability of instrument height information for ships (platform (PT) = 0, 1, 2, 3, 4, 5) for the barometer (HOB), thermometer (HOT), anemometer (HOA) and visual observing platform (HOP) with b) mean heights (solid lines) and standard deviations (dotted lines) for each year. All ICOADS 3.0.0/3.0.1 observations passing 3<sup>rd</sup> iteration quality control are included.

Figure 4 Availability of instrument type information (black) for ships (platform (PT) = 0, 1, 2, 3, 4, 5) for the hygrometer (TOH) for each year. All ICOADS 3.0.0/3.0.1 observations passing 3<sup>rd</sup> iteration quality control are included. The percentage of TOHs in each type category is also shown.

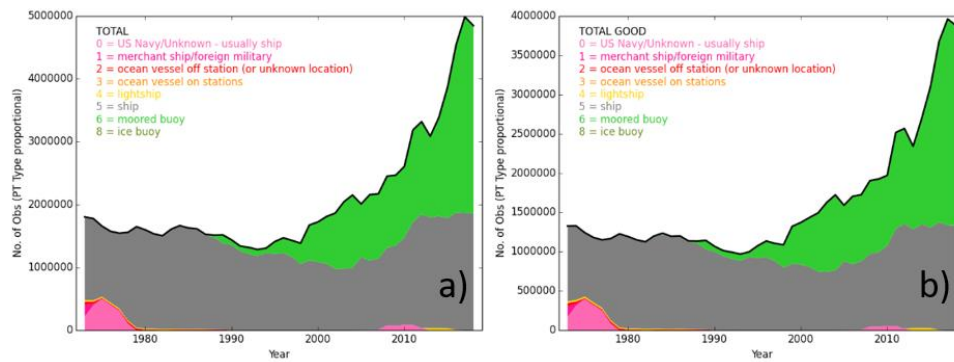

Figure 5 Annual observation count for the initial selection (a) and only those observations passing the final 3<sup>rd</sup> iteration quality control (b), broken down by platform (PT) type.

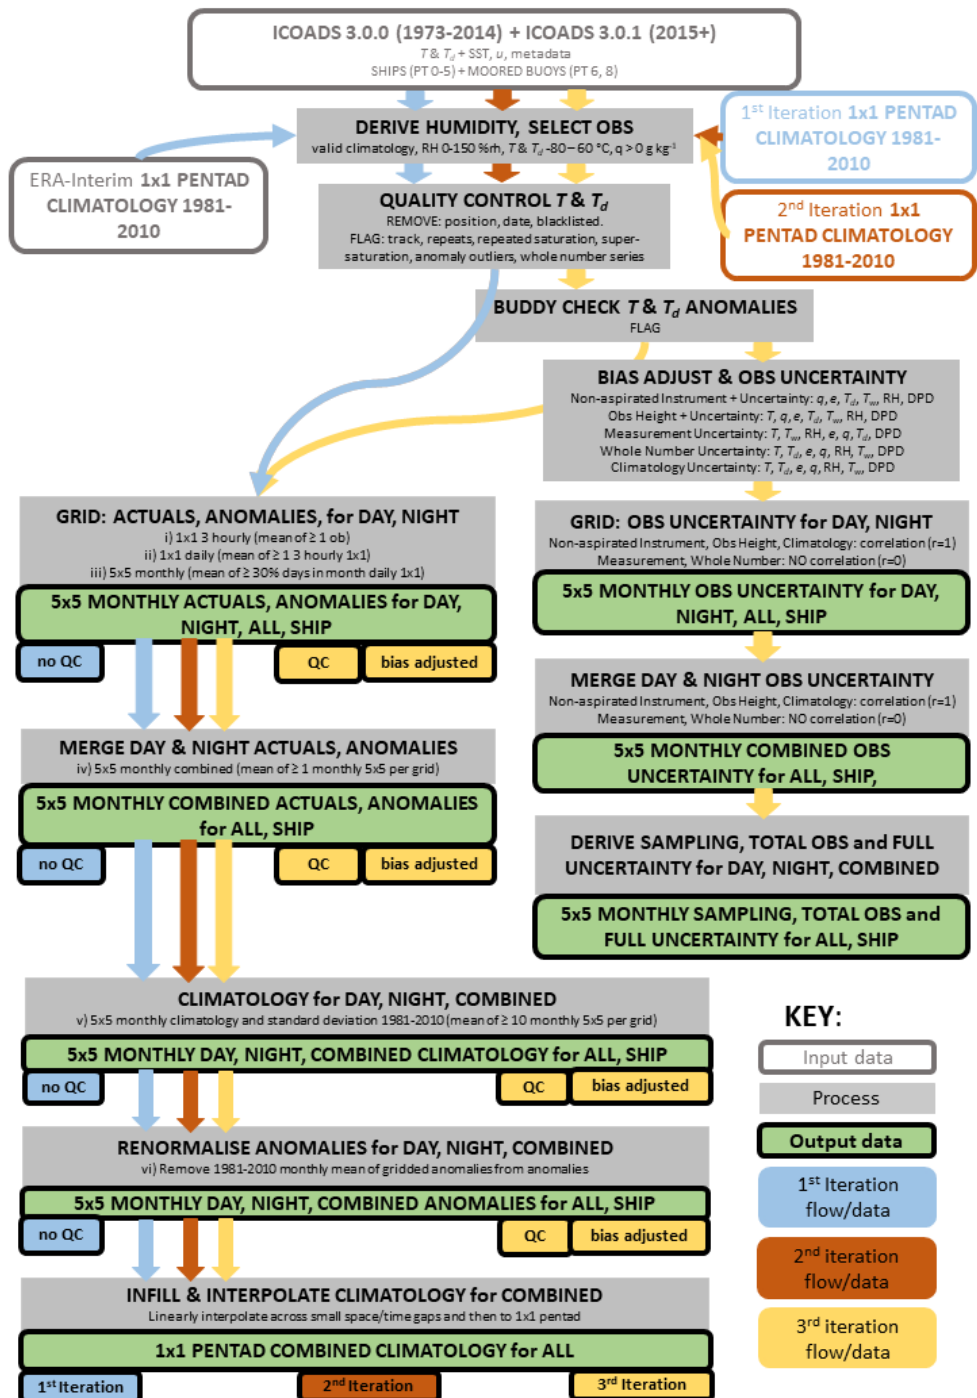

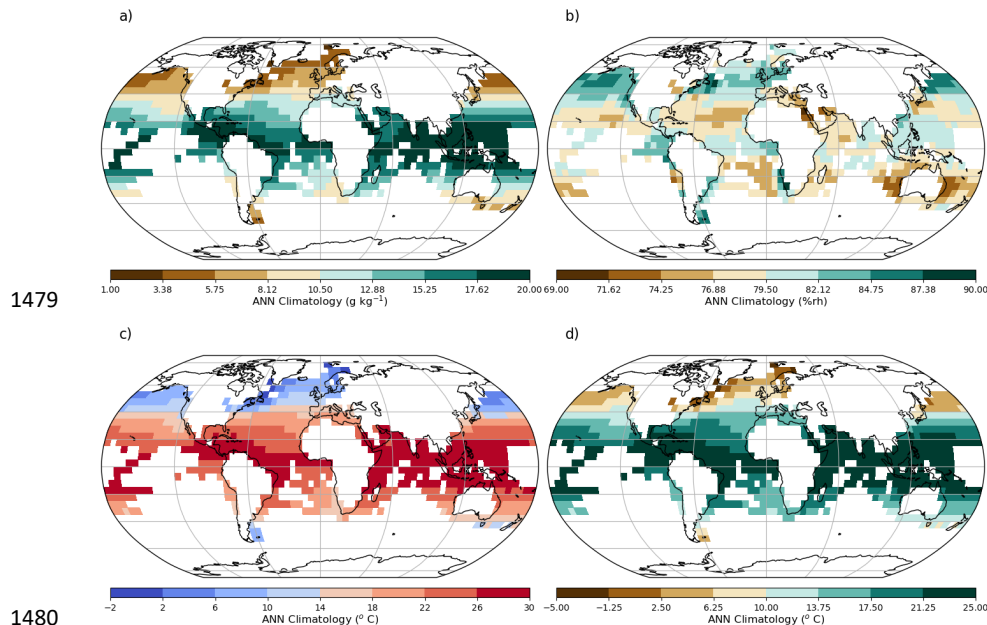

Figure 6 Flow chart of the build process from raw hourly observations to gridded fields.

Figure 7 Annual mean climatologies relative to 1981-2010 for a) specific humidity ( $\text{g kg}^{-1}$ ), b) relative humidity (%rh), c) air temperature ( $^{\circ}\text{C}$ ) and d) dew point temperature ( $^{\circ}\text{C}$ ) for 3<sup>rd</sup> iteration quality-controlled and bias-adjusted ship version. Climatological means are calculated for gridboxes and months with at least 10 years present over the climatology period. Annual mean climatologies require at least 9 months of the year to be represented climatologically.

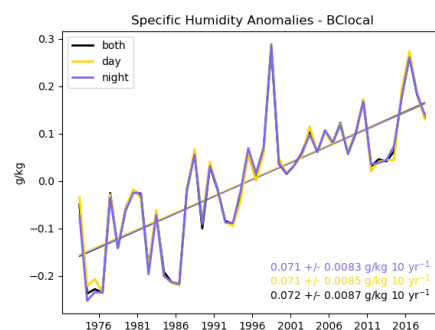

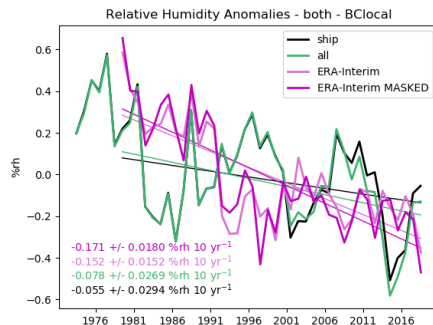

Figure 8 Global (70 °S to 70 °N) annual average anomaly timeseries and decadal trends ( $\pm$  90 % confidence interval) for specific humidity. a) Processing comparison for ships only: raw data (noQC), 3<sup>rd</sup> iteration quality-controlled with no bias adjustment (NBC), 3<sup>rd</sup> iteration quality-controlled and bias-adjusted (BClocal), 3<sup>rd</sup> iteration quality-controlled and bias-adjusted for ship height only (BClocalHGT), 3<sup>rd</sup> iteration quality-controlled and bias-adjusted for instrument ventilation only (BClocalINST). b) Platform and alternative product comparison: 3<sup>rd</sup> iteration quality-controlled and bias-adjusted ship-only (ship), 3<sup>rd</sup> iteration quality-controlled and bias-adjusted for ships and moored buoys (all), NOCSv2.0 in-situ quality-controlled and bias-adjusted product based on ships only (NOCS-q), ERA-Interim reanalysis 2m fields using complete ocean coverage at the 1° by 1° scale (ERA-Interim), ERA-Interim reanalyses 2m fields using complete ocean coverage at the 1° by 1° scale and masked to HadISDH.marine spatio-temporal coverage (ERA-Interim MASKED). Trends cover the common 1979 to 2015 period. 1979 to 2018 trends for ERA-Interim are  $0.034 \pm 0.098$  and  $0.029 \pm 0.0098$  for the full and masked versions respectively. c) Time of observation comparison for 3<sup>rd</sup> iteration quality-controlled and bias-adjusted ship-only: all times (both), daytime hours only (day), night time hours only (night). Linear trends were fitted using the median of pairwise slopes.

Figure 11 Global (70 °S to 70 °N) annual average anomaly timeseries and decadal trends (+/- 90 % confidence interval) for marine air temperature. See Figure 8 caption for details. Trends cover the common 1979 to 2018 period.

1539  
 1540 Figure 12 Global average timeseries of annual mean climate anomalies for all variables. The 2 sigma uncertainty  
 1541 ranges for total observation (blue), sampling (red) and coverage (gold) uncertainty contributions combined are  
 1542 shown. All series have been given a zero mean over the common 1981-2010 period. Linear trends were fitted  
 1543 using the median of pairwise slopes with the range representing the 90 % confidence interval in the trend.  
 1544  
 1545  
 1546  
 1547

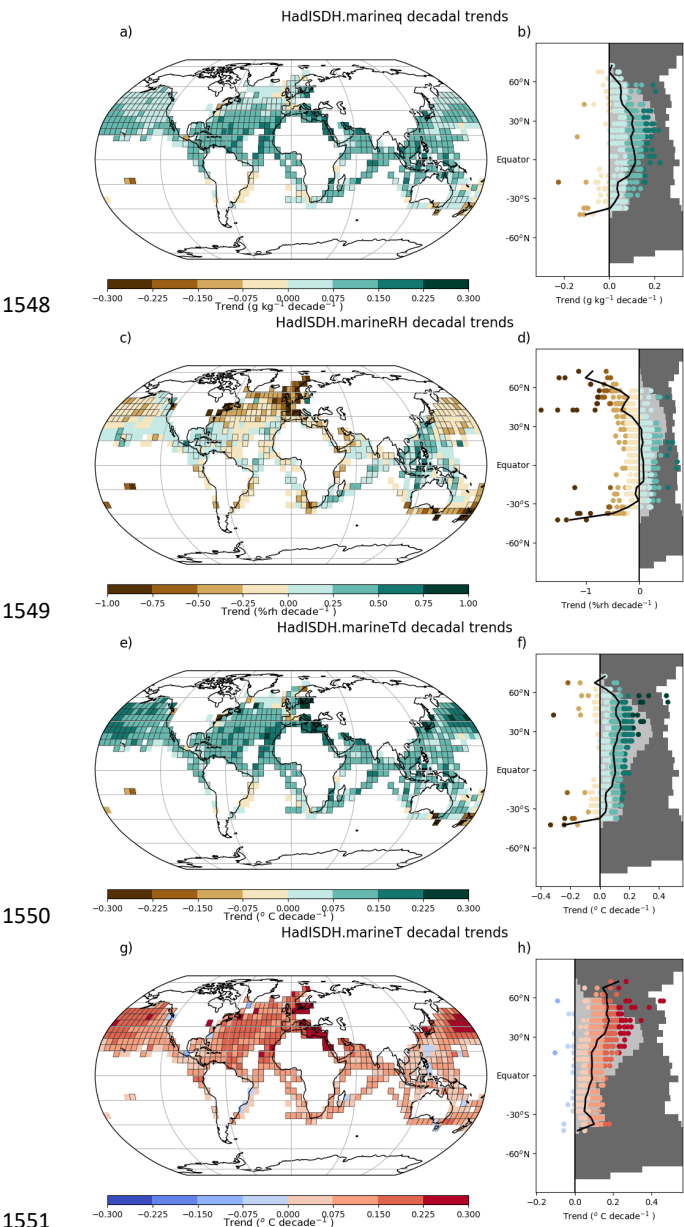

Figure 13 Linear decadal trends from 1973 to 2018 for a, b) specific humidity ( $\text{g kg}^{-1}$ ), c, d) relative humidity (%rh), e, f) dew point temperature ( $^{\circ}\text{C}$ ) and g, h) air temperature ( $^{\circ}\text{C}$ ) for the 3<sup>rd</sup> iteration quality-controlled and bias-adjusted ships only. Trends have been fitted using the median of pairwise slopes when there are at least 70 % percent of months present over the trend period. Gridboxes with boundaries show significant trends in that the 90 % confidence interval around the trend magnitude is the same sign as the trend and does not encompass zero. The right-hand panels (b, d, f, h) show the distribution of gridbox trends by latitude with the mean shown as a solid black line. The dark grey shading shows the proportion of the globe at that latitude which is ocean. The light grey shading shows the proportion of the globe that contains observations.
