24
25
26 **Abstract.** Here we present a global and regionally-resolved terrestrial net biosphere exchange
27 (NBE) dataset with corresponding uncertainties between 2010–2018: CMS-Flux NBE 2020. It is
28 estimated using the NASA Carbon Monitoring System Flux (CMS-Flux) top-down flux
29 inversion system that assimilates column CO₂ observations from Greenhouse gases Observing
30 SATellite (GOSAT) and the NASA's Observing Carbon Observatory -2 (OCO-2). The regional
31 monthly fluxes are readily accessible as tabular files, and the gridded fluxes are available in
32 NetCDF format. The fluxes and their uncertainty estimates are evaluated by extensively
33 comparing the posterior CO₂ mole fractions with aircraft CO₂ observations. We describe the
34 characteristics of the dataset as global total, regional climatological mean, and regional annual
35 fluxes and seasonal cycles. We find that the global total fluxes of the dataset agree with
36 atmospheric CO₂ growth observed by the surface-observation network within uncertainty.
37 Averaged between 2010 and 2018, the tropical regions range from close-to neutral in tropical
38 South America to a net source in Africa; these contrast with the extra-tropics, which are a net
39 sink of 2.5 ± 0.3 gigaton carbon per year. The regional satellite-constrained NBE estimates
40 provide a unique perspective for understanding the terrestrial biosphere carbon dynamics and
41 monitoring changes in regional contributions to the changes of atmospheric CO₂ growth rate.
42 The gridded and regional aggregated dataset can be accessed at:
43 <https://doi.org/10.25966/4v02-c391> (Liu et al., 2020).

46 **1 Introduction**

47 New “top-down” inversion frameworks that harness satellite observations provide an important
48 complement to global aggregated fluxes (e.g., Global Carbon Project, Friedlingstein et al., 2019)
49 and inversions based on surface CO₂ observations (e.g., Crowell et al., 2019). These satellite-
50 constrained estimates resolve regional fluxes, and also disentangle net biosphere exchange (NBE)
51 into constituent carbon fluxes including plant gross primary productivity (GPP) and biomass
52 burning through solar-induced fluorescence and carbon monoxide proxies, respectively (Bowman
53 et al, 2017, Liu et al., 2017). Both the spatial and process resolution are critical for evaluating
54 models and reducing uncertainties about future carbon-climate feedbacks (e.g., Friedlingstein et
55 al., 2014). The NBE are far more variable than ocean fluxes (Lovenduski and Bonan, 2017) or
56 fossil fuel emissions (Yin et al, 2019), and are thus the focus of this dataset estimated from a top-
57 down atmospheric CO₂ inversion of satellite column CO₂ dry-air mole fraction (X_{CO_2}). We present
58 the global and regional NBE dataset as a series of maps, time series and tables, and disseminate it
59 as a public dataset for further analysis and comparison to other sources of flux information. Finally,
60 we provide a comprehensive evaluation of both mean and uncertainty estimates against an
61 independent airborne dataset. Subsequent papers will present the partitioning of the NBE into
62 constituent gross fluxes.

63

64 Global top-down atmospheric CO₂ flux inversions have been historically used to estimate regional
65 terrestrial NBE, which is a sum of net ecosystem exchange and biomass burning carbon fluxes.
66 They make uses of the spatiotemporal variability of atmospheric CO₂, which is dominated by NBE,
67 to infer net carbon exchange at the surface (Chevallier et al., 2005; Baker et al., 2006; Liu et al.,
68 2014). The accuracy of the NBE from top-down flux inversion is determined by the density and

69 accuracy of the CO₂ observations, the accuracy of modeled atmospheric transport, and knowledge
70 of the prior uncertainties of the flux inventories.

71

72 For CO₂ flux inversions based on high precision *in situ* and flask observations, the measurement
73 error is low (<0.2 parts per million (ppm)) and not a significant source of error; however, these
74 observations are limited spatially, and are concentrating primarily over North America (NA) and
75 Europe (Crowell et al., 2019). Satellite X_{CO₂} from CO₂-dedicated satellites, such as the Greenhouse
76 Gases Observing Satellite (GOSAT) (launched in July 2009) and the Observing Carbon
77 Observatory 2 (OCO-2) (Crisp et al., 2017) have much broader spatial coverage (O'Dell et al.,
78 2018), and fill the observational gaps of conventional surface CO₂ observations, but they have up
79 to an order of magnitude higher single-sounding uncertainty and potential systematic errors
80 compared to the *in situ* and flask CO₂ observations. Recent progress in instrument error
81 characterization, spectroscopy, and retrieval methods have significantly improved the accuracy
82 and precision of the X_{CO₂} retrievals (O'Dell et al., 2018; Kiel et al., 2019). The single sounding
83 random error of X_{CO₂} from OCO-2 is ~1.0 ppm (Kulawik et al., 2019). A recent study by Byrne et
84 al. (2020) shows less than a 0.5 ppm difference between posterior X_{CO₂} constrained by a recent
85 data set, ACOS-GOSAT b7 X_{CO₂} retrievals, and those constrained by conventional surface CO₂
86 observations. Chevallier et al. (2019) also showed that OCO-2 based flux inversion had similar
87 performance to surface CO₂ based flux inversions when comparing posterior CO₂ mole fractions
88 to aircraft CO₂ in the free troposphere. Results from these studies show that systematic
89 uncertainties in CO₂ retrievals from satellites are comparable to, or smaller than, other uncertainty
90 sources in atmospheric inversions (e.g. transport).

91

92 A newly-developed biogeochemical model-data fusion system, CARDAMOM, made progress in
93 producing NBE uncertainties, along with mean values that are consistent with a variety of
94 observations assimilated through a Markov Chain Monte Carlo (MCMC) method (Bloom et al.,
95 2016; 2020). Transport model errors in general have also been reduced relative to earlier transport
96 model intercomparison efforts, such as TRANSCOM 3 (Gurney et al., 2004; Gaubert et al., 2019).
97 Advancements in satellite retrieval, transport, and prior terrestrial biosphere modeling have led to
98 more mature inversions constrained by satellite X_{CO_2} observations.

99

100 Two satellites, GOSAT and OCO-2, have now produced more than 10 years of observations. Here
101 we harness the CMS-Flux inversion framework (Liu et al., 2014; 2017; 2018; Bowman et al., 2017)
102 to generate an NBE product: CMS-Flux NBE 2020, by assimilating both GOSAT and OCO-2 from
103 2010–2018. The dataset is the longest satellite-constrained NBE product so far. The CMS-Flux
104 framework exploits globally available X_{CO_2} to infer spatially-resolved total surface-atmosphere
105 exchange, which can be subsequently decomposed into individual fluxes using ancillary
106 measurements (i.e., GPP, respiration, fires, fossil fuel, etc.). The flux estimates from the CMS-
107 Flux framework have been used to assess the impacts of El Niño on terrestrial biosphere fluxes
108 (Bowman et al, 2017; Liu et al, 2017) and the role of droughts in the North America (NA) carbon
109 balance (Liu et al, 2018). These fluxes have furthermore been ingested into land-surface data
110 assimilation systems to quantify heterotrophic respiration (Konings et al., 2019), evaluate
111 structural and parametric uncertainty in carbon-climate models (Quetin et al., 2020), and inform
112 climate dynamics (Bloom et al., 2020). We present the regional NBE and its uncertainty based on
113 two types of regional masks: (1) latitude and continent; and)2) distribution of biome types (defined

114 by plant functional types), and continent. The gridded NBE dataset and its uncertainty are also
115 available, so that users can aggregate the fluxes and uncertainties based on self-defined regions.

116

117 The outline of the paper is as follows: Section 2 describes methods, and Sections 3 and 4 describe
118 the dataset and the major NBE characteristics, respectively. We extensively evaluate the posterior
119 fluxes and uncertainties by comparing the posterior CO₂ mole fractions against aircraft
120 observations and a gross primary production (GPP) product (section 5). In Section 6, we discuss
121 the strength and weakness, and potential usage of the data. A summary is provided in Section 7,
122 and Section 8 is dataset availability and future plan.

123

124 **2 Methods**

125 **2.1 CMS-Flux inversion system**

126 The CMS-Flux framework is summarized in Figure 1. The center of the system is the CMS-Flux
127 inversion system, which optimizes NBE and air-sea net carbon exchanges with a 4D-Var inversion
128 system (Liu et al., 2014). In the current system, we assume that no uncertainty in fossil fuel
129 emissions, since the uncertainty in fossil fuel emissions at regional scales is substantially less than
130 NBE uncertainties, which is a widely adopted assumption in global flux inversion systems (e.g.,
131 Crowell et al., 2019). The 4D-Var minimizes a cost function that include the sum of two terms:

$$132 \quad J(\mathbf{x}) = (\mathbf{x} - \mathbf{x}_b)^T \mathbf{B}^{-1} (\mathbf{x} - \mathbf{x}_b) + (\mathbf{y} - h(\mathbf{x}))^T \mathbf{R}^{-1} (\mathbf{y} - h(\mathbf{x})) \quad (1)$$

133 The first term measures the differences between the optimized fluxes and the prior fluxes
134 normalized by the prior flux error covariance \mathbf{B} , and the second term measures the differences
135 between observations (\mathbf{y}) and the corresponding model simulated value ($h(\mathbf{x})$) normalized by the
136 observation error covariance \mathbf{R} . The term $h(\cdot)$ is the observation operator that calculates

137 observation-equivalent model-simulated X_{CO_2} . The 4D-Var uses the adjoint (i.e., the backward
138 integration of the transport model) (Henze et al., 2004) of the GEOS-Chem transport model to
139 calculate the sensitivity of the observations to surface fluxes. The configurations of the inversion
140 system are summarized in Table 1. We run both the forward and adjoint at $4^\circ \times 5^\circ$ spatial resolution,
141 and optimize monthly NBE and air-sea carbon fluxes at each grid point from January 2010 to
142 December 2018. Inputs for the system include prior carbon fluxes, meteorological drivers, and the
143 satellite X_{CO_2} (Figure 1). Section 2.2 (Table 2) describes the prior flux and its uncertainties, and
144 section 2.3 (Table 3) describes the observations and the corresponding uncertainties.

145

146 **2.2 The prior CO_2 fluxes and uncertainties**

147 Prior CO_2 fluxes include NBE, air-sea net carbon fluxes, and fossil fuel emissions (see Table 2).
148 The data sources for the prior fluxes are listed in Table 7. Methods to generate prior ocean carbon
149 fluxes and fossil fuel emissions are documented in Brix et al., (2015), Caroll et al. (2020), and Oda
150 et al. (2018). The focus of this dataset is optimized terrestrial biosphere fluxes, so we briefly
151 describe the prior terrestrial biosphere fluxes and its uncertainties.

152

153 We construct the NBE prior using the CARDAMOM framework (Bloom et al., 2016).
154 CARDAMOM data assimilation system explicitly represents the time-resolved uncertainties in
155 NBE. The prior estimates are already constrained with multiple data streams accounting for
156 measurement uncertainties following a similar Bayesian approach used in the 4D-variational
157 approach. We use the CARDAMOM setup as described by Bloom et al. (2016, 2020) resolved at
158 monthly timescales; data constraints include GOME-2 solar-induced fluorescence (Joiner et al.,
159 2013), MODIS Leaf Area Index (LAI), and biomass and soil carbon (details on the data

160 assimilation are provided in Bloom et al. (2020)). In addition, mean GPP and fire carbon emissions
161 from 2010 - 2017 are constrained by FLUXCOM GPP (Tramontana et al., 2016) and GFEDv4.1s
162 (Randerson et al., 2018) respectively, both assimilated with an uncertainty of 20%. We use the
163 Olsen and Randerson (2001) approach to downscale monthly GPP and respiration fluxes to 3-
164 hourly timescales, based on ERA-interim re-analysis of global radiation and surface temperature.
165 Fire fluxes are downscaled using the GFEDv4.1 daily and diurnal scale factors on monthly
166 emissions (Giglio et al., 2013). Posterior CARDAMOM NBE estimates are then summarized as
167 NBE mean and standard deviation values.

168

169 The NBE from CARDAMON shows net carbon uptake of 2.3 GtC/year over the tropics and close
170 to neutral in the extratropics (Figure S1). The year-to-year variability (i.e., interannual variability,
171 IAV) estimated from CARDAMOM from 2010–2017 is generally less than 0.1 gC/m²/day outside
172 of the tropics (Figure S1). Because of the weak interannual variability estimated by CARDAMOM,
173 we use the same 2017 NBE prior for 2018.

174

175 CARDAMOM generates uncertainty along with the mean state. The relative uncertainty over the
176 tropics is generally larger than 100%, and the magnitude is between 50% and 100% over the extra-
177 tropics (Figure S2). We assume no correlation in prior flux errors in either space or time. Temporal
178 and spatial error correlation estimates can in principle be computed by CARDAMOM. We
179 anticipate incorporating these error correlations in subsequent versions of this dataset.

180

181 **2.3 Column CO₂ observations from GOSAT and OCO-2**

182 We use satellite-column CO₂ retrievals from Atmospheric Carbon Observations from Space
183 (ACOS) team for both GOSAT (version 7.3) and OCO-2 (version 9) (Table 3). The use of the

184 same retrieval algorithm and validation strategy adopted by ACOS team to process both GOSAT
185 and OCO-2 spectra maximize the consistency between these two datasets. Both GOSAT and OCO-
186 2 satellites carry high-resolution spectrometers optimized to return high precision measurements
187 of reflected sunlight within CO₂ and O₂ absorption bands in the shortwave infrared (Crisp et al.,
188 2012). Both satellites fly in a sun-synchronous orbit. GOSAT has a 13:00 ± 0.15 hours local
189 crossing time and a three-day ground track repeat cycle. The footprint of GOSAT is ~10.5 km in
190 diameter in sun-nadir view (Crisp et al., 2012). The daily number of soundings processed by the
191 ACOS-GOSAT retrieval algorithm is between a few hundreds to ~2000. Further quality control
192 and filtering reduce the ACOS-GOSAT X_{CO2} retrievals to 100 – 300 daily (Figure S5 in Liu et al.,
193 2017). We only assimilate ACOS-GOSAT land nadir good quality observations.

194

195 OCO-2 has a 13:30 local crossing time and 16-day ground track repeat cycle. The nominal
196 footprints of OCO-2 are 1.25 km wide and ~2.4 km along the orbit. Because of its small footprint
197 and sampling strategy, OCO-2 has many more X_{CO2} retrievals than ACOS-GOSAT. OCO-2 has
198 four observing modes: land nadir, land glint, ocean glint, and target. Following Liu et al. (2017),
199 we only use land nadir observations from OCO-2 to generate a set of super observations by
200 aggregating the observations within ~100 km (along the same orbit). The super observations have
201 more uniform spatial coverage and are more comparable to the spatial representation of ACOS-
202 GOSAT observations (see Figure S5 in Liu et al., 2017).

203

204 We directly use observational uncertainty provided with ACOS-GOSAT b7.3 to represent the
205 observation error, **R**, in Eq 1. The uncertainty of the OCO-2 super observations is the sum of the
206 variability of X_{CO2} used to generate each individual super observation and the mean uncertainty

207 provided in the original OCO-2 retrievals. More detailed information about OCO-2 super
208 observations can be found in Liu et al. (2017). Kulawik et al. (2019) showed that both OCO-2 and
209 ACOS-GOSAT bias-corrected retrievals have mean biases of -0.1 ppm when compared against
210 X_{CO_2} from Total Carbon Column Observing Network (TCCON) (Wunch et al., 2011), indicating
211 consistency between ACOS-GOSAT and OCO-2 retrievals. The magnitude of observation errors
212 used in \mathbf{R} is generally above 1.0 ppm, larger than the sum of random error and biases in the
213 observations. The ACOS-GOSAT b7.3 observations from July 2009–June 2015 are used to
214 optimize fluxes between 2010 and 2014, and the OCO-2 X_{CO_2} observations from Sep 2014–June
215 2019 are used to optimize fluxes between 2015 and 2018.

216

217 The observational coverage of ACOS-GOSAT and OCO-2 is spatiotemporally dependent, with
218 more coverage during summer than winter over the NH, and more observations over mid-latitudes
219 than over the tropics (Figure S3). The variability (i.e., standard deviation) of annual total number
220 of observations from 2010–2014 is within 4% of the annual mean number for ACOS-GOSAT.
221 Except for a data gap in 2017 caused by a malfunction of OCO-2 instrument, the variability of
222 annual total number of observations between 2015 and 2018 is within 8% of the annual mean
223 number for OCO-2.

224

225 **2.4 Uncertainty quantification**

226 The posterior flux error covariance is analytically the inverse Hessian, which incorporates the
227 transport, measurement, and background errors at the 4D-Var solution (Eq. 13 in Bowman et al,
228 2017). For large-order systems, the posterior errors cannot be explicitly calculated. Consequently,
229 we rely on a Monte Carlo approach to quantify posterior flux uncertainties following Chevallier et
230 al. (2010) and Liu et al. (2014). In this approach, an ensemble of flux inversions is carried out with

231 an ensemble of priors and simulated observations to sample the uncertainties of prior fluxes (i.e.,
232 \mathbf{B} in eq. 1) and observations (\mathbf{R} in Eq. 1), respectively. The magnitude of posterior flux
233 uncertainties is a function of assumed uncertainties in prior fluxes and observations, as well as the
234 density of observations. Since the density of GOSAT and OCO-2 observations are stable (section
235 2.3) within their respective data record, we characterize the posterior flux uncertainties for 2010
236 and 2015 only, and assume the flux uncertainties for 2011–2014 are the same as 2010 and flux
237 uncertainties for 2016–2018 are the same as 2015.

238 **2.5 Evaluation of posterior fluxes**

239 Direct NBE estimates from flux towers only provide a spatial representation of a few kilometers
240 (Running et al., 1999), not appropriate to evaluate regional NBE from top-down flux inversions.
241 Thus, we use two methods to indirectly evaluate the posterior NBE and its uncertainties. One is to
242 compare annual NBE anomalies and seasonal cycle to a gross primary production (GPP) product.
243 The other is to compare posterior CO₂ mole fractions to independent aircraft observations (i.e., not
244 assimilated in the inversion). The second method has been broadly used to indirectly evaluate
245 posterior fluxes from top-down flux inversions (e.g., Stephens et al., 2007; Liu and Bowman, 2016;
246 Chevallier et al., 2019; Crowell et al., 2019).

247 **2.5.1 Evaluation against independent gross primary production (GPP) product**

248 NBE is a small residual difference between two large terms: total ecosystem respiration (TER)
249 and GPP, plus fire. A positive NBE anomaly (i.e., less uptake from the atmosphere) has been
250 shown to correspond to reduced GPP caused by climate anomalies (e.g., Bastos et al., 2018), and
251 the magnitude of net uptake is proportional to GPP in most biomes observed by flux tower
252 observations (e.g, Falk et al., 2008). Since NBE is related not only to GPP, the comparison to GPP
253 only serves as a qualitative measure of the NBE quality. For example, we would expect that the

254 posterior NBE seasonality to be anti-correlated with GPP in the temperate and high latitudes. In
255 this study, we use FLUXSAT GPP (Joiner et al., 2018), which is an upscaled GPP product based
256 on flux tower GPP observations and satellite-based geometry adjusted reflectance from the
257 MODerate-resolution Imaging Spectroradiometer (MODIS) and solar-induced chlorophyll
258 fluorescence observations from Global Ozone Monitoring Experiment – 2 (GOME-2) (Joiner et
259 al., 2013). Joiner et al. (2018) show that the agreement between FLUXSAT-GPP and GPP from
260 flux towers is better than other available upscaled GPP products.

261 **2.5.2 Evaluation against aircraft CO₂ observations**

262 The aircraft observations used in this study include those published in ObsPack August 2019
263 (CarbonTracker team, 2019), which include regular vertical profiles from flask samples collected
264 on light aircraft by NOAA (Sweeney et al., 2015) and other laboratories, aircraft campaigns from
265 Atmospheric Tomography (ATom, Wofsy et al., 2018) and HIAPER Pole-to-Pole (HIPPO, Wofsy
266 et al., 2011), regular (two to four weekly) vertical profiles from the Instituto de Pesquisas Espaciais
267 (INPE) over tropical South America (SA) (Gatti et al., 2014), and the O₂/N₂ Ratio and CO₂
268 airborne Southern Ocean (ORCAS) Study aircraft campaign (Stephens et al., 2017) (Table 3).
269 Figure 2 shows the aircraft observation coverage and density between 2010 and 2018. Most of the
270 aircraft observations are concentrated over NA. ATom had four (1–4) campaigns between August
271 2016 to May 2018, spanning four seasons over the Pacific and Atlantic Ocean. HIPPO had five
272 (1–5) campaigns over Pacific, and only HIPPO 3–5 occurred between 2010 and 2011. HIPPO 1–
273 2 occurred in 2009. Based on the spatial distribution of aircraft observations, we divide the
274 comparison into nine regions: Alaska, mid-latitude NA, Europe, East Asia, South Asia, Africa,
275 Australia, Southern Ocean, and South America (Table 4 and Figure 2).

276

277 We calculate several quantities to evaluate the posterior fluxes and its uncertainty with aircraft
278 observations. One is the monthly mean differences between posterior and aircraft CO₂ mole
279 fractions. The second is the monthly root mean square errors (RMSE) over each nine sub-regions,
280 which is defined as:

$$281 \quad RMSE = \left(\frac{1}{n} \sum_{i=1}^n (y_{aircraft}^o - y_{aircraft}^b)_i^2 \right)^{\frac{1}{2}} \quad (2)$$

282 where $y_{aircraft}^o$ is i^{th} aircraft observation, $y_{aircraft}^b$ is the corresponding posterior CO₂ mole
283 fractions sampled at i^{th} aircraft locations, and n is the number of aircraft observations over each
284 region. The RMSE is computed over the n aircraft observations within one of the nine sub-regions.
285 The mean differences indicate the magnitude of mean posterior CO₂ bias, while the RMSE
286 includes both random and systematic errors in posterior CO₂. The bias and RMSE could be due to
287 errors in either posterior fluxes or transport or both. When transport errors are smaller than errors
288 in posterior fluxes, the magnitude of biases and *RMSE* indicates the accuracy of posterior fluxes.
289

290 To evaluate the magnitude of posterior flux uncertainty estimates, we compare *RMSE* against the
291 standard deviation of ensemble simulated aircraft observations (equation 3) from the Monte Carlo
292 method (*RMSE_{MC}*). The quantity *RMSE_{MC}* can be written as:

$$293 \quad RMSE_{MC} = \left[\frac{1}{n_{ens}} \sum_{iens=1}^{n_{ens}} ((y_{aircraft}^{b(MC)})_{iens} - \bar{y}_{aircraft}^{b(MC)})^2 \right]^{\frac{1}{2}} \quad (3)$$

294 The variable $(y_{aircraft}^{b(MC)})_{iens}$ is the i^{th} ensemble member of simulated aircraft observations from
295 Monte Carlo ensemble simulations, $\bar{y}_{aircraft}^{b(MC)}$ is the mean, and n_{ens} is the total number of ensemble
296 members. For simplicity, in equation (3), we drop the indices for the aircraft observations used in
297 equation (2). In the absence of transport errors, when the estimated posterior flux uncertainty
298 reflects the “true” posterior flux uncertainty, we show in the *Appendix* that:

299 $RMSE^2 = R_{aircraft} + RMSE_{MC}^2$ (4)

300 where $R_{aircraft}$ is the aircraft observation error variance, which could be neglected on regional
301 scales. We further calculate the ratio r between $RMSE$ and $RMSE_{MC}$:

302 $r = \frac{RMSE}{RMSE_{MC}}$ (5)

303 A ratio close to one indicates that the posterior flux uncertainty reflects the true uncertainty in the
304 posterior fluxes when the transport errors are small.

305

306 The presence of transport errors will make the comparison between $RMSE$ and $RMSE_{MC}$
307 potentially difficult to interpret. Even when $RMSE_{MC}$ represents the actual uncertainty in posterior
308 fluxes, the $RMSE$ could be larger than $RMSE_{MC}$, since the differences between aircraft
309 observations and model simulated posterior mole fractions $RMSE$ could be due to errors in both
310 transport and the posterior fluxes, while $RMSE_{MC}$ only reflects the impact of posterior flux
311 uncertainty on simulated aircraft observations. In this study, we assume the primary sources of
312 $RMSE$ come from errors in posterior fluxes.

313

314 The $RMSE$ and $RMSE_{MC}$ comparison only shows differences in CO_2 space. We further calculate
315 the sensitivity of $RMSE$ to posterior flux using GEOS-Chem adjoint. We first define a cost
316 function J as:

317 $J = RMSE^2$ (6)

318 The sensitivity of the mean-square error to a flux, x , at location i and month j is

319 $w_{i,j} = \frac{\partial J}{\partial x_{i,j}} \times x_{i,j}$ (7)

320 This sensitivity is normalized by the flux magnitude. Equation 7 can be interpreted as the
321 sensitivity of the $RMSE^2$ to a fractional change in the fluxes. We can estimate the time-integrated
322 magnitude of the sensitivity over the entire assimilation window by calculating:

$$323 \quad S_i = \frac{\sum_{j=1}^M |w_{i,j}|}{\sum_{k=1}^P \sum_{j=1}^M |w_{k,j}|} \quad (8)$$

324 where P is the total number of grid points and M is the total number of months from the time of
325 the aircraft data to the beginning of the inversion. The numerator of equation (8) quantifies the
326 absolute total sensitivity of the $RMSE^2$ to the fluxes at the i^{th} grid. Normalized by the total absolute
327 sensitivity across the globe, the quantity S_i indicates the relative sensitivity of $RMSE^2$ to fluxes at
328 the i^{th} grid point. Note that S_i is unitless, and it only quantifies sensitivity, not the contribution of
329 fluxes at each grid to $RMSE^2$.

330

331 **2.6 Regional masks**

332 We provide posterior NBE from 2010 – 2018 using two sets of aggregated regions, for a few
333 selected FLUXNET tower sites, and the underlying gridded product. The regional mask in Figure
334 3A is based on a combination of seven plant function types condensed from MODIS IGBP and the
335 TRANSCOM -3 region mask (Gurney et al., 2004). There are 28 regions in Figure 3A: six in NA,
336 four in SA, five in Eurasia (north of 40°N), three in tropical Asia, three in Australia, and seven in
337 Africa. The regional mask in Figure 3B is based on latitude and continents, and there are 13 regions
338 in total.

339

340 **3 Dataset description**

341

342 We present the gridded fluxes as globally, latitudinally, and regionally time series. We show the
343 nine-year average fluxes aggregated into 28 and 13 geographic regions (Figure 3). The

344 aggregations are geographic (latitude and continent), bio-climatic (biome by continent), and flux-
345 oriented (for a set of selected flux sites). For each region in the geographic and biome aggregations,
346 we show nine-year mean annual net fluxes and uncertainties, and then the annual fluxes for each
347 region as a set of time-series plots. The month-by-month fluxes and uncertainties are available in
348 tabular format, so the actual aggregated fluxes may be readily compared to bottom-up extrapolated
349 fluxes and Earth System models. Users can also aggregate the gridded fluxes and uncertainties
350 based on their own defined regional masks. Table 5 provides a complete list of all data products
351 available in the dataset. In section 4, we describe the major characteristics of the dataset.

352 **4 Characteristics of the dataset**

353 **4.1 Global fluxes**

354 The annual atmospheric CO₂ growth rate, which is the sum of fossil fuel emissions and total annual
355 sink over land and ocean, is well-observed by NOAA surface CO₂ observing network
356 (<https://www.esrl.noaa.gov/gmd/ccgg/ggrn.php>) (Freidlingstein et al., 2019). We compare the global total
357 flux estimates constrained by GOSAT and OCO-2 with the NOAA CO₂ growth rate from 2010–
358 2018, and discuss the mean carbon sink over land and ocean. Over these nine years, the satellite-
359 constrained atmospheric CO₂ growth rate agrees with the NOAA observed CO₂ growth rate within
360 the uncertainty of posterior fluxes (Figure 4). The mean annual global surface CO₂ flux (in Gt C/yr)
361 is derived from the NOAA observed CO₂ growth rate (in ppm/yr) using a conversion factor of
362 2.124 GtC/ppm (Le Quéré et al., 2018). The estimated growth rate has the largest discrepancy with
363 the NOAA observed growth rate in 2014, which may be due to a failure of one of the two solar
364 paddles in May 2014 (Kuze et al., 2016). Over the nine years, the estimated total accumulated
365 carbon in the atmosphere is 41.5 ± 2.4 GtC, which is slightly lower than the accumulated carbon
366 based on NOAA CO₂ growth rate (45.2 ± 0.4 GtC). On average, the land sink is $20 \pm 8\%$ of fossil

367 fuel emissions, and the ocean sink is $30 \pm 1\%$ of fossil fuel emissions (Figure 4). These numbers
368 are within the ranges of the corresponding estimates from GCP 2019 (Freidlingstein et al., 2019).
369 The mean NBE and ocean sink from GCP 2019 are $21 \pm 10\%$ (~ 1.0 GtC estimated residual NBE
370 uncertainty) and $26 \pm 5\%$ (~ 0.5 GtC estimated ocean flux uncertainty) of fossil fuel emissions
371 respectively between 2010–2018. The GCP NBE here is calculate as the residual differences
372 between fossil fuel, ocean fluxes, and atmospheric CO₂ growth rate, and it is also equivalent to the
373 sum of carbon fluxes from land use changes, land sink, and residual balance reported by GCP.
374 Over these nine years, we estimate that the land sink ranges from 37% of fossil fuel emissions in
375 2011 (a La Niña year) to only 5% in 2015 (an El Niño year), consistent with GCP estimated range
376 of 35% in 2011 to 7% in 2015. We estimate that the ocean sinks range from 39% in 2015 to 23%
377 of fossil fuel emissions in 2012, larger than the GCP estimated ocean flux ranges of 25% to 28%
378 of fossil fuel emissions (Freidlingstein et al., 2019).

379 **4.2 Mean regional fluxes and uncertainties**

380 Figure 5 shows the nine-year mean regional annual fluxes, uncertainty, and its variability between
381 2010–2018. Table 6 shows an example of the dataset corresponding to Figure 5 A, C, and E. It
382 shows large net carbon uptake occurs over Eurasia, NA, and Southern Hemisphere (SH) mid-
383 latitudes. The largest net carbon uptake is over eastern US (-0.4 ± 0.1 GtC (1σ uncertainty)) and
384 high latitude Eurasia (-0.4 ± 0.1 GtC) (Figure 5A, B). We estimate a net land carbon sink of $2.5 \pm$
385 0.3 GtC/year between 2010–2013 over the NH mid to high latitudes, which agrees with 2.4 ± 0.6
386 GtC estimates over the same time periods based on a two-box model (Ciais et al., 2019). Net uptake
387 in the tropics ranges from close-to-neutral in tropical South America (0.0 ± 0.1 GtC) to a net source
388 in northern Africa (0.6 ± 0.2 GtC) (Figure 5A, B). The tropics exhibit both large uncertainty and
389 large variability. The NBE interannual variability over northern Africa and tropical SA are 0.5 GtC

390 and 0.3 GtC respectively, larger than the 0.2 GtC and 0.1 GtC uncertainty (Figure 5C, D). We also
391 find collocation of regions with large NBE and GPP interannual variability (Figure S4).

392

393 **4.3 Interannual variabilities and uncertainties**

394 Here we present hemispheric and regional NBE interannual variabilities and corresponding
395 uncertainties (Figures 6 and 7, and corresponding tabular data files). In Figure 6, we further divide
396 the globe into three large latitude bands: tropics (20°S–20°N), NH extra-tropics (20°N–85°N), and
397 SH extra-tropics (60°S–20°S). The tropical NBE contributes 90% to the global NBE interannual
398 variability (IAV). The IAV of NBE over the extra-tropics is only about one-third of that over the
399 tropics. The dominant role of tropical NBE in the global IAV of NBE agrees with Figure 4 in
400 Sellers et al. (2018). The top-down global annual NBE anomaly is within the 1.0 GtC/yr
401 uncertainty of residual NBE (i.e., fossil fuel – atmospheric growth – ocean sink) calculated from
402 GCP-2019 (Friedlinston et al., 2019) (Figure 6).

403

404 Figure 7 shows the annual NBE anomalies and uncertainties over a few selected regions. Positive
405 NBE indicates reduced net uptake relative to the 2010–2018 mean, and vice versa. Also shown in
406 Figure 7 are GPP anomalies estimated from FLUXSAT. Positive GPP indicates increased
407 productivity, and vice versa. GPP drives NBE in years where anomalies are inversely correlated
408 (e.g., positive NBE and negative GPP), and TER drives NBE in years where anomalies of GPP
409 and NBE have the same sign or weakly correlated. Over tropical SA evergreen broadleaf forest,
410 the largest positive NBE anomalies occur during 2015–2016 El Niño, corresponding to large
411 reductions in productivity, consistent with Liu et al. (2017). In 2017, the region sees increased net
412 uptake and increased productivity, implying a recovery from the 2015–2016 El Niño event. The

413 variability in GPP explains 80% of NBE variability over this region over the nine-year period. In
414 Australian shrubland, our inversion captures the increased net uptake in 2010 and 2011 due to
415 increased precipitation (Pouter et al., 2014) and increased productivity. The variability in GPP
416 explains 70% of the interannual variability in NBE. Over tropical south America Savanna, the
417 NBE interannual variability also shows strong negative correlations with GPP, with GPP
418 explaining 40% of NBE interannual variability. Over the mid-latitude regions where the IAV is
419 small, the R^2 between GPP and NBE is also small (0.0–0.5) as expected. But the increased net
420 uptake generally corresponds to increased productivity. We also do not expect perfect negative
421 correlation between NBE anomalies and GPP anomalies, as discussed in section 2.5. The
422 comparison between NBE and GPP provides insight into when and where net fluxes are likely
423 dominated by productivity.

424

425 **4.4 Seasonal cycle**

426 We provide a top-down CO_2 constrained regional mean NBE seasonal cycle and its variability and
427 uncertainty. The seasonal cycle of NBE, including its phase (i.e., transition from source to sink)
428 and amplitude (peak-to-trough difference), have large uncertainties, not only over the less-
429 observed tropical regions, but also over the extra-tropics (e.g., Yang et al., 2007; Keppel-Aleks et
430 al., 2012). Figure 8 shows NBE and GPP seasonal cycles for six selected regions. In general, the
431 months that have larger productivity corresponds to months with a net uptake of carbon from the
432 atmosphere. The NH mid-to-high latitudes have larger seasonal cycle amplitudes (Figure 8A, B)
433 compared to the other regions, and their NBE seasonalities are more closely linked to that of GPP
434 ($R^2 = 0.9$). In the tropics, the relationship between NBE and GPP seasonality is less clear partially

435 due to the weak seasonality of NBE (Figure 8E, F). The variability and uncertainty of monthly
436 mean fluxes are larger over the tropics and the SH extratropics than over the NH extratropics.

437 **5 Evaluation against independent aircraft CO₂ observations**

438 **5.1 Comparison to aircraft observations over nine sub-regions**

439 In this section, we evaluate posterior CO₂ against aircraft observations over nine sub-regions listed
440 in Table 4 and Figure 2. We compare the posterior to aircraft CO₂ mole fractions above planetary
441 boundary layer and up to mid troposphere (1–5 km) at the locations and time of aircraft
442 observations, and then calculate the monthly mean error statistics between 1–5 km. The aircraft
443 observations between 1–5 km are more sensitive to regional fluxes (Liu et al., 2015; Liu and
444 Bowman, 2016). Scatter plots in the left column of Figure 9 show regional monthly mean de-
445 trended aircraft CO₂ observations (x-axis) versus the simulated detrended posterior CO₂ (y-axis).
446 We used NOAA global CO₂ trend to detrend both the observations and model simulated mole
447 fractions (ftp://aftp.cmdl.noaa.gov/products/trends/co2/co2_trend_gl.txt). Over the NH regions (A,
448 B, C, D) and Africa (F), the R² is equal or above 0.9, which indicates that the posterior CO₂ captures
449 the observed seasonality. The low R² (0.7) value in South Asia is caused by one outlier. Over
450 Southern Ocean, Australia, and SA, the R² is between 0.2 and 0.4, reflecting weaker CO₂
451 seasonality over these regions.

452

453 The right panel of Figure 9 shows the monthly mean differences between posterior CO₂ and aircraft
454 observations (black), the number of aircraft observations (blue bar, right y-axis), *RMSE* (equation
455 2) (blue line), and *RMSE_{MC}* (equation 3) (red line). The magnitude of mean differences between
456 posterior CO₂ and aircraft observations is less than 0.5 ppm except over Southern Ocean, which
457 has a -0.8 ppm bias. The mean differences between posterior CO₂ and aircraft observations are

458 primarily caused by errors in transport and biases in assimilated satellite observations, while
459 $RMSE_{MC}$ is ‘internal flux error’ projected into mole fraction space. With the exception of the
460 Southern Ocean, for all regions mean bias is significantly less than $RMSE_{MC}$, which suggests that
461 transport and data bias in satellite observations may be much smaller than the internal flux errors.

462

463 As demonstrated in section 2.5, comparing $RMSE$ and $RMSE_{MC}$ is a test of the accuracy of posterior
464 flux uncertainty estimate. Over all the regions, the differences between $RMSE$ and $RMSE_{MC}$ are
465 smaller than 0.3 ppm, which indicates a comparable magnitude between empirical posterior flux
466 uncertainty estimates from Monte Carlo method and the actual posterior flux uncertainty over the
467 regions that these aircraft observations are sensitive to. These aircraft observations are sensitive to
468 fluxes over a broad region as shown in Figure S5.

469

470 **5.2 Comparison to aircraft observations from ATom and HIPPO aircraft campaigns**

471 Figures 10 and 11 show comparisons to aircraft CO_2 from ATom 1–4 campaigns spanning four
472 seasons, and HIPPO 3–5 over the Pacific Ocean between 1–5 km. The vertical curtain comparisons
473 are shown in Figure S6 and S7. The mean differences between posterior CO_2 and aircraft CO_2 are
474 quite uniform (within 0.5 ppm) throughout the column except over the Atlantic Ocean during
475 ATom 1–2 and the Southern Ocean during ATom 1 (Figures S6 and S7). Also shown in Figures
476 10 and 11 are $RMSE$ of each aircraft campaign (middle column) and the ratio between $RMSE$ and
477 $RMSE_{MC}$ (right column). A ratio larger than one between $RMSE$ and $RMSE_{MC}$ indicates errors in
478 either transport or low of posterior flux uncertainty estimates (section 2.5).

479

480 Over most of flight tracks during ATom 1–4, the posterior CO₂ errors are between -0.5 and 0.5
481 ppm, the *RMSE* is smaller than 0.5 ppm, and the ratio between *RMSE* and *RMSE_{MC}* is smaller than
482 or equal to 1. However, off the coast of Africa during ATOM -1 and -2 and over Southern Ocean
483 during ATOM-1, the mean differences between posterior CO₂ and aircraft observations are larger
484 than 0.5 ppm. During ATOM-1 (29 July – 23 Aug 2016), the mean differences between posterior
485 CO₂ and aircraft CO₂ show large negative biases, while during ATOM-2 (26 Jan 2017–21 Feb
486 2017), it has large positive biases off the coast of Africa. The ratio between *RMSE* and *RMSE_{MC}*
487 is significantly larger than one over these regions, which indicates an underestimation of posterior
488 flux uncertainty or large magnitude of transport errors during that time period.

489

490 We further run adjoint sensitivity analyses over the three regions with ratios significantly larger
491 than one to identify the posterior fluxes that could contribute to the large differences between
492 posterior CO₂ and aircraft observations during ATOM 1–2. We run the adjoint model backward
493 for three months from the observation time and calculate S_i defined in equation (7). Adjoint
494 sensitivity analysis indicates that the large mismatch between aircraft observations and model
495 simulations during ATOM-1 and -2 off the coast of Africa could be potentially driven by errors in
496 posterior fluxes over tropical Africa (Figure S8). These large posterior CO₂ errors and large ratio
497 over Southern Ocean during ATOM-1 are driven by flux errors in oceanic fluxes around 30°S and
498 over Australia (Figure S9).

499

500 During the HIPPO aircraft campaigns, the absolute errors in posterior CO₂ across Pacific are less
501 than 0.5 ppm except over the Arctic Ocean and over Alaska in summer (Figure 11), consistent
502 with Figure 10A. The large errors over the Arctic Ocean may be related to both transport errors

503 and the accuracy of high latitude fluxes. Byrne et al. (2020) provide a brief summary of these
504 challenges in simulating CO₂ over high latitudes with 4° x 5° resolution transport model.
505 Increasing the resolution of the transport model may reduce transport errors over high latitudes.

506

507 We run adjoint sensitivity analysis over the high-latitude regions where the differences between
508 posterior CO₂ and aircraft observations are large (Figure 11). The adjoint sensitivity analysis
509 (Figure S10) shows that the large errors over these regions could be driven by errors in fluxes over
510 Alaska as well as broad NH mid-latitude regions.

511

512 **6 Discussion**

513 Evaluation of posterior flux uncertainty estimates by comparing posterior CO₂ error statistics
514 (*RMSE*, Equation 2) with the standard deviation of ensemble simulated CO₂ from Monte Carlo
515 uncertainty quantification method (*RMSE_{MC}*, equation 3) has its limitations. When *RMSE* and
516 *RMSE_{MC}* are similar in magnitude, this indicates small magnitude of transport errors and
517 reasonable posterior uncertainty estimates. A much larger *RMSE* than *RMSE_{MC}* could be due to
518 errors in either transport or underestimation of posterior flux uncertainty or both. The presence of
519 transport errors makes the interpretation of the *RMSE* and *RMSE_{MC}* complex. A better, independent
520 quantification of transport errors is needed in the future in order to rigorously use the comparison
521 statistics between aircraft observations and posterior CO₂ to diagnose flux errors.

522

523 Comparison to aircraft observations shows regionally-dependent accuracy in posterior fluxes.
524 ATom observations show seasonally-dependent biases over the Atlantic, implying possible
525 seasonally dependent errors in posterior fluxes over northern to central Africa. Therefore, we
526 recommend combining NBE with other ancillary variables, e.g., GPP, to better understand carbon

527 dynamics. Combining NBE with component carbon fluxes can shed light on the processes
528 controlling the changes of NBE (e.g., Bowman et al, 2017; Liu et al., 2017). NBE can be written
529 as:

$$530 \text{ NBE} = \text{TER} + \text{fire} - \text{GPP} \quad (8)$$

531 where TER is total ecosystem respiration (TER) (Figure 1). Satellite carbon monoxide (CO)
532 observations provide constraints on fire emissions (Arellano et al, 2006, van der Werf, 2008; Jones
533 et al, 2009; Jiang et al., 2015, Bowman et al, 2017; Liu et al., 2017). In addition to FLUXSAT-
534 GPP product used here, solar induced chlorophyll fluorescence (SIF) can be directly used as a
535 proxy for GPP (e.g., Parazoo et al, 2014). Once NBE, fire, and GPP carbon fluxes are quantified,
536 TER can be calculated as a residual (e.g., Bowman et al, 2017; Liu et al., 2017, 2018).

537

538 Because of the diffusive manner of atmospheric transport and the limited observation coverage,
539 the gridded flux values are not independent from each other. The errors and relative uncertainties
540 of the fluxes at each individual grid point are larger than regional aggregated fluxes. For the same
541 reason, comparing NBE with flux tower observations needs caution, though we provide NBE at a
542 few flux tower sites.

543

544 The variability and changes are more robust than the mean NBE fluxes from top-down flux
545 inversions in general (Baker et al., 2006b). The errors in transport and potential biases in
546 observations are mostly stable in time, so biases in the mean fluxes tend to cancel out when
547 computing interannual variability and year-to-year changes (Schuh et al., 2019; Crowell et al.,
548 2019).

549

550 The global fossil fuel emissions have ~5% uncertainty (GCP, 2019). However, they are regionally
551 inhomogeneous. We neglect the uncertainties in fossil fuel emissions, which will introduce
552 additional error in regions of rapid fossil fuel growth or in areas with noisier statistics (Yin et al.,
553 2019). In the future, we will account for uncertainties in fossil fuel emissions.

554

555 The posterior NBE includes all types of land fluxes except fossil fuel emissions, which is
556 equivalent to the sum of land use change fluxes and land sinks published by GCP. The sum of
557 regional NBE and fossil fuel emissions is an index of the contribution of any specific region to the
558 changes of atmospheric CO₂ growth rate. Even over the continental US, where fossil fuel
559 emissions are ~1.5 GtC/year, the changes of regional NBE can significantly modify contributions
560 to the changes of atmospheric CO₂ (Liu et al., 2018). Since NBE has high variability and its
561 predicted changes in the future are likely to have large uncertainties, quantifying regional NBE is
562 critical to monitoring regional contributions to atmospheric CO₂ growth rate, and ultimately to
563 guide mitigation to limit warming to 1.5°C above pre-industrial level (IPCC, AR6).

564

565 **7 Summary**

566 Terrestrial biosphere carbon fluxes are the largest contributor to the interannual variability of the
567 atmospheric CO₂ growth rate. Therefore, monitoring its change at regional scales is essential for
568 understanding how it responds to CO₂, climate and land use. Here, we present the longest terrestrial
569 flux estimates and their uncertainties constrained by X_{CO₂} from 2010–2018 on self-consistent
570 global and regional scales (CMS-Flux NBE 2020). We qualitatively evaluate the net flux estimates
571 by comparing its variability with GPP variability, and provide comprehensive evaluation of
572 posterior fluxes and the uncertainties by comparing posterior CO₂ with independent aircraft CO₂.

573 The estimated posterior flux uncertainty agrees with the expected uncertainty in the posterior
574 fluxes based on the comparison to aircraft CO₂ observations. This dataset can be used in
575 understanding controls on regional NBE interannual variability, evaluating biogeochemical
576 models, and provide support the monitoring of the regional contributions to the changes in
577 atmospheric CO₂.

578

579 **8 Data availability and future update**

580 The CMS-Flux NBE 2020 data is available at: <https://doi.org/10.25966/4v02-c391> (Liu et al.,
581 2020). The regional aggregated fluxes are provided as *csv* files with file size ~10MB, and the
582 gridded data is provided in NetCDF format with file size ~10MB. The full ensemble posterior
583 fluxes used to estimate posterior flux uncertainties are provided in NetCDF format with file size
584 ~20MB. Table 7 lists the sources of the data used in producing and evaluating the CMS-Flux NBE
585 2020 data product.

586

587 The quality of X_{CO₂} from satellite observations is continually improving. The OCO-2 v10 X_{CO₂}
588 will be released in June 2020, and the full GOSAT record (June 2009–Jan 2020) processed by the
589 same retrieval algorithm as OCO-2 will be released around the same time. Continuing to improving
590 the quality of satellite observations and extending the NBE estimates beyond 2018 in the future
591 will help us better understand interactions between terrestrial biosphere carbon cycle and climate
592 and provide support in monitoring the regional contributions to the changes of atmospheric CO₂.
593 Thus, we plan a future update of the dataset on an annual basis, with a goal to support current
594 scientific research and policy making.

595 **9 Author contributions**

596 JL designed the study and led the writing of the paper in close collaboration with KB and DS. LB
597 helped generate the plots and created all the data files. AAB provided the prior of the terrestrial
598 biosphere carbon fluxes. NP helped interpret the GPP evaluation. DM and DC generated the prior
599 ocean carbon fluxes. TO generated the ODIAC fossil fuel emissions. JJ provided the FLUXSAT
600 GPP product. BD and SW provided and contributed to the interpretation of HIPPO aircraft CO₂
601 observation comparisons. BS, KM, and CS provided ORCAS aircraft CO₂ observations and
602 contributed interpretation of aircraft CO₂ observation comparisons. LVG and JM provided INPE
603 aircraft CO₂ observations and contributed interpretation of aircraft CO₂ observation comparisons.
604 CS and KM provided ATom and NOAA aircraft CO₂ observations and contributed interpretation
605 of aircraft CO₂ observation comparisons. We furthermore acknowledge funding from the EU for
606 the ERC project “ASICA” (grant number 649087) to Wouter Peters (Groningen University) and
607 EU and NERC (UK) funding to Emanuel Gloor (University of Leeds), which contributed to the
608 INPE Amazon greenhouse sampling program. All authors contributed to the writing, and have
609 reviewed and approved the paper.

610 **10 Competing interest**

611 The authors declare that they have no conflict of interest.

612 **Acknowledgement**

613 Resources supporting this work were provided by the NASA High-End Computing (HEC)
614 Program through the NASA Advanced Supercomputing (NAS) division at Ames Research Center.
615 We acknowledge the funding support from NASA OCO-2/3 Science Team, Carbon Monitoring
616 System (CMS), and Making Earth Science Data Records for Use in Research Environments
617 (MEaSUREs) programs. Tomohiro Oda is supported by the NASA Carbon Cycle Science program
618 (grant no. NNX14AM76G). We acknowledge EU and NERC (UK) funding to Emanuel

619 Gloor, University of Leeds which substantially contributed to the INPE Amazon
620 greenhouse sampling program. Part of the research was carried out at Jet Propulsion
621 Laboratory, Caltech.

622

623 **Appendix**

624 As shown in Kalnay (2003):

$$625 \quad RMSE^2 = R_{aircraft} + HP^a H^T \quad (A.1)$$

626 where $R_{aircraft}$ is the aircraft observation error variance, and P^a is the posterior flux error
627 covariance. The H is linearized observation operator, which transfers posterior flux errors to
628 aircraft observation space, and H^T is its adjoint. In the Monte Carlo method, the posterior flux
629 error covariance P^a is approximated by:

$$630 \quad P^a = \frac{1}{n_{ens}} X^a X^{aT} \quad (A.2)$$

631 where X^a is the ensemble perturbations written as:

$$632 \quad X^a = x^a - \bar{x}^a \quad (A.3)$$

633 where x^a is the ensemble posterior fluxes from Monte Carlo, and \bar{x}^a is the mean.

634 Therefore, $HP^a H^T$ can be written as:

$$635 \quad HP^a H^T = \frac{1}{n_{ens}} [h(x^a) - h(\bar{x}^a)][h(x^a) - h(\bar{x}^a)]^T \quad (A.4)$$

636 The right hand side is the same as the definition of $RMSE_{MC}$ in the main text.

637 Therefore, when the posterior flux uncertainty estimated by Monte Carlo method represents the
638 actual uncertainty in posterior fluxes, equation (A.1) can be written as:

$$639 \quad RMSE^2 = R_{aircraft} + RMSE_{MC}^2 \quad (A.5).$$

640 It is the same as equation (3) in the main text.
