11

12 **Abstract**

13 Deep convection possesses markedly distinct properties at different spatiotemporal scales. We
14 present an original high-resolution (4 km, hourly) unified data product of mesoscale convective
15 systems (MCSs) and isolated deep convection (IDC) in the United States east of the Rocky
16 Mountains and examine their climatological characteristics from 2004 to 2017. The data product
17 is produced by applying an updated Flexible Object Tracker algorithm to hourly satellite
18 brightness temperature, radar reflectivity, and precipitation datasets. Analysis of the data product
19 shows that MCSs are much larger and longer-lasting than IDC, but IDC occurs about 100 times
20 more frequently than MCSs, with a mean convective intensity comparable to that of MCSs.
21 Hence both MCS and IDC are essential contributors to precipitation east of the Rocky
22 Mountains, although their precipitation shows significantly different spatiotemporal
23 characteristics. IDC precipitation concentrates in summer in the Southeast with a peak in the late
24 afternoon, while MCS precipitation is significant in all seasons, especially for spring and
25 summer in the Great Plains. The spatial distribution of MCS precipitation amounts varies by
26 seasons, while diurnally, MCS precipitation generally peaks during nighttime except in the
27 Southeast. Potential uncertainties and limitations of the data product are also discussed. The data
28 product is useful for investigating the atmospheric environments and physical processes
29 associated with different types of convective systems, quantifying the impacts of convection on
30 hydrology, atmospheric chemistry, and severe weather events, and evaluating and improving the
31 representation of convective processes in weather and climate models. The data product is
32 available at <http://dx.doi.org/10.25584/1632005> (Li et al., 2020).

33

34 **1 Introduction**

35 In the atmosphere, deep convection refers to thermally driven turbulent mixing that
36 displaces air parcels from the lower atmosphere to the troposphere above 500 hPa (Davison,
37 1999), leading to the development of convective storms. The heavy rain-rates associated with
38 deep convection can significantly affect the water cycle (Hu et al., 2020) and other aspects such
39 as soil erosion (Nearing et al., 2004), surface water quality (Carpenter et al., 2018; Motew et al.,
40 2018), and managed and unmanaged ecosystems (Angel et al., 2005; Derbile and Kasei, 2012;
41 Rosenzweig et al., 2002) that are essential elements of the biogeochemical cycle. By
42 redistributing heat, mass, and momentum within the atmosphere, deep convection also has
43 important effects on atmospheric chemistry (Anderson et al., 2017; Andreae et al., 2001; Choi et
44 al., 2014; Grewe, 2007; Thompson et al., 1997; Twohy et al., 2002), large-scale environments
45 (Houze Jr, 2004; Piani et al., 2000; Stensrud, 1996, 2013; Wang, 2003), and radiation balance
46 (Feng et al., 2011; Zhang et al., 2017).

47 Besides its effects on the energy, water, and biogeochemical cycles, deep convection also
48 has more direct societal impacts. As a significant source of natural hazards such as tornadoes,
49 hail, wind gusts, lightning, and flash flooding, deep convection poses critical threats to human
50 life and property (Brooks et al., 2003; Doswell III et al., 1996; Koehler, 2020; Taszarek et al.,
51 2020). During 1950 – 1994, deep convection thunderstorms produced 47% of annual rainfall and
52 up to 72% of summer rainfall on average east of the Rocky Mountains (Changnon, 2001b).
53 During the same period, both the number of severe thunderstorms and deep convection
54 precipitation has increased in most regions of the contiguous United States (CONUS)
55 (Changnon, 2001a, b; Groisman et al., 2004). Folger and Reed (2013) found that hazards

56 associated with thunderstorms accounted for 57% of annual insured catastrophe losses since
57 1953. Since the 1980s, the inflation-adjusted economic losses due to convective storms increased
58 from about \$5 billion to about \$20 billion in the recent decade ([https://www.iii.org/fact-
60 statistic/facts-statistics-tornadoes-and-thunderstorms](https://www.iii.org/fact-
59 statistic/facts-statistics-tornadoes-and-thunderstorms)). With warmer temperatures, the
61 environments of hazardous convective weather are projected to become more frequent in the
62 future (Diffenbaugh et al., 2013; Seeley and Romps, 2015), although few robust trends have
emerged in the recent decades (Houze Jr et al., 2019; Tippett et al., 2015).

63 The crucial roles of deep convection motivate the need for more accurate and
64 comprehensive datasets to improve understanding and modeling of this process and its impacts.
65 To this end, datasets with information on the location and time of occurrence, intensity, and other
66 properties of deep convection are necessary to understand and quantify its impacts on the
67 hydrologic cycle, severe weather hazards, large-scale circulations, etc. While field campaign data
68 can provide detailed information on deep convection properties, they are limited in space-time
69 coverage for statistical analysis. A corresponding reliable long-term dataset is undoubtedly
70 useful for model evaluation and development (Prein et al., 2017; Yang et al., 2017).

71 Deep convection can exist as isolated convective storms or organized storms with
72 mesoscale structures. A mesoscale convective system (MCS) is an aggregate of convective
73 storms organized into a larger and longer-lived system, which is the largest type of deep
74 convection. Due to their much longer duration and broader spatial coverage, MCSs generally
75 have stronger and longer-lasting influences on large-scale circulations than isolated deep
76 convection (IDC) events (Bigelbach et al., 2014; Stensrud, 1996, 2013). MCSs may also produce
77 higher rain rates, larger echo top heights, and greater water and ice masses than IDC (Rowe et

78 al., 2011, 2012). The enhanced rain rates in MCSs might be caused by larger amounts of ice
79 falling out and melting, higher amounts of liquid water below the melting level, and higher
80 concentrations of smaller drops (Rowe et al., 2011, 2012). Rowe et al. (2012) also suggested that
81 the enhanced rainfall from MCSs might be associated with more favorable environmental
82 conditions, such as higher convective available potential energy (CAPE) and wind shear. CAPE
83 and wind shear can impose different impacts on the initiation and evolution of IDC and MCSs
84 (French and Parker, 2008).

85 Considering the significant differences between IDC and MCS events, a reliable long-term
86 dataset not only describing the characteristics of deep convection but also separating IDC events
87 from MCSs is useful. With the deployment of operational remote sensing platforms such as
88 geostationary satellites and ground-based radar network several decades ago, scientists have
89 developed numerical algorithms to automatically detect deep convective systems and track their
90 evolutions over large areas and for long durations on the basis of continuous measurements from
91 remote sensors (Cintineo et al., 2013; Feng et al., 2011; Feng et al., 2012; Futyan and Del Genio,
92 2007; Geerts, 1998; Hodges and Thorncroft, 1997; Liu et al., 2007; Machado et al., 1998).
93 Objective tracking of deep convection has been applied to geostationary satellite data (Cintineo
94 et al., 2013; Sieglaff et al., 2013; Walker et al., 2012) and Next Generation Weather Radar
95 (NEXRAD) data (Haberlie and Ashley, 2019; Pinto et al., 2015) in the United States (US) over
96 different periods. However, a long-term climatological data product of MCS and IDC events
97 over the CONUS has heretofore not been developed.

98 Here, building on the work by Feng et al. (2019), which developed an algorithm for MCS
99 tracking and a dataset for MCSs for eastern CONUS, we produce a unified high-resolution data

100 product of both MCS and IDC events and analyze their characteristics east of the Rocky
101 Mountains for 2004 – 2017. The data product is developed by applying an updated Flexible
102 Object Tracker (FLEXTRKR) algorithm (Feng et al., 2018; Feng et al., 2019) and the Storm
103 Labeling in Three Dimensions (SL3D) algorithm (Starzec et al., 2017) to the NCEP (National
104 Centers for Environmental Prediction) / CPP (the Climate Prediction Center) L3 4 km Global
105 Merged IR V1 brightness temperature (T_b) dataset (Janowiak et al., 2017), the 3-D Gridded
106 NEXRAD Radar (Gridrad) dataset (Homeyer and Bowman, 2017), the NCEP Stage IV
107 precipitation dataset (Lin and Mitchell, 2005), and melting level heights from ERA5 (ECMWF,
108 2018). Section 2 describes the updated FLEXTRKR and SL3D algorithms in detail, as well as
109 the source datasets used by the algorithms. In Section 3, we first compare the climatological
110 characteristics between MCS and IDC events based on the MCS/IDC data product. Then, as an
111 application of the data product, we examine the spatiotemporal precipitation characteristics of
112 MCS and IDC events. In Section 4, we discuss the uncertainties and limitations of the data
113 product. Section 5 provides the availability information of the data product. Finally, we
114 summarize the study in Section 6.

115 **2 Source datasets and algorithms**

116 2.1 Source datasets

117 *2.1.1 Merged 4-km Infrared brightness temperature dataset*

118 In this study, we identify cold clouds associated with MCSs and IDC by using the NOAA
119 NCEP/ CPP L3 half-hourly 4 km Global Merged IR V1 infrared T_b data for 2004 – 2017
120 (Janowiak et al., 2017). The dataset is a combination of various geostationary IR satellites with

121 parallax correction and viewing angle correction, therefore, providing continuous coverage
122 globally from 60°S – 60°N with a horizontal resolution of about 4 km and a temporal resolution
123 of 0.5 hours (Janowiak et al., 2001). We only use the hourly T_b data in the FLEXTRKR
124 algorithm discussed below, as all other datasets are only available at an hourly interval.

125 *2.1.2 Three-dimensional Gridded NEXRAD Radar (Gridrad) dataset*

126 Gridrad is an hourly 3-D radar reflectivity (Z_H) mosaic combining individual NEXRAD
127 radar observations to a Cartesian gridded dataset, with a horizontal resolution of $0.02^\circ \times 0.02^\circ$
128 and a vertical resolution of 1 km. The dataset covers 115° W to 69° W in longitude, 25° N to 49°
129 N in latitude, and 1 to 24 km in altitude above sea level (ASL). Homeyer and Bowman (2017)
130 produced the dataset by applying a four-dimensional binning procedure to merge level-2 Z_H data
131 from 125 National Weather Service (NWS) NEXRAD weather radars to Gridrad grid boxes at
132 analysis times. Only the level-2 observations within 300 km of each radar and 3.8 minutes of the
133 analysis time were used in the binning procedure. The Gridrad Z_H was the weighted average of
134 the level-2 observations within the Gridrad grid boxes to reduce the potential loss of information.
135 The weight calculation of each level-2 observation followed a Gaussian scheme in both space
136 and time. Observation weight was negatively correlated with the distance of the observation from
137 the source radar and the time difference between the observation and analysis time. The Gridrad
138 dataset provides the total weight of the level-2 observations within each Gridrad grid box, which
139 is useful for quality control. In addition, the number of level-2 radar observations (N_{obs}) and the
140 number of level-2 radar observations with echoes (N_{echo}) within each Gridrad grid box around
141 analysis times (± 3.8 min) are also available in the Gridrad dataset.

142 We obtain the Gridrad datasets between 2004 and 2017 from NCAR/UCAR Research Data
143 Archive (RDA) (<https://rda.ucar.edu/datasets/ds841.0/>, last access: Jan 2, 2020). Following the
144 quality control criteria of Homeyer and Bowman (2017) (<http://gridrad.org/software.html>, last
145 access: Jan 22, 2020), we remove potential low-quality observations, scanning artifacts, and non-
146 meteorological echoes from biological scatters and artifacts. Then we regrid Gridrad Z_H onto the
147 4 km satellite Merged IR grids by using the “bilinear” method from the Earth System Modeling
148 Framework (ESMF) Python module (<https://www.earthsystemcog.org/projects/esmpy/>) as
149 follows.

150 First, we convert the Gridrad logarithmic reflectivity Z_H to linear reflectivity (Z' : $\text{mm}^6 \text{m}^{-3}$).
151 We then set Z' in grid boxes with radar observations but no echoes ($N_{\text{obs}} > 0$, but $Z_H = \text{NaN}$;
152 NaN , Not-A-Number) to 0 ($Z' = 0$). Here the physical interpretation is that NEXRAD scans
153 those grid boxes, but no detectable hydrometers return any echo. The primary motivation of this
154 procedure is to avoid the reduction of the number of valid reflectivity values after re-gridding, as
155 the ESMF bilinear method treats destination point as NaN as long as there is one NaN value in
156 the source points. A common scenario is at the edge between hydrometeor echoes and clear air.
157 Setting Z' of those grid boxes having radar observations but no echoes to NaN would cause all
158 surrounding destination points to become NaN even though all other source points have valid Z'
159 values, which would reduce the number of re-gridded valid Z_H ($Z_H \neq \text{NaN}$) by about 20% for
160 2004 – 2017. After the “bilinear” re-gridding of Z' , we convert the linear reflectivity Z' back to
161 the logarithmic reflectivity Z_H . And we set Z_H equal to NaN for those grid boxes with Z' equal
162 to 0. Now the NaN values are acceptable and won't affect the SL3D algorithm and FLEXTRKR
163 algorithm discussed below.

164 2.1.3 NCEP Stage IV precipitation dataset

165 The NCEP Stage IV precipitation dataset provides hourly rain accumulations over polar
166 stereographic grids across the CONUS with a resolution of 4.76 km at 60°N since 2002. The
167 dataset is a mosaic of precipitation estimates from 12 River Forecast Centers (RFCs) over the
168 CONUS (Stage IV data in Alaska and Puerto Rico are archived separately) (Lin and Mitchell,
169 2005; Nelson et al., 2016). Each RFC produces its precipitation estimates through a combination
170 of radar and rain gauge data based on the multisensory precipitation estimator (MPE) algorithm
171 (for most RFCs), P3 algorithm (for Arkansas-Red basin RFC), or Mountain Mapper algorithm
172 (for California-Nevada, Northwest, and Colorado-basin RFCs with missing radar-derived
173 estimates) (Nelson et al., 2016). Some manual quality control steps are conducted to remove bad
174 radar and gauge data before radar-gauge merging (Lin and Mitchell, 2005; Nelson et al., 2016).
175 The Stage IV dataset has been widely used as a basis to evaluate model simulations, satellite
176 precipitation estimates, and radar precipitation estimates (Davis et al., 2006; Gourley et al., 2011;
177 Kalinga and Gan, 2010; Lopez, 2011; Yuan et al., 2008). Here, we obtain the hourly Stage IV
178 precipitation for 2004 — 2017 from the NCAR/UCAR RDA
179 (<https://rda.ucar.edu/datasets/ds507.5/>, last access: Dec 28, 2019). We regrid the original Stage
180 IV precipitation from polar stereographic grids to the 4 km satellite Merged IR grids by using the
181 “neareststod” method from the ESMF ‘NCL’ module
182 (<https://www.ncl.ucar.edu/Applications/ESMF.shtml>). The “neareststod” method maps each
183 destination point to the closest source point.

184 2.1.4 ERA5 melting level dataset

185 Melting hydrometeors produce intense radar echoes in a horizontal layer about 0.5 km thick
186 located just below the 0°C level (melting level), which is known as “bright band” (Giangrande et
187 al., 2008; Steiner et al., 1995). The bright-band signatures are often pronounced for stratiform
188 precipitation, while convective precipitation produces well-defined vertical cores of maximum
189 reflectivity, diluting bright-band signals (Giangrande et al., 2008; Steiner et al., 1995).
190 Therefore, the SL3D algorithm that is described below examines Z_H above the melting level to
191 avoid the false identification of stratiform rain as convective (Starzec et al., 2017). In this study,
192 we use the hourly melting level heights from the ERA5 reanalysis dataset.

193 ERA5, as the successor to ERA-Interim, contains many modeling improvements and more
194 observations based on 4D-Var data assimilation using Cycle 41r2 of the Integrated Forecasting
195 System (IFS) at the European Centre for Medium-Range Weather Forecasts (ECMWF). ERA5
196 provides hourly estimates of atmospheric variables at a horizontal resolution of 31 km and 137
197 vertical levels from the surface to 0.01 hPa from 1979 to the present (Hersbach et al., 2019). We
198 obtain ERA5 “Zero degree level” (melting level heights above ground) for 2004 – 2017 and
199 “Orography” (geopotential at the ground surface) from the Climate Data Store (CDS) disks
200 (ECMWF, 2018) (last access: Jan 24, 2020). The CDS archived ERA5 variables have been
201 interpolated to regular latitude/longitude grids with a resolution of $0.25^\circ \times 0.25^\circ$. We calculate
202 melting level heights ASL from “Zero degree level” and “Orography” (divided by 9.80665 m s^{-2}
203 to obtain ground surface height). Finally, we regrid the hourly 0.25° melting level heights ASL
204 to the 4-km satellite Merged IR grids by using the ESMF “neareststod” method.

205 We summarize the basic information of the four types of source datasets in Table S1. And,
206 we define our data product domain as $110^{\circ}\text{W} - 70^{\circ}\text{W}$ in longitude and $25^{\circ}\text{N} - 51^{\circ}\text{N}$ in latitude
207 (Figure 1), which covers the US east of the Rocky Mountains and excludes the western US. The
208 domain coverage takes into consideration the availability of the GridRad radar dataset, the
209 relatively scarce radar coverage over the Rocky Mountains, and associated uncertainties in radar-
210 based Stage IV precipitation estimates in complex terrains (Nelson et al., 2016). As shown in
211 Figure 1a, we further define four regions in the domain following Feng et al. (2019): Northern
212 Great Plains (NGP), Southern Great Plains (SGP), Southeast (SE), and Northeast (NE).

213
 214 Figure 1. (a) Data product domain and region definitions. Blue shading denotes the Northern
 215 Great Plains (NGP), green-yellow shading denotes the Southern Great Plains (SGP), light steel
 216 blue shading denotes the Southeast (SE), and orange shading denotes the Northeast (NE). The
 217 locations of some US states within each region are also labeled. TX is for Texas, OK for
 218 Oklahoma, KS for Kansas, NE for Nebraska, IA for Iowa, MO for Missouri, AR for Arkansas,

219 LA for Louisiana, MS for Mississippi, AL for Alabama, TN for Tennessee, KY for Kentucky,
220 and FL for Florida. (b) The location of the data product domain (red box) in North America.

221 2.2 Algorithm description

222 2.2.1 SL3D algorithm

223 The SL3D algorithm exploits Gridrad Z_H to classify each grid column with radar echoes
224 into five categories: convective, precipitating stratiform, non-precipitating stratiform, anvil, and
225 convective updraft (Starzec et al., 2017). SL3D identifies these five categories successively
226 following the criteria listed in Table S2. We run the SL3D algorithm for 2004 – 2017 by using
227 the re-gridded ERA5 melting level heights and Gridrad Z_H dataset described in Section 2.1.
228 Figure 2e shows an example of the SL3D classification results based on Gridrad Z_H (Figure 2d)
229 at 2005-07-04T03:00:00Z. A sizeable convective system with intense radar echoes and
230 precipitation is observed in Kansas, and many isolated convection events are also observed in the
231 Southeast. The SL3D classification results will be used in the following FLEXTRKR algorithm
232 to identify convective core features (CCFs, continuous updraft/convective areas with
233 precipitation $> 0 \text{ mm h}^{-1}$, which are used to indicate the existence of convective activity in the
234 IDC definition; red regions in Figure 3) and precipitation features (PFs, continuous
235 updraft/convective/precipitating-stratiform areas with precipitation $> 1 \text{ mm h}^{-1}$; green areas in
236 Figure 3, which are used to denote the sizes of convective systems in the MCS and IDC
237 definitions).

238 2.2.2 MCS/IDC identification and tracking

239 The FLEXTRKR algorithm was first developed and used by Feng et al. (2019) to track
240 MCSs. In this study, we further update the algorithm so that it can identify and track MCS and
241 IDC events simultaneously.

242 Figure 3 displays the schematic of FLEXTRKR (Feng et al., 2019). The first step is to
243 identify cold cloud systems (CCSs; continuous areas with $T_b < 241$ K) at each hour by applying a
244 multiple T_b threshold “detect and spread” approach (Futyan and Del Genio, 2007). We search for
245 cold cloud cores with $T_b < 225$ K and spread the cold cloud cores to contiguous areas with $T_b <$
246 241 K. Cloud systems that do not contain a cold cloud core but with $T_b < 241$ K are also labeled
247 as long as they can form continuous areas with at least 64 km^2 (4 pixels). In addition, as
248 described in Feng et al. (2019), CCSs that share the same coherent precipitation feature are
249 combined as a single CCS. A coherent precipitation feature is defined as continuous areas with
250 smoothed Z_H at 2 km > 28 dBZ (if Z_H is not available at 2 km, use Z_H at 3 km instead if it is
251 available) (Feng et al., 2019). We use a 5×5 pixel moving window to smooth Z_H . Figure 2b
252 shows an example of the CCSs identified in the first step based on T_b at 2005-07-04T03:00:00Z.
253 “Cloud 1” in Figure 2b corresponds to a large area of low T_b in the central US (Figure 2a).

254 In step 2, CCSs between two consecutive hours are linked if their spatial overlaps are $>$
255 50%. “Linked” means the CCSs are considered to be from the same cloud systems. FLEXTRKR
256 produces tracks by extending the link between two consecutive time steps to the entire tracking
257 period, as shown in Figure 3. Each track represents the lifecycle of a cloud system. We calculate
258 a series of CCS summary statistics associated with each track, such as CCS-based lifetime of the
259 track (the duration of the track when CCSs are present), CCS area, CCS major axis length, CCS

260 propagation speed, etc. Besides, SL3D classification (Figure 2e) and Stage IV precipitation
261 (Figures 2c) within the tracked CCS are associated with the tracks and their merges and splits
262 (described below). Then, we can obtain CCF and PF statistics of each track, such as convective
263 and stratiform area, precipitation intensity and coverage, radar-derived echo-top heights, PF
264 major axis length, CCF major axis length, intense convective cells (convective cells with column
265 maximum reflectivity ≥ 45 dBZ and precipitation > 1 mm h⁻¹; pink areas in Figure 3, which are
266 used to indicate intense convective activity in the following MCS definition), etc.

267 Merging and splitting refer to situations when two or more CCSs are linked to one CCS
268 between consecutive hours (Figures S1 and S2). A track associated with the largest CCS is
269 defined as the main track (Figure S3), and smaller tracks from merges/splits are regarded as parts
270 of the main track when calculating PF and CCF statistics. In the algorithm, we require that a
271 “merge”/“split” track associated with an MCS/IDC event must have a CCS-based lifetime of no
272 more than 5 hours. Otherwise, we treat it as an independent track.

273 The identification of MCS and IDC is based on the CCS, PF, and CCF statistics of the
274 tracks. Following the definition of MCSs by Feng et al. (2019) (Figure 4), we define a track as an
275 MCS if it satisfies the following criteria: 1) there is at least one pixel of cold cloud core during
276 the whole lifecycle of the track; 2) CCS areas associated with the track surpass 60,000 km² for
277 more than six continuous hours; 3) PF major axis length exceeding 100 km and intense
278 convective cell areas of at least 16 km² exist for more than five consecutive hours. Considering
279 the lack of a strict and universal MCS definition (Geerts et al., 2017; Haberlie and Ashley, 2019;
280 Pinto et al., 2015; Prein et al., 2017), we evaluate the impact of different MCS definition criteria
281 on the data product in Section 4.4. For the non-MCS tracks, we further identify IDC with the

282 following two criteria (Figure 4): 1) a CCS with at least 64 km^2 (4 pixels) is detected; 2) at least
283 1 hour during the lifecycle of the track when PF and CCF are present (PF and CCF major axis
284 lengths $\geq 4 \text{ km}$). In addition, for each IDC event, the CCS-based lifetime of associated merge
285 and split tracks cannot surpass the lifetime of the IDC event. Here, the IDC criteria denote a low
286 limit in convective signals that we can identify by using the FLEXTRKR algorithm and given
287 source datasets. Potential uncertainties associated with the limit are discussed in Section 4.3.

288 Note that while we designate the term IDC to differentiate smaller convective storms from
289 MCSs, there are sub-categories of deep convection within IDC. For example, multicellular
290 convection systems that do not grow large enough or last long enough to meet our MCS
291 definition are defined as IDC in our study, even though they are not necessarily “isolated.” Users
292 of the data product can further separate sub-categories within IDC using the derived CCF
293 statistics information to address specific science questions or research objectives.

294 Finally, the FLEXTRKR algorithm maps MCS/IDC track information back to the domain
295 pixels. Figures 2f – 2i give an example of the pixel-level MCS/IDC information at 2005-07-
296 04T03:00:00Z. Figure 2f displays the spatial coverages of MCS/IDC tracks at that time at pixel
297 scale and the corresponding unique numbers of these tracks. From Figure 2f, we know whether a
298 pixel belongs to an MCS/IDC track and the number of the track if the pixel belongs to a track.
299 We can further determine whether the track is an MCS or IDC event from Figure 2g, which
300 shows the types (MCS or IDC) of the tracks in Figure 2f at the pixel scale. Figures 2h and 2i are
301 similar to Figures 2f and 2g, respectively. The difference is that Figures 2h and 2i only show
302 pixels with precipitation $> 1 \text{ mm h}^{-1}$ in that hour. Together, the track-based CCS, PF, and CCF
303 statistics of MCS and IDC events and the pixel-level dataset constitute the unified high-

304 resolution MCS/IDC data product we develop in this study. Original T_b (Figure 2a), Stage IV
305 precipitation (Figure 2c), Gridrad Z_H at 2 km (Figure 2d), and Gridrad derived echo-top heights
306 are also archived in the data product.

307 We run the FLEXTRKR algorithm separately for each year from 2004 to 2017. The starting
308 time of each continuous tracking is 00Z on 1 January, and the ending time is 23Z on 31
309 December. Because winter has the fewest deep convection events, very few MCS/IDC events
310 extend between two different years based on our investigation. Also, the lifetimes of MCS/IDC
311 events are much shorter compared to our tracking period. Therefore, running FLEXTRKR
312 separately for each year rather than continuously for the whole period has little impact on the
313 MCS/IDC statistics.

314
 315 Figure 2. FLEXTRKR pixel-level outputs at 03:00:00Z on July 4, 2005. (a) is satellite T_b . (b)
 316 shows identified CCS labels. CCS labels are unique at each hour. (c) is Stage IV hourly
 317 accumulated precipitation. (d) is Gridrad Z_H at 2 km (if it is not available, Z_H at 3 km is provided
 318 if it is available). (e) is the SL3D classification results: 1, convective updraft; 2, convective; 3,
 319 precipitating stratiform; 4, non-precipitating stratiform; 5, anvil. (f) displays the track numbers to
 320 which pixels belong. Here, the track numbers are not the real values in the MCS/IDC data
 321 product. The track numbers should be unique throughout the whole running period. We adjust
 322 the track numbers here to make the figure clear. Similar to “PF track number.” (g) gives
 323 information on whether the pixels belong to MCS (marked as 1) or IDC (marked as 2) tracks,
 324 which correspond to the tracks shown in (f). (h) also displays the track numbers to which the
 325 pixels belong, but only for pixels with precipitation $> 1 \text{ mm h}^{-1}$. (i) is like (g) but corresponds to
 326 (h). All these variables are stored in the FLEXTRKR hourly pixel-level output files.

331 **3 Results and discussions**

332 3.1 Climatological characteristics of MCS and IDC events

333 According to the MCS/IDC data product, we identify 45,346 IDC and 454 MCS events each
334 year on average between 2004 and 2017 in our data product domain. Summer (June – August)
335 has the most IDC and MCS events with average numbers of 25,073 and 212, while winter has
336 the least with average quantities of 2,545 and 37. During spring and autumn, there are 8,543 and
337 9,185 IDC events and 122 and 83 MCSs, respectively. The seasonal feature with the most
338 occurrences of MCSs in winter and the least in summer is consistent with the results of Geerts
339 (1998) in the Southeast US and Haberlie and Ashley (2019) over portions of the CONUS east of
340 the Continental Divide (ECONUS).

341 We compare the climatological characteristics of MCS and IDC events in Table 1. MCSs
342 have much longer lifetimes than IDC, averaging 21.1 hours (CCS-based) and 18.9 hours (PF-
343 based), compared to 2.1 hours (CCS-based) and 1.7 hours (PF-based) for IDC. Here, PF-based
344 lifetime refers to the lifetime determined by the MCS/IDC PFs. Only those hours with a
345 significant PF present (PF major axis length > 20 km for MCSs; ≥ 4 km for IDC) are counted
346 during the lifecycle of an MCS/IDC event, which represent the active convective period of a
347 storm. We find that MCSs have the longest PF lifetime in winter (21.3 hours) and the shortest in
348 summer (17.9 hours). In comparison, IDC has the longest PF lifetime in winter (1.9 hours), but
349 the summer lifetime (1.7 hours) is comparable to spring and autumn. We examine the seasonal
350 cumulative distribution functions (CDFs) of PF lifetimes for MCS and IDC events for 2004 –
351 2017 in Figure S4. Results show winter has the largest fraction of MCS/IDC events with longer
352 lifetimes than other seasons.

353 As expected, MCSs are much larger than IDC events in spatial coverage and precipitation
354 area, as shown in Table 1 by the comparisons of CCS area, PF major axis length, PF
355 convective/stratiform area, CCF area, and CCF major axis length. Generally, on average, winter
356 MCS/IDC events are the largest in overall spatial coverage (both CCS and PF areas), while
357 summer has the smallest. The larger and longer-lived MCSs in winter than in summer were also
358 observed in the Southeast US in 1994 – 1995 by Geerts (1998). The remarkable seasonal
359 difference in MCS/IDC overall spatial coverage is mainly due to stratiform areas. Convective
360 areas are much smaller than stratiform areas. The PF stratiform area of MCSs in winter is 90,513
361 km², 2.4 times larger than the area of 26,599 km² in summer, but the PF convective area of
362 MCSs in winter is 7,293 km², 14% smaller than 8,465 km² in summer. Similarly, the IDC PF
363 stratiform area in winter is 3,182 km², 2.8 times larger than 828 km² in summer, while the IDC
364 PF convective area in winter is 528 km², slightly larger (9%) than 483 km² in summer. Unlike
365 stratiform areas with the largest value in winter, convective activity is the most intense in
366 summer as indicated by PF mean convective 20-dBZ echo-top height in Table 1. The most
367 intense convective activity reflects the strongest atmospheric thermal instability due to the
368 strongest solar radiation in summer. We further confirm this point by investigating the MCS/IDC
369 initiation time. As shown in Figure S5, most MCS and IDC events initiate in the afternoon of
370 summer when atmospheric instability is the strongest, consistent with Geerts (1998), who found
371 warm-season MCSs generally initiated at 12:00 – 14:00 Local Time in the Southeast US.

372 Although MCSs are much larger than IDC events in spatial coverage, their mean convective
373 20-dBZ echo-top heights, which can be used to represent their mean convective intensities, are
374 similar in Table 1. And their PF mean convective and stratiform rain rates are also comparable.
375 PF mean convective and stratiform rain rates show significant seasonal variations for both MCS

376 and IDC events. Summer MCS and IDC events have the largest rain rates, followed by autumn.
377 Winter has the lowest rain rates compared to other seasons.

378 The high-resolution nature of the MCS/IDC data product enables a detailed examination of
379 the 3-D evolutions of MCS/IDC events to investigate the relationships between atmospheric
380 environments and MCS/IDC characteristics and to examine the impacts of MCSs and IDC on
381 hydrology, atmospheric chemistry, and severe weather hazards. The data product can also be
382 used to evaluate and improve the representation of MCS/IDC processes in weather and climate
383 models. As an example of the application of the MCS/IDC data product, in Section 3.2, we
384 investigate the contributions of MCS and IDC events to precipitation east of the Rocky
385 Mountains for 2004 – 2017.

Table 1. Annual and seasonal mean characteristics of MCS and IDC events in the data product domain for 2004 – 2017

	MCS					IDC				
	Annual	spring	Summer	autumn	winter	annual	spring	summer	autumn	winter
CCS-based lifetime / hour	21.1	21.5	19.9	22.1	24.3	2.1	2.1	2.0	2.0	2.7
CCS area ¹ / km ²	185,436	223,230	130,769	185,246	373,220	6,775	9,400	4,542	6,515	20,902
CCS major axis length / km	693	774	568	726	1,067	99	117	86	100	169
PF-based lifetime ² / hour	18.9	19.3	17.9	19.7	21.3	1.7	1.7	1.7	1.7	1.9
Major axis length of the largest PF ³ / km	397	426	325	436	620	63	69	56	69	93
PF convective area ⁴ / km ²	8,273	8,589	8,465	7,752	7,293	494	509	483	502	528
PF stratiform area / km ²	41,336	47,241	26,559	48,376	90,513	1,261	1,610	828	1,583	3,182
PF mean convective rain rate / mm h ⁻¹	4.4	3.9	4.7	4.5	3.8	4.2	3.4	4.5	4.3	3.0
PF mean stratiform rain rate / mm h ⁻¹	2.6	2.4	2.8	2.6	2.2	2.8	2.5	3.0	2.9	2.3
PF mean convective 20-dBZ echo-top height / km	6.5	6.2	7.2	6.0	4.9	6.6	6.1	7.0	6.2	5.0
Area of the largest CCF / km ²	2,578	2,515	2,983	2,068	1,606	343	359	339	340	349
Major axis length of the largest CCF / km	109	109	117	100	92	29	30	29	29	31

¹ In this table, for hourly characteristics (all variables except for CCS-based lifetime and PF-based lifetime), we generally first calculate the average values of the characteristics during the duration of each MCS/IDC event except for the max 30/40-dBZ echo-top heights, which are the maximum values of the attributes within the period. Then we calculate the mean values of the characteristics of all MCS/IDC events. For example, an MCS has a CCS-based lifetime of 10 hours. During its duration, it has a CCS at each hour. We calculate the average CCS area during the 10 hours, which is the average CCS area of the MCS. Then, we average all MCSs identified during a period to derive the values shown in this row.

² Lifetimes of MCS/IDC events determined by PFs. Only count those hours of an MCS/IDC event with a significant PF present (PF major axis length > 20 km for MCSs; ≥ 4 km for IDC).

³ There can be multiple PFs and CCFs at a given time for an MCS/IDC event. “Largest” means only the largest PF or CCF is used in the calculation.

⁴ There can be multiple PFs and CCFs at a given time for an MCS/IDC event. If not specified, all PFs/CCFs are considered. For example, convective areas of all PFs at a given time are summed to represent the PF convective area of an MCS/IDC event at that time. Similarly, the convective rain rates of all PFs at the given time are averaged to represent the PF mean convective rain rate of the MCS/IDC at that time.

399 3.2 Precipitation characteristics from different sources

400 Here we only consider hourly data with precipitation $> 1 \text{ mm h}^{-1}$ (Feng et al., 2019). At 4
401 km resolution, precipitation less than 1 mm h^{-1} accounts for less than 19% of the total
402 precipitation, and the uncertainty of radar-derived precipitation at such low rainfall intensity is
403 typically large. Including hourly data with precipitation $\leq 1 \text{ mm h}^{-1}$ in the calculation will change
404 the values shown in this study but will neither affect the comparison among MCS, IDC, and non-
405 convective (NC) precipitation nor their spatial distribution patterns. Here, NC precipitation refers
406 to precipitation not associated with any MCS or IDC events and is mainly from stratiform rain.
407 Total precipitation is the sum of MCS, IDC, and NC precipitation. It is noteworthy that NC
408 precipitation may contain some convection-associated rain due to the limitation of the source
409 datasets and the algorithms used in this study. More relevant details are discussed in Section
410 3.2.3 and Section 4.

411 *3.2.1 Annual spatial distributions of different types of precipitation*

412 According to the MCS/IDC data product, the annual average total precipitation east of the
413 Rocky Mountains in the US (US grid cells in Figure 1) is 691 mm between 2004 and 2017 with a
414 mean precipitation intensity of 3.6 mm h^{-1} . MCSs contribute the most to the total precipitation
415 with a fraction of 45%, followed by NC (30%) and IDC (25%). And the mean precipitation
416 intensities of MCSs (4.4 mm h^{-1}) and IDC (3.8 mm h^{-1}) are much larger than NC (2.7 mm h^{-1}).
417 Our MCS precipitation fraction (45%) is higher than that ($\sim 30\%$) from Haberlie and Ashley
418 (2019) over the ECONUS due to their different algorithms and stricter criteria to track and define
419 MCSs.

420 Figure 5 displays the spatial distributions of annual mean precipitation amounts and
421 intensities for different precipitation types for 2004 – 2017. We also calculate the distributions of
422 the fractions of different types of precipitation in Figure 6. MCS precipitation strongly affects the
423 whole eastern US ($105^{\circ}\text{W} - 70^{\circ}\text{W}$, MCS precipitation fractions: $46\% \pm 12\%$), especially in the
424 South Central US (MCS precipitation fractions: $\sim 60\%$). The spatial distribution patterns of MCS
425 annual precipitation amounts and fractions in Figure 5 are similar to those from Haberlie and
426 Ashley (2019), although their MCS precipitation fractions are generally lower than our results.
427 IDC precipitation is concentrated in the SE and NE coastal areas, with peak values in Florida.
428 NC precipitation is substantial in the eastern and southern regions with ample moisture supply
429 and contributes over 35% to the total precipitation across most of the NE region. The coastal area
430 near Louisiana, which is significantly affected by all three types of precipitation, has the most
431 total precipitation with annual amounts of over 1,350 mm. The annual total precipitation
432 amounts in most regions of SE also exceed 1,050 mm due to MCS contributions. While the total
433 precipitation amounts in most regions of Florida are also over 1,050 mm, they are mainly
434 attributed to IDC.

435 The spatial patterns of precipitation intensities are somewhat different from those of
436 precipitation amounts (Figure 5). Generally, the southern regions, especially in the coastal areas,
437 have larger precipitation intensities than the northern areas. The MCS precipitation intensities are
438 the largest in Texas, Louisiana, Oklahoma, and Kansas, significantly shifting west compared to
439 MCS precipitation amounts. Unlike IDC precipitation amounts concentrating in the SE and NE
440 coastal areas, IDC precipitation intensities are the largest over the SGP and SE. IDC precipitation
441 intensities over the NE are much smaller compared to the SGP and SE, similar to NC

442 precipitation intensities. We summarize the annual mean precipitation amounts and intensities of
443 different types of precipitation in the NGP, SGP, SE, and NE in Table S3.

444 The distributions of MCS/IDC precipitation amounts are mainly determined by the
445 distributions of MCS/IDC hours (Figures 5 and 7). Here, the MCS/IDC hour of a grid cell during
446 a period is the number of hours when any MCS/IDC events produce > 1 mm hourly accumulated
447 rainfall in the grid cell. The distributions of MCS/IDC precipitation intensities, although not the
448 main factor, can also affect the distributions of MCS/IDC precipitation amounts. For example,
449 the maximum MCS hours are located around Missouri (Figures 7a), but the maximum MCS
450 precipitation amount is in the coastal area of Louisiana (Figure 5c). The larger MCS precipitation
451 intensities in the southern regions contribute more to the MCS precipitation amount in the
452 southern US. In addition, a large number of IDC events ($\text{IDC hours} > 60 \text{ h yr}^{-1}$) occur in the NE
453 region along the Appalachian Mountains (Figure 7b), but IDC in that region only contributes to
454 20% – 30% of the total precipitation amount (Figure 6b) due to the low precipitation intensities
455 (Figure 5f).

456
 457 Figure 5. Distributions of annual mean precipitation amounts (a, c, e, g) and intensities (b, d, f, h)
 458 for different types of precipitation for 2004 – 2017. (a) and (b) are for total precipitation, (c) and
 459 (d) are for MCS precipitation, (e) and (f) are for IDC precipitation, and (g) and (h) are for NC
 460 precipitation. We only include hourly data with precipitation > 1 mm h⁻¹ in the calculation.

461
 462 Figure 6. Distributions of the fractions of different types of precipitation (MCS, IDC, NC). Here,
 463 precipitation refers to annual mean values for 2004 – 2017. We exclude hourly data with
 464 precipitation $\leq 1 \text{ mm h}^{-1}$ in the calculation.

465
466 Figure 7. Spatial distributions of annual mean MCS/IDC hours for 2004 – 2017. (a) is for MCS,
467 and (b) is for IDC. The annual mean MCS/IDC hour of a grid cell is the number of hours per
468 year when any MCS/IDC events produce > 1 mm hourly accumulated rainfall in the grid cell.

469 3.2.2 Seasonal spatial distributions of different types of precipitation

470 Figures 8, S6, and S7 display the mean seasonal distributions of precipitation amounts,
471 precipitation fractions, and precipitation intensities for different types of precipitation in 2004 –
472 2017. The MCS precipitation center migrates northwards from Arkansas in spring to northern
473 Missouri and Iowa in summer, followed by a southward migration to Louisiana in autumn, and
474 finally to Mississippi and Alabama in the Southeast (Figures 8e – 8h) in winter. The seasonal
475 shift of the MCS precipitation center agrees with the study of Haberlie and Ashley (2019),
476 showing different MCS precipitation distributions between warm and cold seasons over the
477 ECONUS. Spring and summer have much larger MCS precipitation amounts (~100 mm) than
478 autumn (~62 mm) and winter (~50 mm). The mean MCS precipitation amount in spring is close
479 to that in summer. However, the total number of identified MCSs in summer (212) is much
480 higher than that in spring (122), as discussed in Section 3.1; and the mean MCS precipitation
481 intensity in summer (5.2 mm h^{-1}) is also larger than that in spring (4.1 mm h^{-1}) (Figure S7). The
482 inconsistency is because MCSs in spring occur in more favorable large-scale environments with
483 strong baroclinic forcing and low-level moisture convergence (Feng et al., 2019; Song et al.,
484 2019). As a result, spring MCSs are larger and longer-lasting, and they produce more rainfall per
485 MCS event compared to those in summer (Table 1), compensating for the fewer number of MCS
486 events and lower precipitation intensities in spring. The fractions of MCS precipitation amounts
487 are generally $> 35\%$ over the Northern and Southern Great Plains in spring and summer and can
488 reach up to over 70% within the MCS precipitation center (Figures S6a – S6b). The results are
489 roughly consistent with Fritsch et al. (1986), which showed that MCSs accounted for about 30%
490 – 70% of the warm-season (April-September) precipitation over much of the region between the
491 Rocky Mountains and the Mississippi River. The results are also consistent with Haberlie and

492 Ashley (2019) showing MCS precipitation fractions generally > 30% with a peak > 60% over the
493 Great Plains between May and August. Due to the low precipitation amounts of IDC and NC, the
494 fractions of MCS precipitation amounts in autumn and winter are also large, showing over 50%
495 within the MCS precipitation center (Figures S6c – S6d).

496 The IDC precipitation amounts reach a maximum in summer, centered in the coastal areas
497 of the SE, where IDC precipitation contributes to more than 40% of the total precipitation
498 amounts (Figures 8i – 8l and S6e – S6h). Winter has the least IDC precipitation. Areas of high
499 IDC precipitation do not show much seasonal variability, suggesting that IDC is constrained by
500 local conditions such as moisture availability, local solar radiation, and land-atmosphere
501 interactions. The NC precipitation amount also peaks in summer, followed by autumn,
502 particularly in the NE (Figures 8m – 8p). However, because both MCS and IDC precipitation
503 amounts are very high in summer, the fraction of the NC precipitation amount in summer (28%)
504 is smaller than that of winter (32%) (Figures S6i – S6l). Winter NC precipitation center occurs in
505 the SE coastal areas (Figure 8p).

506
 507 Figure 8. Distributions of annual mean seasonal precipitation amounts for different types of
 508 precipitation for 2004 – 2017. The first row is for total precipitation, the second for MCS
 509 precipitation, the third row for IDC precipitation, and the fourth row for NC precipitation. The
 510 first column shows spring precipitation, the second column for summer, the third column for
 511 autumn, and the fourth column for winter. MCS, IDC, and NC precipitation share the same label
 512 bar. We exclude hourly data with precipitation $\leq 1 \text{ mm h}^{-1}$ in the calculation.

513 The precipitation intensities of all three types peak in summer and reach minimums in
 514 winter (Figure S7). In each season, precipitation intensities in the south are larger than those in
 515 the north except for MCS precipitation intensities in summer, which maximize in Oklahoma. We
 516 summarize the mean seasonal precipitation amounts and intensities of different types of
 517 precipitation over the 4 climate regions of Figure 1 in Table S4.

518 *3.2.3 Diurnal cycles of different types of precipitation*

519 Figure 9 shows the monthly mean diurnal cycles of precipitation amounts from MCSs, IDC,
520 and NC in the NGP, SGP, SE, and NE, respectively. Generally, MCS precipitation peaks during
521 nighttime in the NGP, SGP, and NE. The seasonal shift of the peaks from spring in the SGP to
522 summer in the NGP reflects the northward migration of the MCS precipitation center in the
523 Great Plains (Figures 8e and 8f).

524 The SE has significantly different diurnal cycles of MCS precipitation from other regions.
525 In spring, SE MCS precipitation is mainly located in the western areas (Figure 8e), showing
526 similar diurnal characteristics as the SGP MCS precipitation but with peaks in the early morning
527 and late afternoon (Figures 9d and 9g). Besides, the SGP MCS precipitation peaks in May
528 (Figure 9d), while SE peaks in April (Figure 9g), suggesting that the MCS precipitation center
529 first appears in the western SE regions (Alabama, Mississippi, and Louisiana) in April, and then
530 moves northwards to Arkansas in May. In summer, the SE MCS precipitation diurnal cycles are
531 more like those of IDC (Figures 9g and 9h), peaking in the late afternoon and much different
532 from those in the Great Plains. The significantly different precipitation diurnal variations
533 between the Great Plains and SE were also identified by Haberlie and Ashley (2019). We find
534 that most summer MCS precipitation over the SE occurs near the coastal areas (Figure 8f), far
535 from the MCS precipitation center in northern Missouri and Iowa, suggesting either a different
536 MCS genesis mechanism in the SE from those in the SGP and NGP (Feng et al., 2019) or long-
537 duration deep convective systems showing MCS characteristics (Geerts, 1998). In autumn, the
538 SE MCS precipitation peaks in the morning (Figure 9g). The diurnal cycle of MCS precipitation
539 in September shows mixed features of summer and autumn with peaks both in the morning and

540 the afternoon. In winter months, the diurnal cycle of the SE MCS precipitation shifts from the
541 autumn feature to the spring feature, with peaks shifting from the morning to the afternoon. The
542 distinct diurnal cycles of SE MCS precipitation in different seasons in Figure 9g are roughly
543 consistent with the corresponding seasonal diurnal variations of MCS occurrence frequencies
544 from Geerts (1998), where the occurrence time of an MCS was defined as the central time
545 between the initiation and decay of the MCS.

546 The diurnal cycles of IDC precipitation are consistent in all regions (Figures 9b, 9e, 9h, and
547 9k), peaking in the late afternoon in summer (Tian et al., 2005), again reflecting the impact of
548 local instability driven by the solar forcing on IDC development. NC precipitation (Figures 9c,
549 9f, 9i, and 9l) shows some diurnal cycle characteristics similar to IDC precipitation. It may be
550 caused by the limitation of the temporal resolution of the datasets used in the FLEXTRKR
551 algorithm. Weak IDC events that are shorter than 1 hour could be missed by Gridrad in
552 identifying CCFs, as Gridrad Z_H only considers reflectivities within ± 3.8 minutes of the analysis
553 time. These weak IDC could be aliased to NC precipitation, therefore showing some similar
554 diurnal cycles as IDC. Another possible reason is that the FLEXTRKR algorithm may miss some
555 parts of IDC clouds with $T_b \geq 241$ K, which are then classified as NC, so the NC precipitation
556 exhibits some IDC characteristics.

557 The monthly diurnal cycles of precipitation intensities for MCSs, IDC, and NC are
558 generally similar among all regions, peaking in the late afternoon and early morning in the warm
559 season (Figure S8).

560
 561 Figure 9. Monthly mean diurnal cycles of precipitation amounts from MCSs (a, d, g, j), IDC (b,
 562 e, h, k), and NC (c, f, i, l) in the NGP (a, b, c), SGP (d, e, f), SE (g, h, i), and NE (j, k, l) during
 563 2004 – 2017.

564 **4 Uncertainties of the data product**

565 4.1 Uncertainties from source datasets

566 The NCEP/ CPP L3 4 km Global Merged IR V1 T_b dataset has been view-angle corrected
567 and re-navigated for parallax (Janowiak et al., 2001) to reduce errors. However, the US continent
568 is covered by two series of geostationary IR satellites (GOES-W and GEOS-E). During the
569 production of the T_b dataset, the value with the smaller zenith angle is adopted when duplicate
570 data are available in a grid pixel. Measurements from different satellites may be inconsistent.
571 Janowiak et al. (2001) suggest this type of inconsistency to be considered minor.

572 For the Gridrad radar dataset, some bad volumes have been removed during the production
573 of Gridrad Z_H . We further filter out potential low-quality observations, scanning artifacts, and
574 non-meteorological echoes from biological scatters and artifacts following the approaches of
575 Homeyer and Bowman (2017). However, there is another source of error from anomalous
576 propagation caused by non-standard refractions of radar signals in the lower atmosphere, which
577 cannot be mitigated during the filtering procedure. Non-standard refractions can result in
578 underestimation or overestimation of the true radar beam altitude, thus affecting the location of
579 radar reflectivity for binning. Estimating the corresponding uncertainties is out of the scope of
580 this study. However, anomalous propagation is typically limited to radar beams traveling long
581 distances in the boundary layer (Homeyer and Bowman, 2017).

582 Stage IV precipitation is a mosaic of precipitation estimates based on a combination of
583 NEXRAD and gauge data from 12 RFCs. Therefore, the errors of Stage IV are from several
584 sources, such as inherent NEXRAD biases, radar quantitative precipitation estimate (QPE)

585 algorithm biases, bad gauge data removal inconsistency among different RFCs, multisensory
586 processing algorithm inconsistency among different RFCs, and mosaicking border
587 discontinuities (Nelson et al., 2016). The most severe errors occur in the western US, where
588 NEXRAD data are limited, and a gauge-only rainfall estimation algorithm is used (Nelson et al.,
589 2016; Smalley et al., 2014). Hence our data product has a geographical focus east of the Rocky
590 Mountains, with the best NEXRAD coverage in the US. After regridding the Stage IV
591 precipitation into our 4-km domain, we further manually filter out certain “erroneous
592 precipitation” hours and set all precipitation in those hours to missing values. “Erroneous
593 precipitation” is defined as sudden appearance and disappearance of a large contiguous area ($>$
594 $4,800 \text{ km}^2$) with intense precipitation ($> 40 \text{ mm h}^{-1}$) (Figure S9), which is physically not
595 possible. There are 40 hours in total in the period 2004 – 2017 containing such “erroneous
596 precipitation.”

597 As the FLEXTRKR algorithm is applied to a combination of three independent types of
598 remote sensing datasets, we identify the most robust MCS/IDC events satisfying all the criteria
599 based on the three datasets. It reduces the potential false classification of tracks as MCSs or IDC
600 based on any single dataset. And to consider the potential error of ERA5 melting level heights,
601 we require $Z_H \geq 45 \text{ dBZ}$ above $(Z_{\text{melt}} + 1) \text{ km}$ for convective classification in the SL3D algorithm
602 (Table S2).

603 4.2 The impact of missing data

604 In the CCS identification step of the FLEXTRKR algorithm, we require the fraction of
605 missing satellite T_b in the domain at each hour to be less than 20%. Otherwise, the hour is
606 excluded from our data product. During 2004 – 2017, we excluded 716 hours with missing

607 satellite T_b data, accounting for less than 0.6% of the total period. The year with the most
608 missing satellite data is 2008, with 206 missing hours (2.3%), followed by 2004 with 154 hours
609 (1.8%). All other years have no more than 57 missing hours. During the link procedure of the
610 FLEXTRKR algorithm, we search the next hour if a missing hour is encountered, as long as the
611 time gap between the two “linked” hours is less than 4 hours. Otherwise, we start new tracks
612 from the next available hour. This method aims to reduce the impact of the missing hours.
613 Considering the high completeness of the satellite T_b data in 2004 – 2017, we conclude that the
614 missing satellite data have little effect on the data product.

615 We show the distribution of the fractions of valid Stage IV precipitation data in 2004 – 2017
616 in Figure S10. The fractions are over 97% for all grid cells of the US in the domain. Most grid
617 cells in the US have less than 2% missing hours, which should have a negligible impact on the
618 data product.

619 Figure S11 shows the fractions of available Gridrad reflectivity data from 2004 to 2017
620 between 1 km and 12 km ASL. The fractions are relatively high over the majority of the
621 troposphere except for 1 km ASL. Based on the criteria of the SL3D algorithm, Z_H at 1 km is
622 rarely used and can be easily substituted by Z_H at 2 km. Generally, Gridrad has good spatial
623 coverage during the period with most grid cells east of the Rocky Mountains having fractions >
624 90% between 2 and 9 km and 80% between 10 and 12 km. The completeness of the Gridrad
625 dataset is relatively lower compared to the satellite T_b and Stage IV precipitation datasets, and
626 Gridrad Z_H is a crucial variable in the SL3D classification and MCS/IDC identification.
627 Therefore, the missing data of Gridrad Z_H should have some impacts on our data product.

628 However, as an advanced long-term high-resolution 3-D radar reflectivity dataset, Gridrad is
629 valuable for constructing a climatological MCS/IDC data product.

630 4.3 Temporal resolution limitation of the source datasets

631 As we discussed in Section 3.2.3, the diurnal cycles of NC precipitation show some possible
632 aliasing from IDC precipitation. Some weak IDC events are so short that the hourly data cannot
633 properly capture their occurrence, especially for Gridrad Z_H , which only includes reflectivities
634 within ± 3.8 minutes of each hour. We calculate the cumulative distribution functions of PF-
635 based lifetimes for MCS and IDC events and their associated precipitation in the data product for
636 2004 – 2017, as shown in Figure 10. About 75% of IDC events have a PF-based lifetime of 1
637 hour. Therefore, it is almost certain that we miss some IDC events shorter than 1 hour in the data
638 product. Here we give an estimate of the probability p that a given IDC event with a convective
639 signal duration of x minutes is detected by radar, as expressed below:

$$640 \quad p = \frac{2 \times 3.8}{60 - x} \quad (1)$$

641 where the numerator is the time window of Gridrad observation in each hour, and x is the
642 duration of the IDC event. The detection probability is only about 25% when $x = 30$ minutes. To
643 obtain a detection probability of 50%, we require $x \geq 45$ minutes. Hence, we cannot assess the
644 distribution of IDC convective signals with durations less than 1 hour using the currently
645 available datasets. Higher-resolution datasets, such as individual NEXRAD radar data, which
646 typically has an update cycle of 4-5 min, are necessary to derive the information. However, as
647 shown in Figure 10, we find that precipitation from IDC events with a 1-hour PF lifetime only

648 accounts for about 10% of the total IDC precipitation. Therefore, IDC events with PF lifetimes
649 less than 1 hour should have a relatively small impact on precipitation.

650
651 Figure 10. Cumulative distribution functions of PF-based lifetimes for MCS and IDC events and
652 their associated precipitation in the data product domain for 2004 – 2017. The red solid line is for
653 the number of MCSs, the red dash line for MCS associated precipitation, the blue solid line for
654 the number of IDC events, and the blue dash line for IDC associated precipitation.

655 4.4 The impact of MCS and IDC definition criteria

656 The separation between MCSs and long-lasting IDC events is somewhat fuzzy (Feng et al.,
657 2019; Geerts et al., 2017; Haberlie and Ashley, 2019; Pinto et al., 2015; Prein et al., 2017). Here,
658 we briefly examine the impact of different MCS/IDC definition criteria on the data product. We
659 change the definition of MCSs to relax the CCS and PF size and duration thresholds.

660 Specifically, the second and third criteria listed in Section 2.2.2 are modified as follows: 2) CCS
661 areas associated with the track surpass $40,000 \text{ km}^2$ for more than 4 continuous hours; 3) PF
662 major axis length exceeding 80 km and intense convective cell areas $\geq 16 \text{ km}^2$ exist for more

663 than 3 consecutive hours. And we also require that each merge/split-track associated with
664 MCS/IDC events must have a CCS-based lifetime of no more than 3 hours. We keep the
665 definition of IDC the same as described in Section 2.2.2, which is a limit for IDC that we can
666 identify based on the source datasets.

667 By using the new definition, as expected, the lifetimes and spatial coverages of MCSs are
668 reduced, and those of IDC change little because most IDC events cannot satisfy the new MCS
669 criteria (Tables 1 and S5). The annual number of MCSs identified in 2004 – 2017 increases from
670 454 to 857. The number increases from 122 to 207 in spring, 212 to 434 in summer, 83 to 151 in
671 autumn, and 37 to 62 in winter. As PF-based lifetimes of MCS/IDC events in summer are the
672 shortest (Table 1), the new definition has the most significant impact in summer. The annual
673 number of IDC decreases from 45,346 to 45,225. Reducing the merge/split lifetime limit retains
674 more independent IDC events, which is the reason why the decrease in the number of IDC events
675 is smaller than the increase in the number of MCSs. Annual mean MCS precipitation east of the
676 Rocky Mountains increases from 313 mm to 353 mm, while IDC precipitation decreases from
677 170 mm to 130 mm. The fraction of MCS precipitation only increases by 6% (from 45% to
678 51%), compared to the almost doubling of MCS number (from 454 to 857), suggesting the MCS
679 definition in the original data product is capable of capturing most of the important MCSs with
680 heavy precipitation. Similar to MCS numbers, summer has the most increase in MCS
681 precipitation amount, from 100 mm to 119 mm. And annual mean MCS and IDC precipitation
682 intensities decrease slightly as MCS precipitation intensities are somewhat larger than IDC in
683 most regions (Tables S3, S4, S6, and S7). We summarize the regional precipitation statistics of
684 the NGP, SGP, SE, and NE based on the new definition in Tables S6 and S7.

685 Although the new definition changes the absolute values of MCS/IDC characteristics, the
686 contrast between MCS and IDC events is still present. The new definition has small impacts on
687 the spatial distribution patterns of MCS/IDC precipitation. And NC precipitation characteristics
688 are almost the same as before. Therefore, our original definition captures the essential
689 characteristics of MCS and IDC events. In addition, the original data product is complete and
690 flexible. We store all criteria variables of MCS/IDC events in the data product. Users can easily
691 change the definition of MCSs and switch between tracks that are attributed to MCS and IDC
692 without re-running the FLEXTRKR algorithm. There is no need to change the “track” and
693 “merge” lifetime criterion as we do above because they have little impact on the climatological
694 characteristics of MCS and IDC events.

695 4.5 Recommendations for the usage of the MCS/IDC data product

696 Considering the limitations and uncertainties mentioned above, we generally recommend
697 using the data product for observational analyses and model evaluations of convection statistics
698 and characteristics over relatively long periods such as a month, a season, or longer to fully take
699 advantage of the long term dataset, although analysis of individual weather events is also
700 possible as supported by the hourly temporal resolution of the data product. In addition, since the
701 completeness and quality of the source radar dataset degrade dramatically beyond the US border
702 and over the Rocky Mountains (Figure S11), we recommend the usage of the data product within
703 the CONUS east of the Rocky Mountains to alleviate the impact of the termination of MCS/IDC
704 tracks due to poor radar coverage and missing radar data beyond their maximum scan range.

705 Detailed investigation of a short period or a specific MCS/IDC event is acceptable, but
706 cautions should be taken when encountering missing data around the track during the period.

707 Due to the complexity of the algorithms used to develop the data product, it is difficult to
708 quantify the impact of missing data on the MCS/IDC track. Therefore, we do not recommend
709 examining a specific MCS/IDC track if there are too many missing data (precipitation, T_b , or Z_H)
710 along the track. Users planning to apply the data product for a specific case study should
711 examine the availability of the source data first, which are also stored in the data product except
712 for 3-D Z_H due to the large data volume. Users can access the original 3-D Z_H at
713 <https://rda.ucar.edu/datasets/ds841.0/> (Table S1).

714 Lastly, although our sensitivity test in Section 4.4 shows that precipitation characteristics
715 are similar between two different sets of MCS/IDC definition criteria, we still recommend users
716 conduct further sensitivity tests and examine the impact of different definition criteria on the
717 results if the data product is applied to other studies, such as the effects of MCS and IDC events
718 on atmospheric circulation, environmental conditions associated with the initiation and evolution
719 of MCS and IDC events, and MCS/IDC associated weather hazards.

720 **5 Data availability**

721 The high-resolution (4 km hourly) MCS/IDC data product and the corresponding user guide
722 document are available at <http://dx.doi.org/10.25584/1632005> (Li et al., 2020). The original
723 format of the data files is NetCDF-4, and we archive them as compressed files for each year so
724 that the data product is easily accessible. The user guide contains a brief explanation about the
725 approach to develop the data product and a detailed description of the data file content to help
726 users understand the data product.

727 **6 Conclusions**

728 Here we present a unified high-resolution (4 km, hourly) data product that describes the
729 spatiotemporal characteristics of MCS and IDC events from 2004 to 2017 east of the Rocky
730 Mountains over the CONUS. We produce the data product by applying an updated FLEXTRKR
731 algorithm to the NCEP/CPP L3 4 km Global Merged IR V1 T_b dataset, ERA5 melting level
732 heights, the 3-D Gridrad radar reflectivity dataset, and the Stage IV precipitation dataset.
733 Climatological features of the MCS and IDC events from the data product are compared, with a
734 focus on their precipitation characteristics. Consistent with our definitions of MCSs and IDC in
735 the FLEXTRKR algorithm, we find that MCSs have much broader spatial coverage and longer
736 duration than IDC events. While there are many more frequent IDC occurrences than MCSs, the
737 mean convective intensities of IDC events are comparable to those of MCSs. MCS and IDC
738 events both contribute significantly to precipitation east of the Rocky Mountains but with distinct
739 spatiotemporal variabilities. MCS precipitation affects most regions of the eastern US in all
740 seasons, especially in spring and summer. The MCS precipitation center migrates northwards
741 from Arkansas in spring to northern Missouri and Iowa in summer, followed by a southward
742 migration to Louisiana in autumn, and finally to Mississippi and Alabama in the Southeast in
743 winter. IDC precipitation mostly concentrates in the Southeast in summer. IDC precipitation
744 shows a significant diurnal cycle in summer months with a peak around 16:00 – 17:00 Local
745 Time over all regions east of the Rocky Mountains. In contrast, MCS precipitation peaks during
746 nighttime in spring and summer for most regions except for the Southeast, where MCS
747 precipitation peaks in the late afternoon in summer, similar to IDC precipitation. Lastly, we
748 analyze the potential uncertainties of the data product and the sensitivity of the dataset to MCS
749 definitions and give our recommendations for the usage of the data product. The data product

750 will be useful for investigating the atmospheric environments and physical processes associated
751 with convective systems, quantifying the impacts of convection on hydrology, atmospheric
752 chemistry, severe weather hazards, and other aspects of the energy, water, and biogeochemical
753 cycles, and improving the representation of convective processes in weather and climate models.

754 **Author contributions**

755 JL and ZF updated the FLEXTRKR algorithm and prepared the source datasets. JL ran the SL3D
756 and updated FLEXTRKR algorithms for 2004 – 2017. JL collected and archived the MCS/IDC
757 data product and did the analyses. JL led the writing of the manuscript with input from ZF, YQ,
758 and LRL. YQ and LRL guided the development of the data product. JL, ZF, YQ, and LRL
759 reviewed the manuscript.

760 **Competing interests**

761 The authors declare that they have no conflict of interest.

762 **Acknowledgments**

763 This research was supported by the US Department of Energy Office of Science Biological and
764 Environmental Research as part of the Regional and Global Modeling and Analysis (RGMA)
765 program area through the Integrated Coastal Modeling (ICoM) project. LRL and ZF were also
766 partly supported by the Water Cycle and Climate Extremes Modeling (WACCEM) Scientific
767 Focus Area funded by RGMA. The research used computational resources from the National
768 Energy Research Scientific Computing Center (NERSC), a DOE User Facility supported by the
769 Office of Science under Contract DE-AC02-05CH11231. PNNL is operated for DOE by Battelle

770 Memorial Institute under Contract DE-AC05-76RL01830. We thank Dr. Cameron R. Homeyer
771 from the University of Oklahoma for helping us understand the Gridrad dataset and Dr. Jingyu
772 Wang from PNNL for identifying the existence of erroneous Stage IV precipitation. We obtain
773 the NCEP/ CPP L3 half-hourly 4 km Global Merged IR V1 brightness temperature dataset from
774 https://disc.gsfc.nasa.gov/datasets/GPM_MERGIR_1/summary (last access: Dec 28, 2019). The
775 3D Gridrad dataset is from <https://rda.ucar.edu/datasets/ds841.0/> (last access: Jan 2, 2020). We
776 download hourly Stage IV precipitation data from <https://rda.ucar.edu/datasets/ds507.5/> (last
777 access: Dec 28, 2019), and the ERA5 melting level height data was downloaded from
778 <https://doi.org/10.24381/cds.adbb2d47> (last access: Jan 24, 2020).
