11

12 **Abstract**

13 Deep convection possesses markedly distinct properties at different spatiotemporal scales. We
14 present an original high-resolution (4 km, hourly) unified data product of mesoscale convective
15 systems (MCSs) and isolated deep convection (IDC) in the United States east of the Rocky
16 Mountains and examine their climatological characteristics from 2004 to 2017. The data product
17 is produced by applying an updated Flexible Object Tracker algorithm to hourly satellite
18 brightness temperature, radar reflectivity, and precipitation datasets. Analysis of the data product
19 shows that MCSs are much larger and longer-lasting than IDC, but IDC occurs about 100 times
20 more frequently than MCSs, with a mean convective intensity comparable to that of MCSs.
21 Hence both MCS and IDC are essential contributors to precipitation east of the Rocky
22 Mountains, although their precipitation shows significantly different spatiotemporal
23 characteristics. IDC precipitation concentrates in summer in the Southeast with a peak in the late
24 afternoon, while MCS precipitation is significant in all seasons, especially for spring and
25 summer in the Great Plains. The spatial distribution of MCS precipitation amounts varies by
26 seasons, while diurnally, MCS precipitation generally peaks during nighttime except in the
27 Southeast. Potential uncertainties and limitations of the data product are also discussed. The data
28 product is useful for investigating the atmospheric environments and physical processes
29 associated with different types of convective systems, quantifying the impacts of convection on
30 hydrology, atmospheric chemistry, and severe weather events, and evaluating and improving the
31 representation of convective processes in weather and climate models. The data product is
32 available at <http://dx.doi.org/10.25584/1632005> (Li et al., 2020).

33

34 **1 Introduction**

35 In the atmosphere, deep convection refers to thermally driven turbulent mixing that
36 displaces air parcels from the lower atmosphere to the troposphere above 500 hPa (Davison,
37 1999), leading to the development of convective storms. The heavy rain-rates associated with
38 deep convection can significantly affect the water cycle (Hu et al., 2020) and other aspects such
39 as soil erosion (Nearing et al., 2004), surface water quality (Carpenter et al., 2018; Motew et al.,
40 2018), and managed and unmanaged ecosystems (Angel et al., 2005; Derbile and Kasei, 2012;
41 Rosenzweig et al., 2002) that are essential elements of the biogeochemical cycle. By
42 redistributing heat, mass, and momentum within the atmosphere, deep convection also has
43 important effects on atmospheric chemistry (Anderson et al., 2017; Andreae et al., 2001; Choi et
44 al., 2014; Grewe, 2007; Thompson et al., 1997; Twohy et al., 2002), large-scale environments
45 (Houze Jr, 2004; Piani et al., 2000; Stensrud, 1996, 2013; Wang, 2003), and radiation balance
46 (Feng et al., 2011; Zhang et al., 2017).

47 Besides its effects on the energy, water, and biogeochemical cycles, deep convection also
48 has more direct societal impacts. As a significant source of natural hazards such as tornadoes,
49 hail, wind gusts, lightning, and flash flooding, deep convection poses critical threats to human
50 life and property (Brooks et al., 2003; Doswell III et al., 1996; Koehler, 2020; Taszarek et al.,
51 2020). During 1950 – 1994, deep convection thunderstorms produced 47% of annual rainfall and
52 up to 72% of summer rainfall on average east of the Rocky Mountains (Changnon, 2001b).
53 During the same period, both the number of severe thunderstorms and deep convection
54 precipitation has increased in most regions of the contiguous United States (CONUS)
55 (Changnon, 2001a, b; Groisman et al., 2004). Folger and Reed (2013) found that hazards

56 associated with thunderstorms accounted for 57% of annual insured catastrophe losses since
57 1953. Since the 1980s, the inflation-adjusted economic losses due to convective storms increased
58 from about \$5 billion to about \$20 billion in the recent decade ([https://www.iii.org/fact-
60 statistic/facts-statistics-tornadoes-and-thunderstorms](https://www.iii.org/fact-
59 statistic/facts-statistics-tornadoes-and-thunderstorms)). With warmer temperatures, the
61 environments of hazardous convective weather are projected to become more frequent in the
62 future (Diffenbaugh et al., 2013; Seeley and Romps, 2015), although few robust trends have
emerged in the recent decades (Houze Jr et al., 2019; Tippett et al., 2015).

63 The crucial roles of deep convection motivate the need for more accurate and
64 comprehensive datasets to improve understanding and modeling of this process and its impacts.
65 To this end, datasets with information on the location and time of occurrence, intensity, and other
66 properties of deep convection are necessary to understand and quantify its impacts on the
67 hydrologic cycle, severe weather hazards, large-scale circulations, etc. While field campaign data
68 can provide detailed information on deep convection properties, they are limited in space-time
69 coverage for statistical analysis. A corresponding reliable long-term dataset is undoubtedly
70 useful for model evaluation and development (Prein et al., 2017; Yang et al., 2017).

71 Deep convection can exist as isolated convective storms or organized storms with
72 mesoscale structures. A mesoscale convective system (MCS) is an aggregate of convective
73 storms organized into a larger and longer-lived system, which is the largest type of deep
74 convection. Due to their much longer duration and broader spatial coverage, MCSs generally
75 have stronger and longer-lasting influences on large-scale circulations than isolated deep
76 convection (IDC) events (Bigelbach et al., 2014; Stensrud, 1996, 2013). MCSs may also produce
77 higher rain rates, larger echo top heights, and greater water and ice masses than IDC (Rowe et

78 al., 2011, 2012). The enhanced rain rates in MCSs might be caused by larger amounts of ice
79 falling out and melting, higher amounts of liquid water below the melting level, and higher
80 concentrations of smaller drops (Rowe et al., 2011, 2012). Rowe et al. (2012) also suggested that
81 the enhanced rainfall from MCSs might be associated with more favorable environmental
82 conditions, such as higher convective available potential energy (CAPE) and wind shear. CAPE
83 and wind shear can impose different impacts on the initiation and evolution of IDC and MCSs
84 (French and Parker, 2008).

85 Considering the significant differences between IDC and MCS events, a reliable long-term
86 dataset not only describing the characteristics of deep convection but also separating IDC events
87 from MCSs is useful. With the deployment of operational remote sensing platforms such as
88 geostationary satellites and ground-based radar network several decades ago, scientists have
89 developed numerical algorithms to automatically detect deep convective systems and track their
90 evolutions over large areas and for long durations on the basis of continuous measurements from
91 remote sensors (Cintineo et al., 2013; Feng et al., 2011; Feng et al., 2012; Futyan and Del Genio,
92 2007; Geerts, 1998; Hodges and Thorncroft, 1997; Liu et al., 2007; Machado et al., 1998).
93 Objective tracking of deep convection has been applied to geostationary satellite data (Cintineo
94 et al., 2013; Sieglaff et al., 2013; Walker et al., 2012) and Next Generation Weather Radar
95 (NEXRAD) data (Haberlie and Ashley, 2019; Pinto et al., 2015) in the United States (US) over
96 different periods. However, a long-term climatological data product of MCS and IDC events
97 over the CONUS has heretofore not been developed.

98 Here, building on the work by Feng et al. (2019), which developed an algorithm for MCS
99 tracking and a dataset for MCSs for eastern CONUS, we produce a unified high-resolution data

100 product of both MCS and IDC events and analyze their characteristics east of the Rocky
101 Mountains for 2004 – 2017. The data product is developed by applying an updated Flexible
102 Object Tracker (FLEXTRKR) algorithm (Feng et al., 2018; Feng et al., 2019) and the Storm
103 Labeling in Three Dimensions (SL3D) algorithm (Starzec et al., 2017) to the NCEP (National
104 Centers for Environmental Prediction) / CPP (the Climate Prediction Center) L3 4 km Global
105 Merged IR V1 brightness temperature (T_b) dataset (Janowiak et al., 2017), the 3-D Gridded
106 NEXRAD Radar (Gridrad) dataset (Homeyer and Bowman, 2017), the NCEP Stage IV
107 precipitation dataset (Lin and Mitchell, 2005), and melting level heights from ERA5 (ECMWF,
108 2018). Section 2 describes the updated FLEXTRKR and SL3D algorithms in detail, as well as
109 the source datasets used by the algorithms. In Section 3, we first compare the climatological
110 characteristics between MCS and IDC events based on the MCS/IDC data product. Then, as an
111 application of the data product, we examine the spatiotemporal precipitation characteristics of
112 MCS and IDC events. In Section 4, we discuss the uncertainties and limitations of the data
113 product. Section 5 provides the availability information of the data product. Finally, we
114 summarize the study in Section 6.

115 **2 Source datasets and algorithms**

116 2.1 Source datasets

117 *2.1.1 Merged 4-km Infrared brightness temperature dataset*

118 In this study, we identify cold clouds associated with MCSs and IDC by using the NOAA
119 NCEP/ CPP L3 half-hourly 4 km Global Merged IR V1 infrared T_b data for 2004 – 2017
120 (Janowiak et al., 2017). The dataset is a combination of various geostationary IR satellites with

121 parallax correction and viewing angle correction, therefore, providing continuous coverage
122 globally from 60°S – 60°N with a horizontal resolution of about 4 km and a temporal resolution
123 of 0.5 hours (Janowiak et al., 2001). We only use the hourly T_b data in the FLEXTRKR
124 algorithm discussed below, as all other datasets are only available at an hourly interval.

125 *2.1.2 Three-dimensional Gridded NEXRAD Radar (Gridrad) dataset*

126 Gridrad is an hourly 3-D radar reflectivity (Z_H) mosaic combining individual NEXRAD
127 radar observations to a Cartesian gridded dataset, with a horizontal resolution of $0.02^\circ \times 0.02^\circ$
128 and a vertical resolution of 1 km. The dataset covers 115° W to 69° W in longitude, 25° N to 49°
129 N in latitude, and 1 to 24 km in altitude above sea level (ASL). Homeyer and Bowman (2017)
130 produced the dataset by applying a four-dimensional binning procedure to merge level-2 Z_H data
131 from 125 National Weather Service (NWS) NEXRAD weather radars to Gridrad grid boxes at
132 analysis times. Only the level-2 observations within 300 km of each radar and 3.8 minutes of the
133 analysis time were used in the binning procedure. The Gridrad Z_H was the weighted average of
134 the level-2 observations within the Gridrad grid boxes to reduce the potential loss of information.
135 The weight calculation of each level-2 observation followed a Gaussian scheme in both space
136 and time. Observation weight was negatively correlated with the distance of the observation from
137 the source radar and the time difference between the observation and analysis time. The Gridrad
138 dataset provides the total weight of the level-2 observations within each Gridrad grid box, which
139 is useful for quality control. In addition, the number of level-2 radar observations (N_{obs}) and the
140 number of level-2 radar observations with echoes (N_{echo}) within each Gridrad grid box around
141 analysis times (± 3.8 min) are also available in the Gridrad dataset.

142 We obtain the Gridrad datasets between 2004 and 2017 from NCAR/UCAR Research Data
143 Archive (RDA) (<https://rda.ucar.edu/datasets/ds841.0/>, last access: Jan 2, 2020). Following the
144 quality control criteria of Homeyer and Bowman (2017) (<http://gridrad.org/software.html>, last
145 access: Jan 22, 2020), we remove potential low-quality observations, scanning artifacts, and non-
146 meteorological echoes from biological scatters and artifacts. Then we regrid Gridrad Z_H onto the
147 4 km satellite Merged IR grids by using the “bilinear” method from the Earth System Modeling
148 Framework (ESMF) Python module (<https://www.earthsystemcog.org/projects/esmpy/>) as
149 follows.

150 First, we convert the Gridrad logarithmic reflectivity Z_H to linear reflectivity (Z' : $\text{mm}^6 \text{m}^{-3}$).
151 We then set Z' in grid boxes with radar observations but no echoes ($N_{\text{obs}} > 0$, but $Z_H = \text{NaN}$;
152 NaN , Not-A-Number) to 0 ($Z' = 0$). Here the physical interpretation is that NEXRAD scans
153 those grid boxes, but no detectable hydrometeors return any echo. The primary motivation of this
154 procedure is to avoid the reduction of the number of valid reflectivity values after re-gridding, as
155 the ESMF bilinear method treats destination point as NaN as long as there is one NaN value in
156 the source points. A common scenario is at the edge between hydrometeor echoes and clear air.
157 Setting Z' of those grid boxes having radar observations but no echoes to NaN would cause all
158 surrounding destination points to become NaN even though all other source points have valid Z'
159 values, which would reduce the number of re-gridded valid Z_H ($Z_H \neq \text{NaN}$) by about 20% for
160 2004 – 2017. After the “bilinear” re-gridding of Z' , we convert the linear reflectivity Z' back to
161 the logarithmic reflectivity Z_H . And we set Z_H equal to NaN for those grid boxes with Z' equal
162 to 0. Now the NaN values are acceptable and won't affect the SL3D algorithm and FLEXTRKR
163 algorithm discussed below.

164 2.1.3 NCEP Stage IV precipitation dataset

165 The NCEP Stage IV precipitation dataset provides hourly rain accumulations over polar
166 stereographic grids across the CONUS with a resolution of 4.76 km at 60°N since 2002. The
167 dataset is a mosaic of precipitation estimates from 12 River Forecast Centers (RFCs) over the
168 CONUS (Stage IV data in Alaska and Puerto Rico are archived separately) (Lin and Mitchell,
169 2005; Nelson et al., 2016). Each RFC produces its precipitation estimates through a combination
170 of radar and rain gauge data based on the multisensory precipitation estimator (MPE) algorithm
171 (for most RFCs), P3 algorithm (for Arkansas-Red basin RFC), or Mountain Mapper algorithm
172 (for California-Nevada, Northwest, and Colorado-basin RFCs with missing radar-derived
173 estimates) (Nelson et al., 2016). Some manual quality control steps are conducted to remove bad
174 radar and gauge data before radar-gauge merging (Lin and Mitchell, 2005; Nelson et al., 2016).
175 The Stage IV dataset has been widely used as a basis to evaluate model simulations, satellite
176 precipitation estimates, and radar precipitation estimates (Davis et al., 2006; Gourley et al., 2011;
177 Kalinga and Gan, 2010; Lopez, 2011; Yuan et al., 2008). Here, we obtain the hourly Stage IV
178 precipitation for 2004 – 2017 from NCAR/UCAR RDA (<https://rda.ucar.edu/datasets/ds507.5/>,
179 last access: Dec 28, 2019). We regrid the original Stage IV precipitation from polar stereographic
180 grids to the 4 km satellite Merged IR grids by using the “neareststod” method from the ESMF
181 ‘NCL’ module (<https://www.ncl.ucar.edu/Applications/ESMF.shtml>). The “neareststod” method
182 maps each destination point to the closest source point.

183 2.1.4 ERA5 melting level dataset

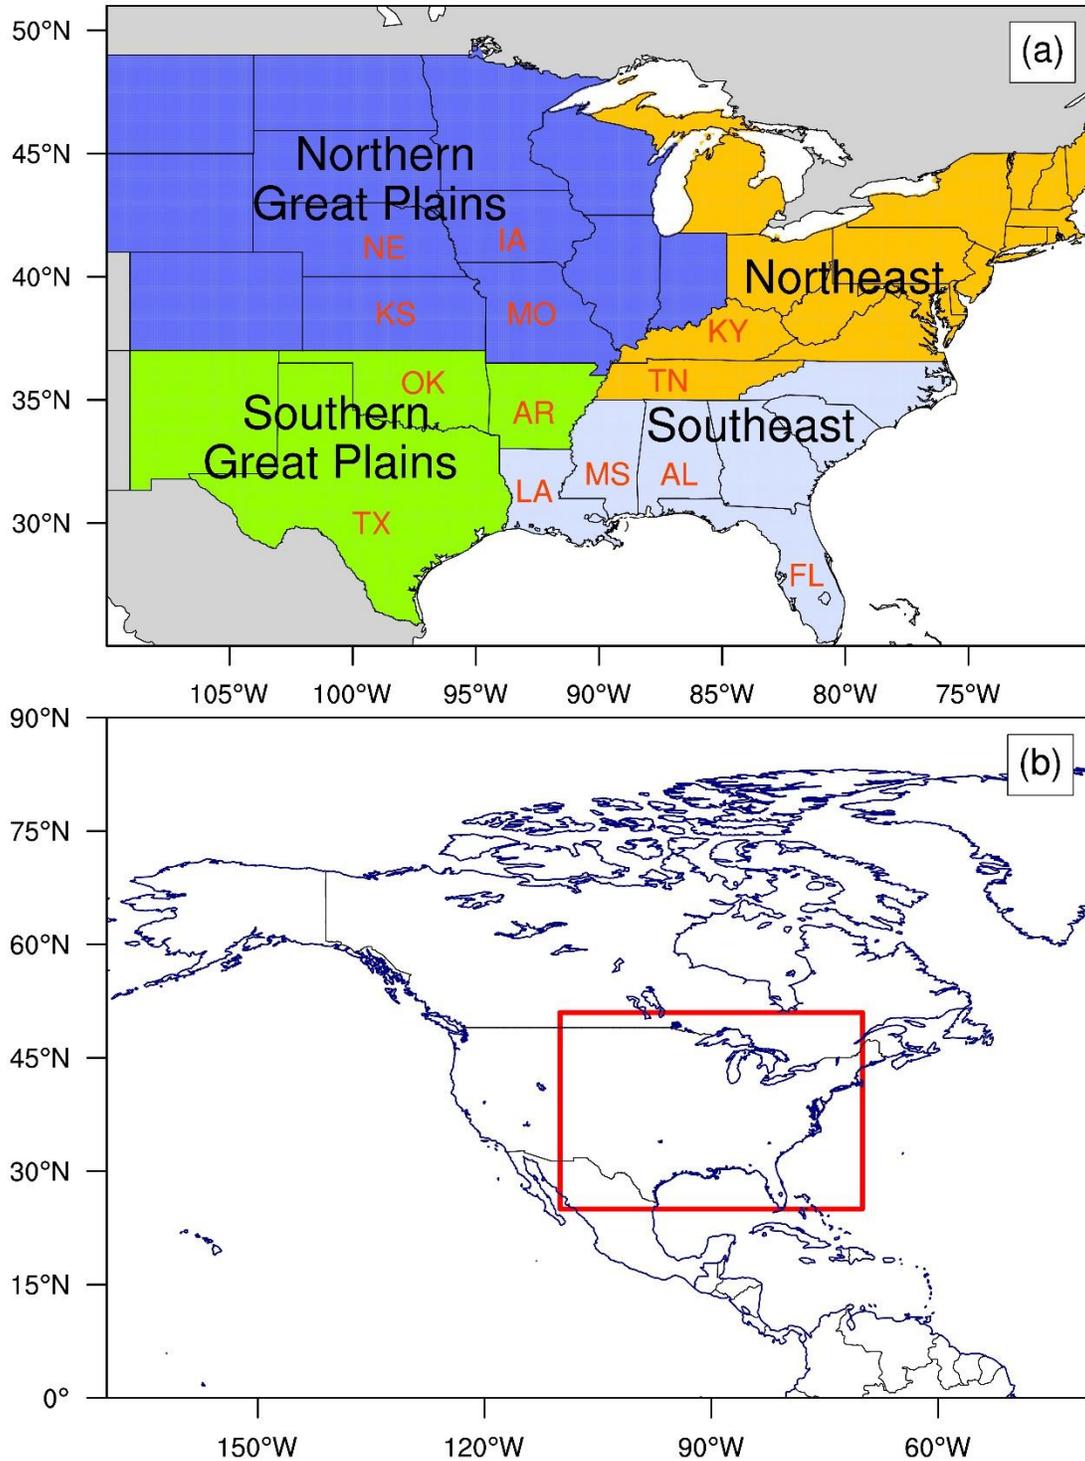

184 Melting hydrometeors produce intense radar echoes in a horizontal layer about 0.5 km thick
185 located just below the 0°C level (melting level), which is known as “bright band” (Giangrande et

186 al., 2008; Steiner et al., 1995). The bright-band signatures are often pronounced for stratiform
187 precipitation, while convective precipitation produces well-defined vertical cores of maximum
188 reflectivity, diluting the bright-band signals (Giangrande et al., 2008; Steiner et al., 1995).
189 Therefore, the SL3D algorithm that is described below examines Z_H above the melting level to
190 avoid the false identification of stratiform rain as convective (Starzec et al., 2017). In this study,
191 we use the hourly melting level heights from the ERA5 reanalysis dataset.

192 ERA5, as the successor to ERA-Interim, contains many modeling improvements and more
193 observations based on 4D-Var data assimilation using Cycle 41r2 of the Integrated Forecasting
194 System (IFS) at the European Centre for Medium-Range Weather Forecasts (ECMWF). ERA5
195 provides hourly estimates of atmospheric variables at a horizontal resolution of 31 km and 137
196 vertical levels from the surface to 0.01 hPa from 1979 to the present (Hersbach et al., 2019). We
197 obtain ERA5 “Zero degree level” (melting level heights above ground) for 2004 – 2017 and
198 “Orography” (geopotential at the ground surface) from the Climate Data Store (CDS) disks
199 (ECMWF, 2018) (last access: Jan 24, 2020). The CDS archived ERA5 variables have been
200 interpolated to regular latitude/longitude grids with a resolution of $0.25^\circ \times 0.25^\circ$. We calculate
201 melting level heights ASL from “Zero degree level” and “Orography” (divided by 9.80665 m s^{-2}
202 to obtain ground surface height). Finally, we regrid the hourly 0.25° melting level heights ASL
203 to the 4-km satellite Merged IR grids by using the ESMF “neareststod” method.

204 We summarize the basic information of the four types of source datasets in Table A1. And,
205 we define our data product domain as $110^\circ\text{W} - 70^\circ\text{W}$ in longitude and $25^\circ\text{N} - 51^\circ\text{N}$ in latitude
206 (Figure 1), which covers the US east of the Rocky Mountains and excludes the western US. The
207 domain coverage takes into consideration the availability of the GridRad radar dataset, the

208 relatively scarce radar coverage over the Rocky Mountains, and associated uncertainties in radar-
209 based Stage IV precipitation estimates in complex terrains (Nelson et al., 2016). As shown in
210 Figure 1a, we further define four regions in the domain following Feng et al. (2019): Northern
211 Great Plains (NGP), Southern Great Plains (SGP), Southeast (SE), and Northeast (NE).

212
 213 **Figure 1.** (a) Data product domain and region definitions. Blue shading denotes the Northern
 214 Great Plains (NGP), green-yellow shading denotes the Southern Great Plains (SGP), light steel
 215 blue shading denotes the Southeast (SE), and orange shading denotes the Northeast (NE). The
 216 locations of some US states within each region are also labeled. TX is for Texas, OK for
 217 Oklahoma, KS for Kansas, NE for Nebraska, IA for Iowa, MO for Missouri, AR for Arkansas,

218 LA for Louisiana, MS for Mississippi, AL for Alabama, TN for Tennessee, KY for Kentucky,
219 and FL for Florida. (b) The location of the data product domain (red box) in North America.

220 2.2 Algorithm description

221 2.2.1 SL3D algorithm

222 The SL3D algorithm exploits Gridrad Z_H to classify each grid column with radar echoes
223 into five categories: convective, precipitating stratiform, non-precipitating stratiform, anvil, and
224 convective updraft (Starzec et al., 2017). SL3D identifies these five categories successively
225 following the criteria listed in Table A2. We run the SL3D algorithm for 2004 – 2017 by using
226 the re-gridded ERA5 melting level heights and Gridrad Z_H dataset described in Section 2.1.
227 Figure 2e shows an example of the SL3D classification results based on Gridrad Z_H (Figure 2d)
228 at 2005-07-04T03:00:00Z. A sizeable convective system with intense radar echoes and
229 precipitation is observed in Kansas, and many isolated convection events are also observed in the
230 Southeast. The SL3D classification results will be used in the following FLEXTRKR algorithm
231 to identify convective core features (CCFs, continuous updraft/convective areas with
232 precipitation $> 0 \text{ mm h}^{-1}$, which are used to indicate the existence of convective activity in the
233 IDC definition; red regions in Figure 3) and precipitation features (PFs, continuous
234 updraft/convective/precipitating-stratiform areas with precipitation $> 1 \text{ mm h}^{-1}$; green areas in
235 Figure 3, which are used to denote the sizes of convective systems in the MCS and IDC
236 definitions).

237 2.2.2 MCS/IDC identification and tracking

238 The FLEXTRKR algorithm was first developed and used by Feng et al. (2019) to track
239 MCSs. In this study, we further update the algorithm so that it can identify and track MCS and
240 IDC events simultaneously.

241 Figure 3 displays the schematic of FLEXTRKR (Feng et al., 2019). The first step is to
242 identify cold cloud systems (CCSs; continuous areas with $T_b < 241$ K) at each hour by applying a
243 multiple T_b threshold “detect and spread” approach (Futyan and Del Genio, 2007). We search for
244 cold cloud cores with $T_b < 225$ K and spread the cold cloud cores to contiguous areas with $T_b <$
245 241 K. Cloud systems that do not contain a cold cloud core but with $T_b < 241$ K are also labeled
246 as long as they can form continuous areas with at least 64 km^2 (4 pixels). In addition, as
247 described in Feng et al. (2019), CCSs that share the same coherent precipitation feature are
248 combined as a single CCS. A coherent precipitation feature is defined as continuous areas with
249 smoothed Z_H at 2 km > 28 dBZ (if Z_H is not available at 2 km, use Z_H at 3 km instead if it is
250 available) (Feng et al., 2019). We use a 5×5 pixel moving window to smooth Z_H . Figure 2b
251 shows an example of the CCSs identified in the first step based on T_b at 2005-07-04T03:00:00Z.
252 “Cloud 1” in Figure 2b corresponds to a large area of low T_b in the central US (Figure 2a).

253 In step 2, CCSs between two consecutive hours are linked if their spatial overlaps are $>$
254 50%. “Linked” means the CCSs are considered to be from the same cloud systems. FLEXTRKR
255 produces tracks by extending the link between two consecutive time steps to the entire tracking
256 period, as shown in Figure 3. Each track represents the lifecycle of a cloud system. We calculate
257 a series of CCS summary statistics associated with each track, such as CCS-based lifetime of the
258 track (the duration of the track when CCSs are present), CCS area, CCS major axis length, CCS

259 propagation speed, etc. Besides, SL3D classification (Figure 2e) and Stage IV precipitation
260 (Figures 2c) within the tracked CCS are associated with the tracks and their merges and splits
261 (described below). Then, we can obtain CCF and PF statistics of each track, such as convective
262 and stratiform area, precipitation intensity and coverage, radar-derived echo-top heights, PF
263 major axis length, CCF major axis length, intense convective cells (convective cells with column
264 maximum reflectivity ≥ 45 dBZ and precipitation > 1 mm h⁻¹; pink areas in Figure 3, which are
265 used to indicate intense convective activity in the following MCS definition), etc.

266 Merging and splitting refer to situations when two or more CCSs are linked to one CCS
267 between consecutive hours (Figures A1 and A2). A track associated with the largest CCS is
268 defined as the main track (Figure A3), and smaller tracks from merges/splits are regarded as
269 parts of the main track when calculating PF and CCF statistics. In the algorithm, we require that
270 a “merge”/“split” track associated with an MCS/IDC event must have a CCS-based lifetime of
271 no more than 5 hours. Otherwise, we treat it as an independent track.

272 The identification of MCS and IDC is based on the CCS, PF, and CCF statistics of the
273 tracks. Following the definition of MCSs by Feng et al. (2019) (Figure 4), we define a track as an
274 MCS if it satisfies the following criteria: 1) there is at least one pixel of cold cloud core during
275 the whole lifecycle of the track; 2) CCS areas associated with the track surpass 60,000 km² for
276 more than six continuous hours; 3) PF major axis length exceeding 100 km and intense
277 convective cell areas of at least 16 km² exist for more than five consecutive hours. Considering
278 the lack of a strict and universal MCS definition (Geerts et al., 2017; Haberlie and Ashley, 2019;
279 Pinto et al., 2015; Prein et al., 2017), we evaluate the impact of different MCS definition criteria
280 on the data product in Section 4.4. For the non-MCS tracks, we further identify IDC with the

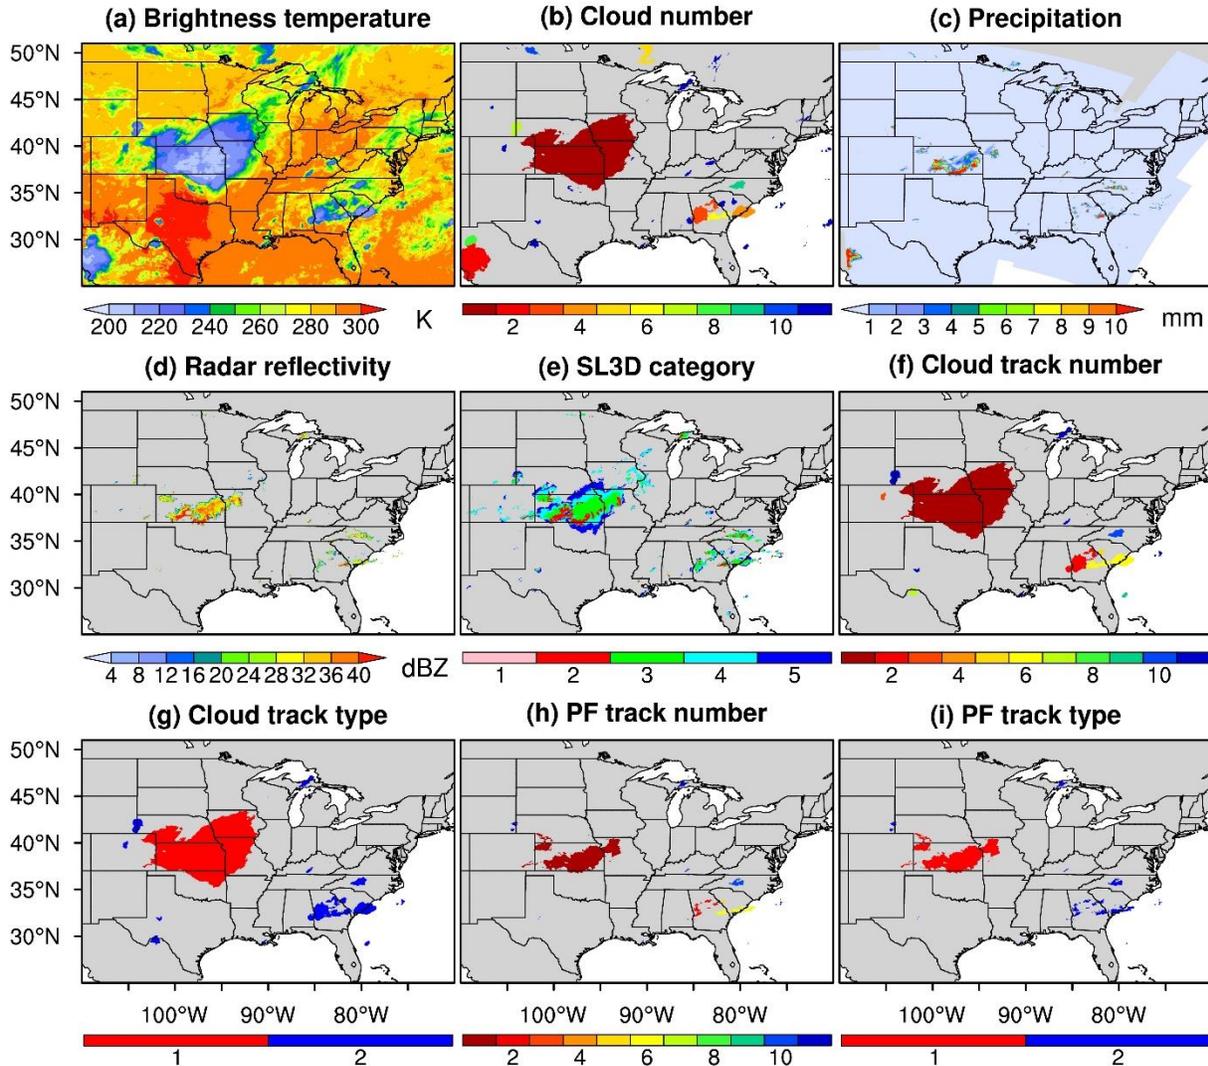

281 following two criteria (Figure 4): 1) a CCS with at least 64 km^2 (4 pixels) is detected; 2) at least
282 1 hour during the lifecycle of the track when PF and CCF are present (PF and CCF major axis
283 lengths $\geq 4 \text{ km}$). In addition, for each IDC event, the CCS-based lifetime of associated merge
284 and split tracks cannot surpass the lifetime of the IDC event. Here, the IDC criteria denote a low
285 limit in convective signals that we can identify by using the FLEXTRKR algorithm and given
286 source datasets. Potential uncertainties associated with the limit are discussed in Section 4.3.

287 Note that while we designate the term IDC to differentiate smaller convective storms from
288 MCSs, there are sub-categories of deep convection within IDC. For example, multicellular
289 convection systems that do not grow large enough or last long enough to meet our MCS
290 definition are defined as IDC in our study, even though they are not necessarily “isolated.” Users
291 of the data product can further separate sub-categories within IDC using the derived CCF
292 statistics information to address specific science questions or research objectives.

293 Finally, the FLEXTRKR algorithm maps MCS/IDC track information back to the domain
294 pixels. Figures 2f – 2i give an example of the pixel-level MCS/IDC information at 2005-07-
295 04T03:00:00Z. Figure 2f displays the spatial coverages of MCS/IDC tracks at that time at pixel
296 scale and the corresponding unique numbers of these tracks. From Figure 2f, we know whether a
297 pixel belongs to an MCS/IDC track and the number of the track if the pixel belongs to a track.
298 We can further determine whether the track is an MCS or IDC event from Figure 2g, which
299 shows the types (MCS or IDC) of the tracks in Figure 2f at pixel scale. Figures 2h and 2i are
300 similar to Figures 2f and 2g, respectively. The difference is that Figures 2h and 2i only show
301 pixels with precipitation $> 1 \text{ mm h}^{-1}$ in that hour. Together, the track-based CCS, PF, and CCF
302 statistics of MCS and IDC events and the pixel-level dataset constitute the unified high-

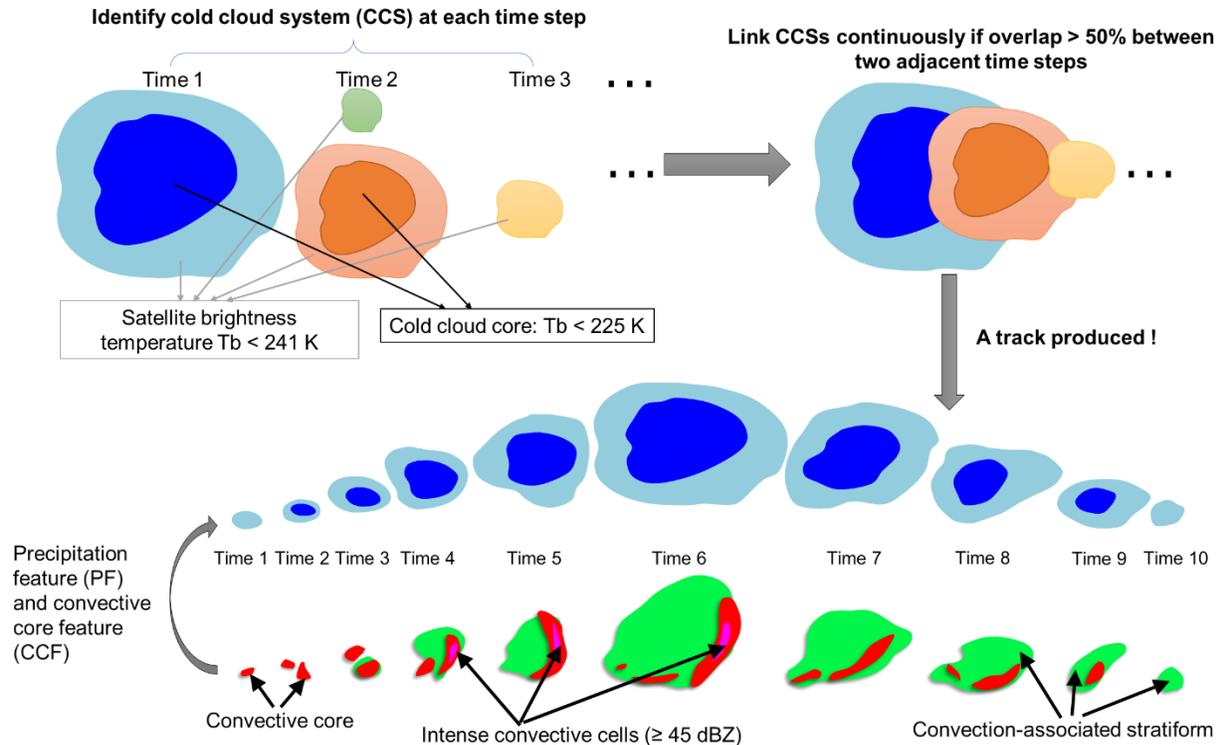

303 resolution MCS/IDC data product we develop in this study. Original T_b (Figure 2a), Stage IV
304 precipitation (Figure 2c), Gridrad Z_H at 2 km (Figure 2d), and Gridrad derived echo-top heights
305 are also archived in the data product.

306 We run the FLEXTRKR algorithm separately for each year from 2004 to 2017. The starting
307 time of each continuous tracking is 00Z on 1 January, and the ending time is 23Z on 31
308 December. Because winter has the fewest deep convection events, very few MCS/IDC events
309 extend between two different years based on our investigation. Also, the lifetimes of MCS/IDC
310 events are much shorter compared to our tracking period. Therefore, running FLEXTRKR
311 separately for each year rather than continuously for the whole period has little impact on the
312 MCS/IDC statistics.

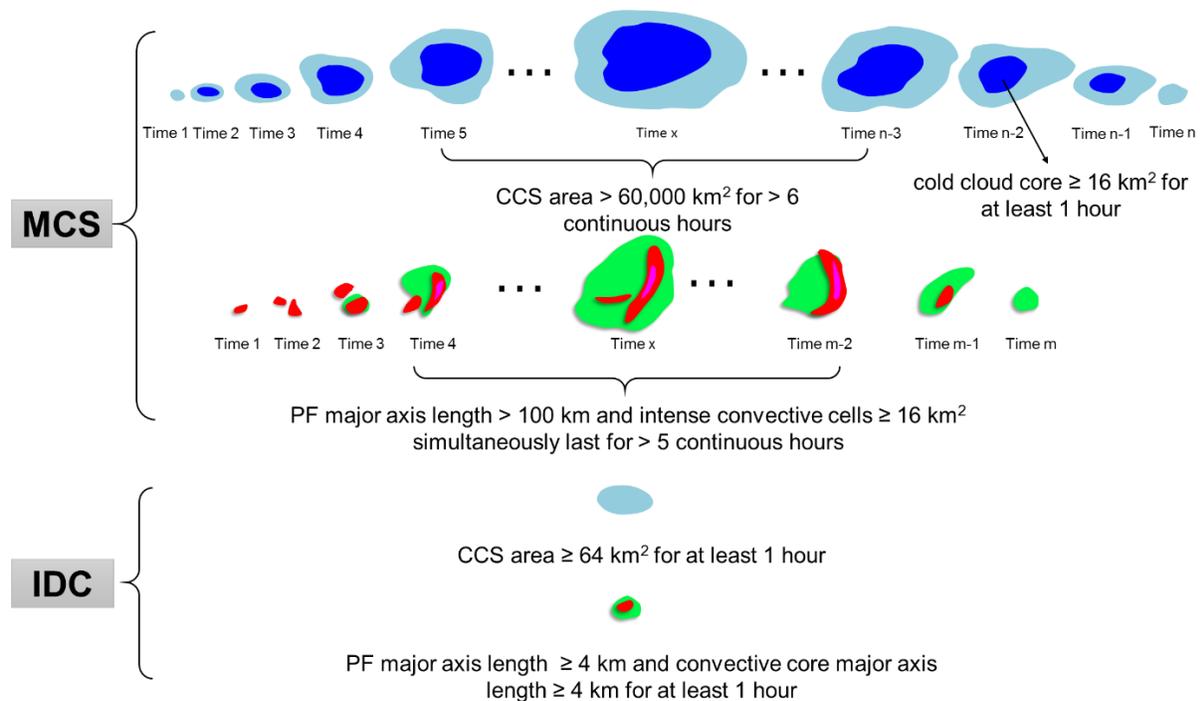

313
 314 **Figure 2.** FLEXTRKR pixel-level outputs at 03:00:00Z on July 4, 2005. (a) is satellite T_b . (b)
 315 shows identified CCS labels. CCS labels are unique at each hour. (c) is Stage IV hourly
 316 accumulated precipitation. (d) is Gridrad Z_H at 2 km (if it is not available, Z_H at 3 km is provided
 317 if it is available). (e) is the SL3D classification results: 1, convective updraft; 2, convective; 3,
 318 precipitating stratiform; 4, non-precipitating stratiform; 5, anvil. (f) displays the track numbers to
 319 which pixels belong. Here, the track numbers are not the real values in the MCS/IDC data
 320 product. The track numbers should be unique throughout the whole running period. We adjust
 321 the track numbers here to make the figure clear. Similar to “PF track number.” (g) gives
 322 information on whether the pixels belong to MCS (marked as 1) or IDC (marked as 2) tracks,
 323 which correspond to the tracks shown in (f). (h) also displays the track numbers to which the
 324 pixels belong, but only for pixels with precipitation $> 1 \text{ mm h}^{-1}$. (i) is like (g) but corresponds to
 325 (h). All these variables are stored in the FLEXTRKR hourly pixel-level output files.

334 **3 Results and discussions**

335 3.1 Climatological characteristics of MCS and IDC events

336 According to the MCS/IDC data product, we identify 45,346 IDC and 454 MCS events each
337 year on average between 2004 and 2017 in our data product domain. Summer (June – August)
338 has the most IDC and MCS events with average numbers of 25,073 and 212, while winter has
339 the least with average quantities of 2,545 and 37. During spring and autumn, there are 8,543 and
340 9,185 IDC events and 122 and 83 MCSs, respectively. The seasonal feature with the most
341 occurrences of MCSs in winter and the least in summer is consistent with the results of Geerts
342 (1998) in the Southeast US and Haberlie and Ashley (2019) over portions of the CONUS east of
343 the Continental Divide (ECONUS).

344 We compare the climatological characteristics of MCS and IDC events in Table 1. MCSs
345 have much longer lifetimes than IDC, averaging 21.1 hours (CCS-based) and 18.9 hours (PF-
346 based), compared to 2.1 hours (CCS-based) and 1.7 hours (PF-based) for IDC. Here, PF-based
347 lifetime refers to the lifetime determined by the MCS/IDC PFs. Only those hours with a
348 significant PF present (PF major axis length > 20 km for MCSs; ≥ 4 km for IDC) are counted
349 during the lifecycle of an MCS/IDC event, which represent the active convective period of a
350 storm. We find that MCSs have the longest PF lifetime in winter (21.3 hours) and the shortest in
351 summer (17.9 hours). In comparison, IDC has the longest PF lifetime in winter (1.9 hours), but
352 the summer lifetime (1.7 hours) is comparable to spring and autumn. We examine the seasonal
353 cumulative distribution functions (CDFs) of PF lifetimes for MCS and IDC events for 2004 –
354 2017 in Figure A4. Results show winter has the largest fraction of MCS/IDC events with longer
355 lifetimes than other seasons.

356 As expected, MCSs are much larger than IDC events in spatial coverage and precipitation
357 area, as shown in Table 1 by the comparisons of CCS area, PF major axis length, PF
358 convective/stratiform area, CCF area, and CCF major axis length. Generally, on average, winter
359 MCS/IDC events are the largest in overall spatial coverage (both CCS and PF areas), while
360 summer has the smallest. The larger and longer-lived MCSs in winter than in summer were also
361 observed in the Southeast US in 1994 – 1995 by Geerts (1998). The remarkable seasonal
362 difference in MCS/IDC overall spatial coverage is mainly due to stratiform areas. Convective
363 areas are much smaller than stratiform areas. The PF stratiform area of MCSs in winter is 90,513
364 km², 2.4 times larger than the area of 26,599 km² in summer, but the PF convective area of
365 MCSs in winter is 7,293 km², 14% smaller than 8,465 km² in summer. Similarly, the IDC PF
366 stratiform area in winter is 3,182 km², 2.8 times larger than 828 km² in summer, while the IDC
367 PF convective area in winter is 528 km², slightly larger (9%) than 483 km² in summer. Unlike
368 stratiform areas with the largest value in winter, convective activity is the most intense in
369 summer as indicated by the PF mean convective 20-dBZ echo-top height in Table 1. The most
370 intense convective activity reflects the strongest atmospheric thermal instability due to the
371 strongest solar radiation in summer. We further confirm this point by investigating the MCS/IDC
372 initiation time. As shown in Figure A5, most MCS and IDC events initiate in the afternoon of
373 summer when atmospheric instability is the strongest, consistent with Geerts (1998), who found
374 warm-season MCSs generally initiated at 12:00 – 14:00 Local Time in the Southeast US.

375 Although MCSs are much larger than IDC events in spatial coverage, their mean convective
376 20-dBZ echo-top heights, which can be used to represent their mean convective intensities, are
377 similar in Table 1. And their PF mean convective and stratiform rain rates are also comparable.
378 PF mean convective and stratiform rain rates show significant seasonal variations for both MCS

379 and IDC events. Summer MCS and IDC events have the largest rain rates, followed by autumn.
380 Winter has the lowest rain rates compared to other seasons.

381 The high-resolution nature of the MCS/IDC data product enables a detailed examination of
382 the 3-D evolutions of MCS/IDC events to investigate the relationships between atmospheric
383 environments and MCS/IDC characteristics and to examine the impacts of MCSs and IDC on
384 hydrology, atmospheric chemistry, and severe weather hazards. The data product can also be
385 used to evaluate and improve the representation of MCS/IDC processes in weather and climate
386 models. As an example of the application of the MCS/IDC data product, in Section 3.2, we
387 investigate the contributions of MCS and IDC events to precipitation east of the Rocky
388 Mountains for 2004 – 2017.

Table 1. Annual and seasonal mean characteristics of MCS and IDC events in the data product domain for 2004 – 2017

	MCS					IDC				
	Annual	spring	Summer	autumn	winter	annual	spring	summer	autumn	winter
CCS-based lifetime / hour	21.1	21.5	19.9	22.1	24.3	2.1	2.1	2.0	2.0	2.7
CCS area ¹ / km ²	185,436	223,230	130,769	185,246	373,220	6,775	9,400	4,542	6,515	20,902
CCS major axis length / km	693	774	568	726	1,067	99	117	86	100	169
PF-based lifetime ² / hour	18.9	19.3	17.9	19.7	21.3	1.7	1.7	1.7	1.7	1.9
Major axis length of the largest PF ³ / km	397	426	325	436	620	63	69	56	69	93
PF convective area ⁴ / km ²	8,273	8,589	8,465	7,752	7,293	494	509	483	502	528
PF stratiform area / km ²	41,336	47,241	26,559	48,376	90,513	1,261	1,610	828	1,583	3,182
PF mean convective rain rate / mm h ⁻¹	4.4	3.9	4.7	4.5	3.8	4.2	3.4	4.5	4.3	3.0
PF mean stratiform rain rate / mm h ⁻¹	2.6	2.4	2.8	2.6	2.2	2.8	2.5	3.0	2.9	2.3
PF mean convective 20-dBZ echo-top height / km	6.5	6.2	7.2	6.0	4.9	6.6	6.1	7.0	6.2	5.0
Area of the largest CCF / km ²	2,578	2,515	2,983	2,068	1,606	343	359	339	340	349
Major axis length of the largest CCF / km	109	109	117	100	92	29	30	29	29	31

¹ In this table, for hourly characteristics (all variables except for CCS-based lifetime and PF-based lifetime), we generally first calculate the average values of the characteristics during the duration of each MCS/IDC event except for the max 30/40-dBZ echo-top heights, which are the maximum values of the attributes within the period. Then we calculate the mean values of the characteristics of all MCS/IDC events. For example, an MCS has a CCS-based lifetime of 10 hours. During its duration, it has a CCS at each hour. We calculate the average CCS area during the 10 hours, which is the average CCS area of the MCS. Then, we average all MCSs identified during a period to derive the values shown in this row.

² Lifetimes of MCS/IDC events determined by PFs. Only count those hours of an MCS/IDC event with a significant PF present (PF major axis length > 20 km for MCSs; ≥ 4 km for IDC).

³ There can be multiple PFs and CCFs at a given time for an MCS/IDC event. “Largest” means only the largest PF or CCF is used in the calculation.

⁴ There can be multiple PFs and CCFs at a given time for an MCS/IDC event. If not specified, all PFs/CCFs are considered. For example, convective areas of all PFs at a given time are summed to represent the PF convective area of an MCS/IDC event at that time. Similarly, the convective rain rates of all PFs at the given time are averaged to represent the PF mean convective rain rate of the MCS/IDC at that time.

402 3.2 Precipitation characteristics from different sources

403 Here we only consider hourly data with precipitation $> 1 \text{ mm h}^{-1}$ (Feng et al., 2019). At 4
404 km resolution, precipitation less than 1 mm h^{-1} accounts for less than 19% of the total
405 precipitation, and the uncertainty of radar-derived precipitation at such low rainfall intensity is
406 typically large. Including hourly data with precipitation $\leq 1 \text{ mm h}^{-1}$ in the calculation will
407 change the values shown in this study but will neither affect the comparison among MCS, IDC,
408 and non-convective (NC) precipitation nor their spatial distribution patterns. Here, NC
409 precipitation refers to precipitation not associated with any MCS or IDC events and is mainly
410 from stratiform rain. Total precipitation is the sum of MCS, IDC, and NC precipitation. It is
411 noteworthy that NC precipitation may contain some convection-associated rain due to the
412 limitation of the source datasets and the algorithms used in this study. More relevant details are
413 discussed in Section 3.2.3 and Section 4.

414 *3.2.1 Annual spatial distributions of different types of precipitation*

415 According to the MCS/IDC data product, the annual average total precipitation east of the
416 Rocky Mountains in the US (US grid cells in Figure 1) is 691 mm between 2004 and 2017 with
417 a mean precipitation intensity of 3.6 mm h^{-1} . MCSs contribute the most to the total precipitation
418 with a fraction of 45%, followed by NC (30%) and IDC (25%). And the mean precipitation
419 intensities of MCSs (4.4 mm h^{-1}) and IDC (3.8 mm h^{-1}) are much larger than NC (2.7 mm h^{-1}).
420 Our MCS precipitation fraction (45%) is higher than that ($\sim 30\%$) from Habberle and Ashley
421 (2019) over the ECONUS due to their different algorithms and stricter criteria to track and
422 define MCSs.

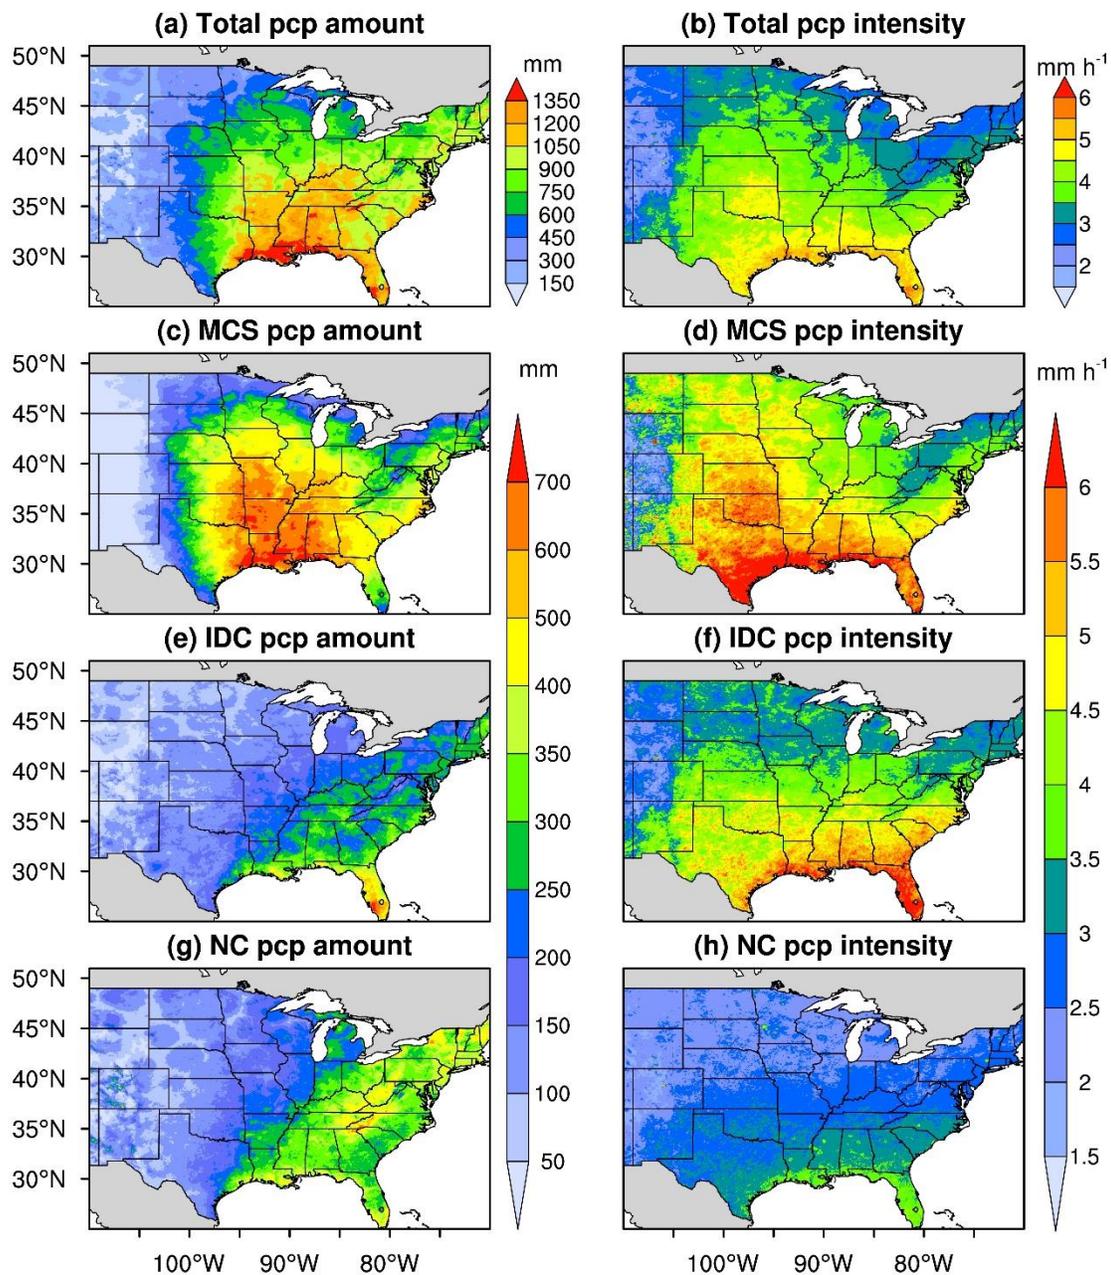

423 Figure 5 displays the spatial distributions of annual mean precipitation amounts and
424 intensities for different precipitation types for 2004 – 2017. We also calculate the distributions

425 of the fractions of different types of precipitation in Figure 6. MCS precipitation strongly
426 affects the whole eastern US ($105^{\circ}\text{W} - 70^{\circ}\text{W}$, MCS precipitation fractions: $46\% \pm 12\%$),
427 especially in the South Central US (MCS precipitation fractions: $\sim 60\%$). The spatial
428 distribution patterns of MCS annual precipitation amounts and fractions in Figure 5 are similar
429 to those from Haberlie and Ashley (2019), although their MCS precipitation fractions are
430 generally lower than our results. IDC precipitation is concentrated in the SE and NE coastal
431 areas, with peak values in Florida. NC precipitation is substantial in the eastern and southern
432 regions with ample moisture supply and contributes over 35% to the total precipitation across
433 most of the NE region. The coastal area near Louisiana, which is significantly affected by all
434 three types of precipitation, has the most total precipitation with annual amounts of over 1,350
435 mm. The annual total precipitation amounts in most regions of SE also exceed 1,050 mm due to
436 MCS contributions. While the total precipitation amounts in most regions of Florida are also
437 over 1,050 mm, they are mainly attributed to IDC.

438 The spatial patterns of precipitation intensities are somewhat different from those of
439 precipitation amounts (Figure 5). Generally, the southern regions, especially in the coastal
440 areas, have larger precipitation intensities than the northern areas. The MCS precipitation
441 intensities are the largest in Texas, Louisiana, Oklahoma, and Kansas, significantly shifting
442 west compared to MCS precipitation amounts. Unlike IDC precipitation amounts concentrating
443 in the SE and NE coastal areas, IDC precipitation intensities are the largest over the SGP and
444 SE. IDC precipitation intensities over the NE are much smaller compared to the SGP and SE,
445 similar to NC precipitation intensities. We summarize the annual mean precipitation amounts
446 and intensities of different types of precipitation in the NGP, SGP, SE, and NE in Table A3.

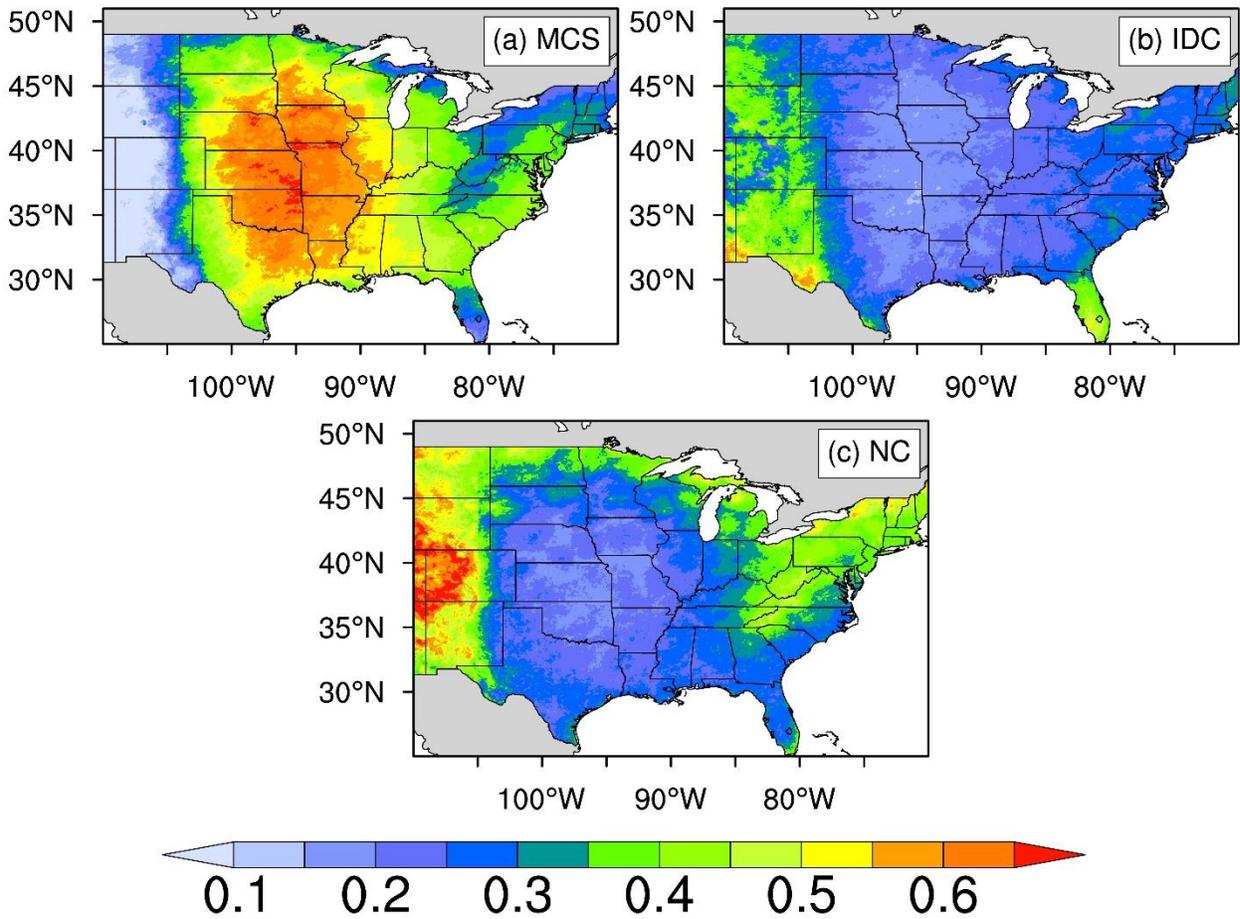

447 The distributions of MCS/IDC precipitation amounts are mainly determined by the
448 distributions of MCS/IDC hours (Figures 5 and 7). Here, the MCS/IDC hour of a grid cell

449 during a period is the number of hours when any MCS/IDC events produce > 1 mm hourly
450 accumulated rainfall in the grid cell. The distributions of MCS/IDC precipitation intensities,
451 although not the main factor, can also affect the distributions of MCS/IDC precipitation
452 amounts. For example, the maximum MCS hours are located around Missouri (Figures 7a), but
453 the maximum MCS precipitation amount is in the coastal area of Louisiana (Figure 5c). The
454 larger MCS precipitation intensities in the southern regions contribute more to the MCS
455 precipitation amount in the southern US. In addition, a large number of IDC events (IDC
456 hours $> 60 \text{ h yr}^{-1}$) occur in the NE region along the Appalachian Mountains (Figure 7b), but
457 IDC in that region only contributes to 20% – 30% of the total precipitation amount (Figure 6b)
458 due to the low precipitation intensities (Figure 5f).

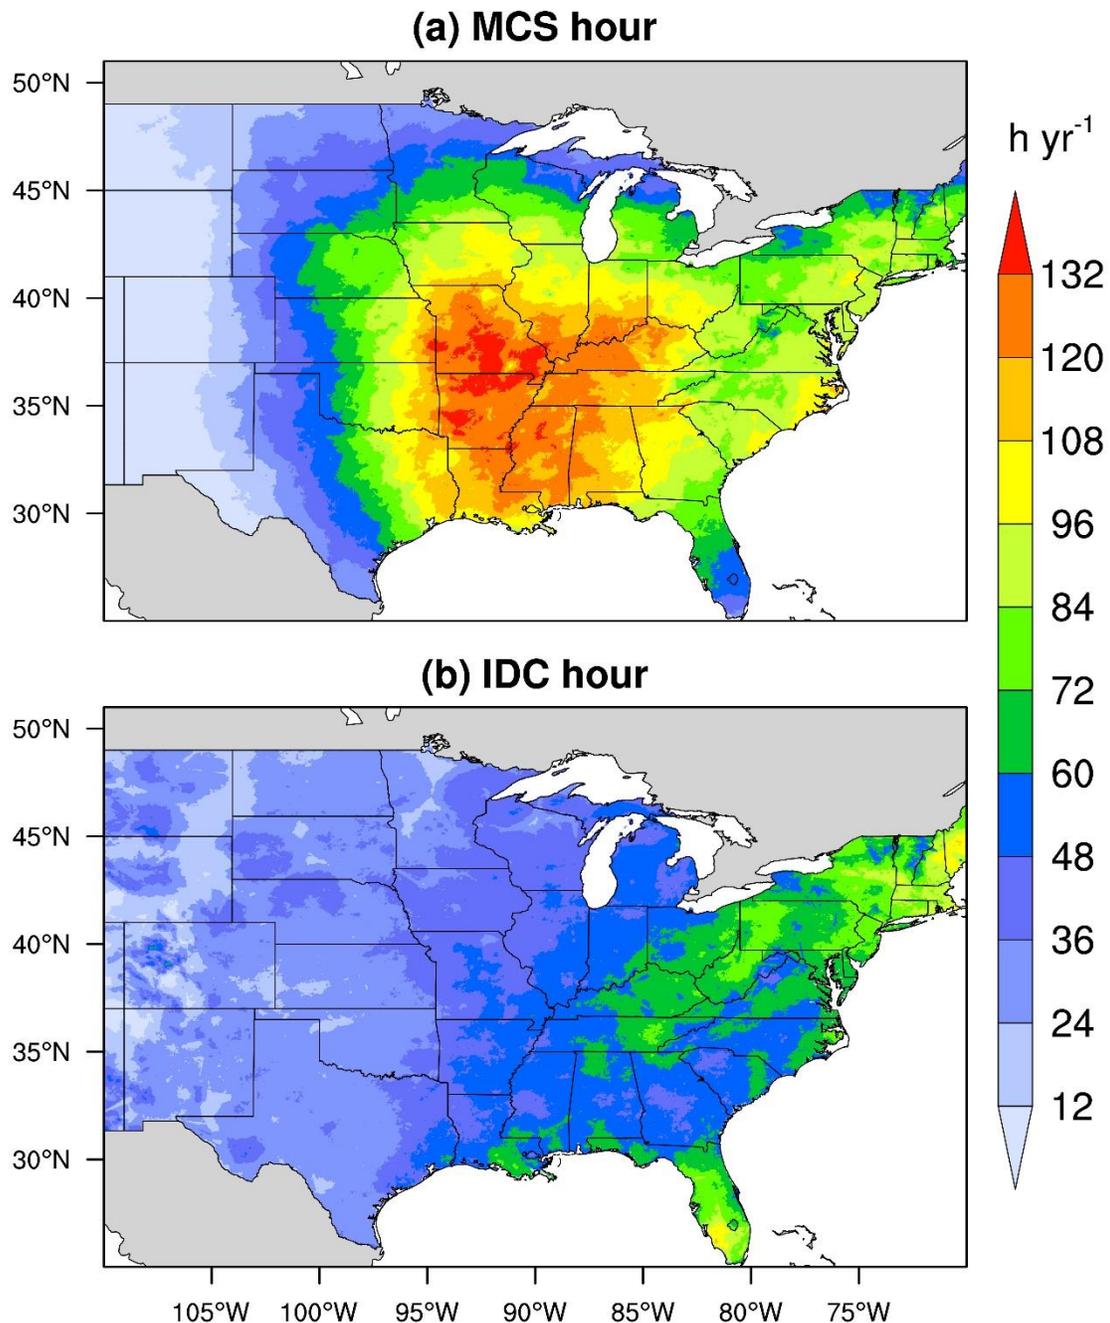

459
 460
 461
 462
 463

Figure 5. Distributions of annual mean precipitation amounts (a, c, e, g) and intensities (b, d, f, h) for different types of precipitation for 2004 – 2017. (a) and (b) are for total precipitation, (c) and (d) are for MCS precipitation, (e) and (f) are for IDC precipitation, and (g) and (h) are for NC precipitation. We only include hourly data with precipitation > 1 mm h⁻¹ in the calculation.

464
 465
 466
 467

Figure 6. Distributions of the fractions of different types of precipitation (MCS, IDC, NC). Here, precipitation refers to annual mean values for 2004 – 2017. We exclude hourly data with precipitation $\leq 1 \text{ mm h}^{-1}$ in the calculation.

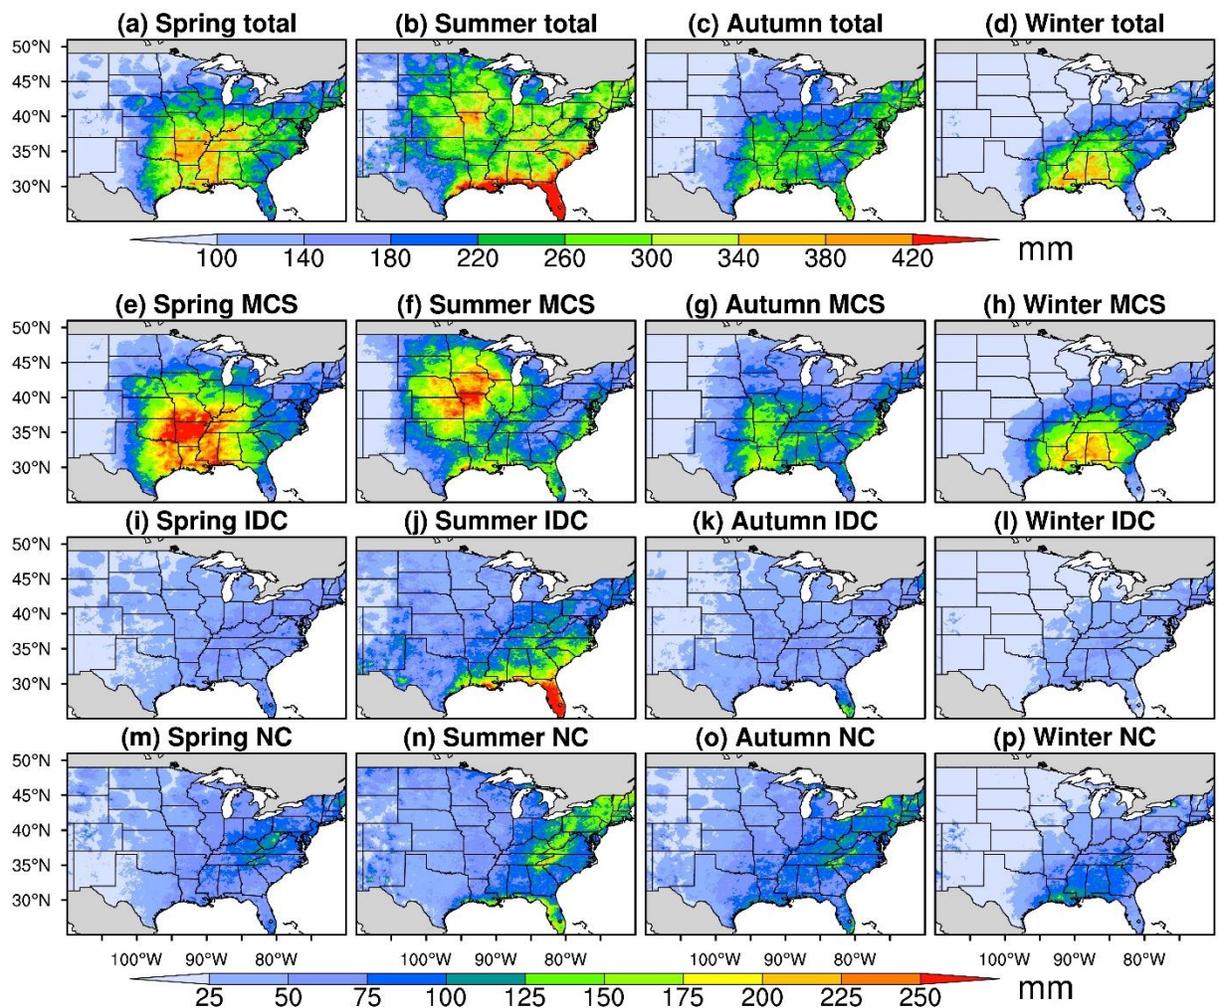

468
469 **Figure 7.** Spatial distributions of annual mean MCS/IDC hours for 2004 – 2017. (a) is for
470 MCS, and (b) is for IDC. The annual mean MCS/IDC hour of a grid cell is the number of hours
471 per year when any MCS/IDC events produce > 1 mm hourly accumulated rainfall in the grid
472 cell.

473 *3.2.2 Seasonal spatial distributions of different types of precipitation*

474 Figures 8, A6, and A7 display the mean seasonal distributions of precipitation amounts,
475 precipitation fractions, and precipitation intensities for different types of precipitation in 2004 –

476 2017. The MCS precipitation center migrates northwards from Arkansas in spring to northern
477 Missouri and Iowa in summer, followed by a southward migration to Louisiana in autumn, and
478 finally to Mississippi and Alabama in the Southeast (Figures 8e – 8h) in winter. The seasonal
479 shift of the MCS precipitation center agrees with the study of Haberlie and Ashley (2019),
480 showing different MCS precipitation distributions between warm and cold seasons over the
481 ECONUS. Spring and summer have much larger MCS precipitation amounts (~100 mm) than
482 autumn (~62 mm) and winter (~50 mm). The mean MCS precipitation amount in spring is close
483 to that in summer. However, the total number of identified MCSs in summer (212) is much
484 higher than that in spring (122), as discussed in Section 3.1; and the mean MCS precipitation
485 intensity in summer (5.2 mm h^{-1}) is also larger than that in spring (4.1 mm h^{-1}) (Figure A7). The
486 inconsistency is because MCSs in spring occur in more favorable large-scale environments with
487 strong baroclinic forcing and low-level moisture convergence (Feng et al., 2019; Song et al.,
488 2019). As a result, spring MCSs are larger and longer-lasting, and they produce more rainfall
489 per MCS event compared to those in summer (Table 1), compensating for the fewer number of
490 MCS events and lower precipitation intensities in spring. The fractions of MCS precipitation
491 amounts are generally > 35% over the Northern and Southern Great Plains in spring and
492 summer and can reach up to over 70% within the MCS precipitation center (Figures A6a –
493 A6b). The results are roughly consistent with Fritsch et al. (1986), which showed that MCSs
494 accounted for about 30% – 70% of the warm-season (April-September) precipitation over much
495 of the region between the Rocky Mountains and the Mississippi River. The results are also
496 consistent with Haberlie and Ashley (2019) showing MCS precipitation fractions generally >
497 30% with a peak > 60% over the Great Plains between May and August. Due to the low
498 precipitation amounts of IDC and NC, the fractions of MCS precipitation amounts in autumn
499 and winter are also large, showing over 50% within the MCS precipitation center (Figures A6c
500 – A6d).

501 The IDC precipitation amounts reach a maximum in summer, centered in the coastal areas
 502 of the SE, where IDC precipitation contributes to more than 40% of the total precipitation
 503 amounts (Figures 8i – 8l and A6e – A6h). Winter has the least IDC precipitation. Areas of high
 504 IDC precipitation do not show much seasonal variability, suggesting that IDC is constrained by
 505 local conditions such as moisture availability, local solar radiation, and land-atmosphere
 506 interactions. The NC precipitation amount also peaks in summer, followed by autumn,
 507 particularly in the NE (Figures 8m – 8p). However, because both MCS and IDC precipitation
 508 amounts are very high in summer, the fraction of the NC precipitation amount in summer (28%)
 509 is smaller than that of winter (32%) (Figures A6i – A6l). Winter NC precipitation center occurs
 510 in the SE coastal areas (Figure 8p).

511

512 **Figure 8.** Distributions of annual mean seasonal precipitation amounts for different types of
513 precipitation for 2004 – 2017. The first row is for total precipitation, the second for MCS
514 precipitation, the third row for IDC precipitation, and the fourth row for NC precipitation. The
515 first column shows spring precipitation, the second column for summer, the third column for
516 autumn, and the fourth column for winter. MCS, IDC, and NC precipitation share the same
517 label bar. We exclude hourly data with precipitation $\leq 1 \text{ mm h}^{-1}$ in the calculation.

518 The precipitation intensities of all three types peak in summer and reach minimums in
519 winter (Figure A7). In each season, precipitation intensities in the south are larger than those in
520 the north except for MCS precipitation intensities in summer, which maximize in Oklahoma.
521 We summarize the mean seasonal precipitation amounts and intensities of different types of
522 precipitation over the 4 climate regions of Figure 1 in Table A4.

523 *3.2.3 Diurnal cycles of different types of precipitation*

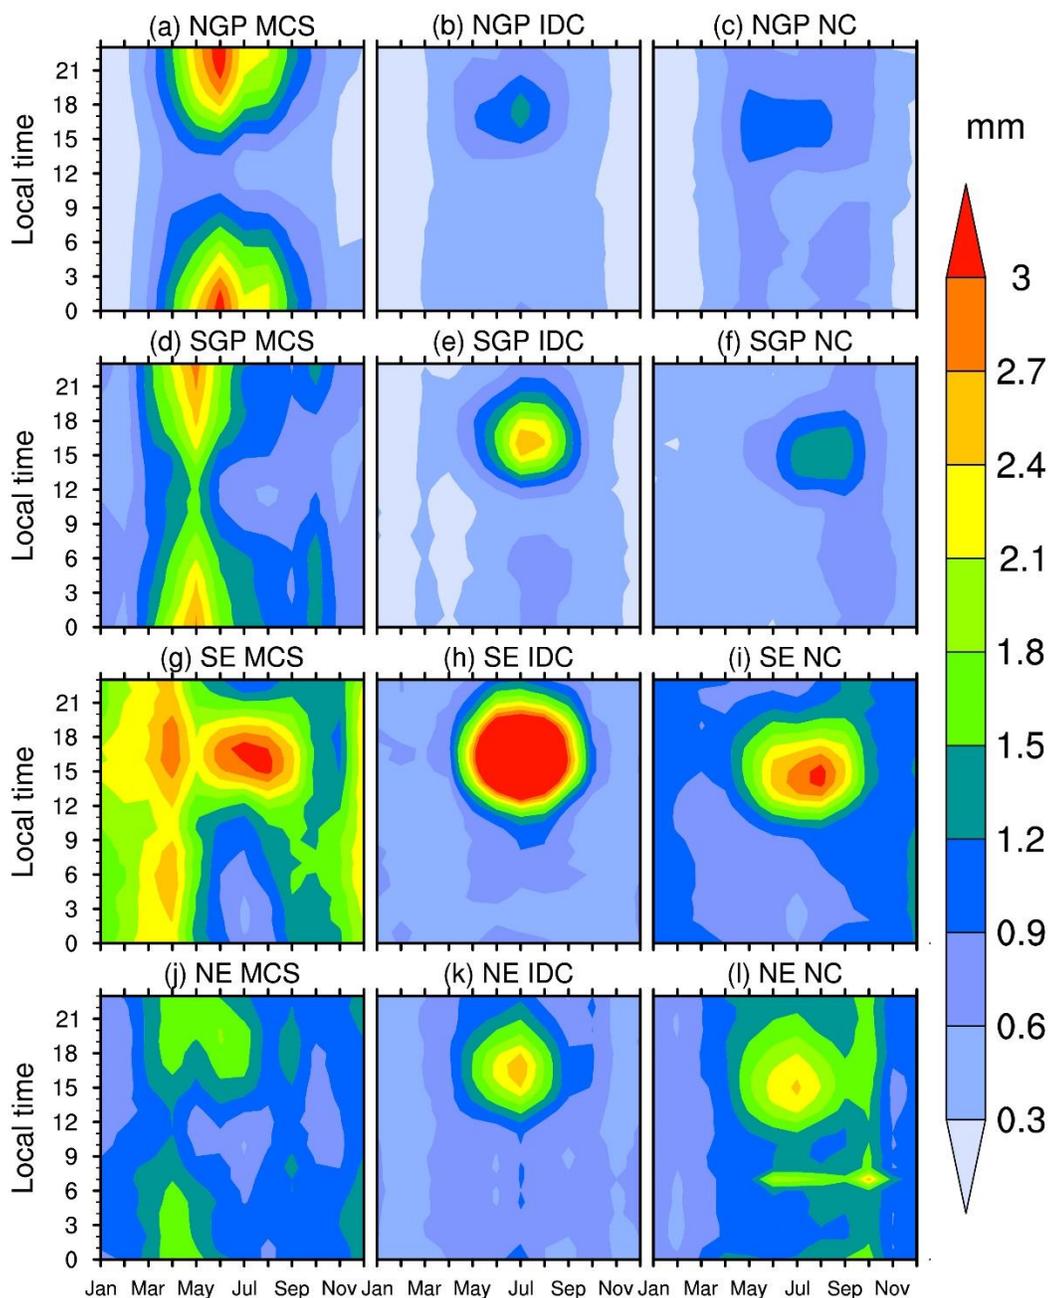

524 Figure 9 shows the monthly mean diurnal cycles of precipitation amounts from MCSs,
525 IDC, and NC in the NGP, SGP, SE, and NE, respectively. Generally, MCS precipitation peaks
526 during nighttime in the NGP, SGP, and NE. The seasonal shift of the peaks from spring in the
527 SGP to summer in the NGP reflects the northward migration of the MCS precipitation center in
528 the Great Plains (Figures 8e and 8f).

529 The SE has significantly different diurnal cycles of MCS precipitation from other regions.
530 In spring, SE MCS precipitation is mainly located in the western areas (Figure 8e), showing
531 similar diurnal characteristics as the SGP MCS precipitation but with peaks in the early
532 morning and late afternoon (Figures 9d and 9g). Besides, the SGP MCS precipitation peaks in
533 May (Figure 9d), while SE peaks in April (Figure 9g), suggesting that the MCS precipitation
534 center first appears in the western SE regions (Alabama, Mississippi, and Louisiana) in April,
535 and then moves northwards to Arkansas in May. In summer, the SE MCS precipitation diurnal
536 cycles are more like those of IDC (Figures 9g and 9h), peaking in the late afternoon and much
537 different from those in the Great Plains. The significantly different precipitation diurnal

538 variations between the Great Plains and SE were also identified by Haberlie and Ashley (2019).
539 We find that most summer MCS precipitation over the SE occurs near the coastal areas (Figure
540 8f), far from the MCS precipitation center in northern Missouri and Iowa, suggesting either a
541 different MCS genesis mechanism in the SE from those in the SGP and NGP (Feng et al., 2019)
542 or long-duration deep convective systems showing MCS characteristics (Geerts, 1998). In
543 autumn, the SE MCS precipitation peaks in the morning (Figure 9g). The diurnal cycle of MCS
544 precipitation in September shows mixed features of summer and autumn with peaks both in the
545 morning and the afternoon. In winter months, the diurnal cycle of the SE MCS precipitation
546 shifts from the autumn feature to the spring feature, with peaks shifting from the morning to the
547 afternoon. The distinct diurnal cycles of SE MCS precipitation in different seasons in Figure 9g
548 are roughly consistent with the corresponding seasonal diurnal variations of MCS occurrence
549 frequencies from Geerts (1998), where the occurrence time of an MCS was defined as the
550 central time between the initiation and decay of the MCS.

551 The diurnal cycles of IDC precipitation are consistent in all regions (Figures 9b, 9e, 9h,
552 and 9k), peaking in the late afternoon in summer (Tian et al., 2005), again reflecting the impact
553 of local instability driven by the solar forcing on IDC development. NC precipitation (Figures
554 9c, 9f, 9i, and 9l) shows some diurnal cycle characteristics similar to IDC precipitation. It may
555 be caused by the limitation of the temporal resolution of the datasets used in the FLEXTRKR
556 algorithm. Weak IDC events that are shorter than 1 hour could be missed by Gridrad in
557 identifying CCFs, as Gridrad Z_H only considers reflectivities within ± 3.8 minutes of the
558 analysis time. These weak IDC could be aliased to NC precipitation, therefore showing some
559 similar diurnal cycles as IDC. Another possible reason is that the FLEXTRKR algorithm may
560 miss some parts of IDC clouds with $T_b \geq 241$ K, which are then classified as NC, so the NC
561 precipitation exhibits some IDC characteristics.

562 The monthly diurnal cycles of precipitation intensities for MCSs, IDC, and NC are
 563 generally similar among all regions, peaking in the late afternoon and early morning in the
 564 warm season (Figure A8).

565 **Figure 9.** Monthly mean diurnal cycles of precipitation amounts from MCSs (a, d, g, j), IDC (b,
 566 e, h, k), and NC (c, f, i, l) in the NGP (a, b, c), SGP (d, e, f), SE (g, h, i), and NE (j, k, l) during
 567 2004 – 2017.
 568

569 **4 Uncertainties of the data product**

570 4.1 Uncertainties from source datasets

571 The NCEP/ CPP L3 4 km Global Merged IR V1 T_b dataset has been view-angle corrected
572 and re-navigated for parallax (Janowiak et al., 2001) to reduce errors. However, the US
573 continent is covered by two series of geostationary IR satellites (GOES-W and GEOS-E).
574 During the production of the T_b dataset, the value with the smaller zenith angle is adopted when
575 duplicate data are available in a grid pixel. Measurements from different satellites may be
576 inconsistent. Janowiak et al. (2001) suggest this type of inconsistency to be considered minor.

577 For the Gridrad radar dataset, some bad volumes have been removed during the production
578 of Gridrad Z_H . We further filter out potential low-quality observations, scanning artifacts, and
579 non-meteorological echoes from biological scatters and artifacts following the approaches of
580 Homeyer and Bowman (2017). However, there is another source of error from anomalous
581 propagation caused by non-standard refractions of radar signals in the lower atmosphere, which
582 cannot be mitigated during the filtering procedure. Non-standard refractions can result in
583 underestimation or overestimation of the true radar beam altitude, thus affecting the location of
584 radar reflectivity for binning. Estimating the corresponding uncertainties is out of the scope of
585 this study. However, anomalous propagation is typically limited to radar beams traveling long
586 distances in the boundary layer (Homeyer and Bowman, 2017).

587 Stage IV precipitation is a mosaic of precipitation estimates based on a combination of
588 NEXRAD and gauge data from 12 RFCs. Therefore, the errors of Stage IV are from several
589 sources, such as inherent NEXRAD biases, radar quantitative precipitation estimate (QPE)
590 algorithm biases, bad gauge data removal inconsistency among different RFCs, multisensory

591 processing algorithm inconsistency among different RFCs, and mosaicking border
592 discontinuities (Nelson et al., 2016). The most severe errors occur in the western US, where
593 NEXRAD data are limited, and a gauge-only rainfall estimation algorithm is used (Nelson et
594 al., 2016; Smalley et al., 2014). Hence our data product has a geographical focus east of the
595 Rocky Mountains, with the best NEXRAD coverage in the US. After regriding the Stage IV
596 precipitation into our 4-km domain, we further manually filter out certain “erroneous
597 precipitation” hours and set all precipitation in those hours to missing values. “Erroneous
598 precipitation” is defined as sudden appearance and disappearance of a large contiguous area ($>$
599 $4,800 \text{ km}^2$) with intense precipitation ($> 40 \text{ mm h}^{-1}$) (Figure A9), which is physically not
600 possible. There are 40 hours in total in the period 2004 – 2017 containing such “erroneous
601 precipitation.”

602 As the FLEXTRKR algorithm is applied to a combination of three independent types of
603 remote sensing datasets, we identify the most robust MCS/IDC events satisfying all the criteria
604 based on the three datasets. It reduces the potential false classification of tracks as MCSs or
605 IDC based on any single dataset. And to consider the potential error of ERA5 melting level
606 heights, we require $Z_H \geq 45 \text{ dBZ}$ above $(Z_{\text{melt}} + 1) \text{ km}$ for convective classification in the SL3D
607 algorithm (Table A2).

608 4.2 The impact of missing data

609 In the CCS identification step of the FLEXTRKR algorithm, we require the fraction of
610 missing satellite T_b in the domain at each hour to be less than 20%. Otherwise, the hour is
611 excluded from our data product. During 2004 – 2017, we excluded 716 hours with missing
612 satellite T_b data, accounting for less than 0.6% of the total period. The year with the most
613 missing satellite data is 2008, with 206 missing hours (2.3%), followed by 2004 with 154 hours

614 (1.8%). All other years have no more than 57 missing hours. During the link procedure of the
615 FLEXTRKR algorithm, we search the next hour if a missing hour is encountered, as long as the
616 time gap between the two “linked” hours is less than 4 hours. Otherwise, we start new tracks
617 from the next available hour. This method aims to reduce the impact of the missing hours.
618 Considering the high completeness of the satellite T_b data in 2004 – 2017, we conclude that the
619 missing satellite data have little effect on the data product.

620 We show the distribution of the fractions of valid Stage IV precipitation data in 2004 –
621 2017 in Figure A10. The fractions are over 97% for all grid cells of the US in the domain. Most
622 grid cells in the US have less than 2% missing hours, which should have a negligible impact on
623 the data product.

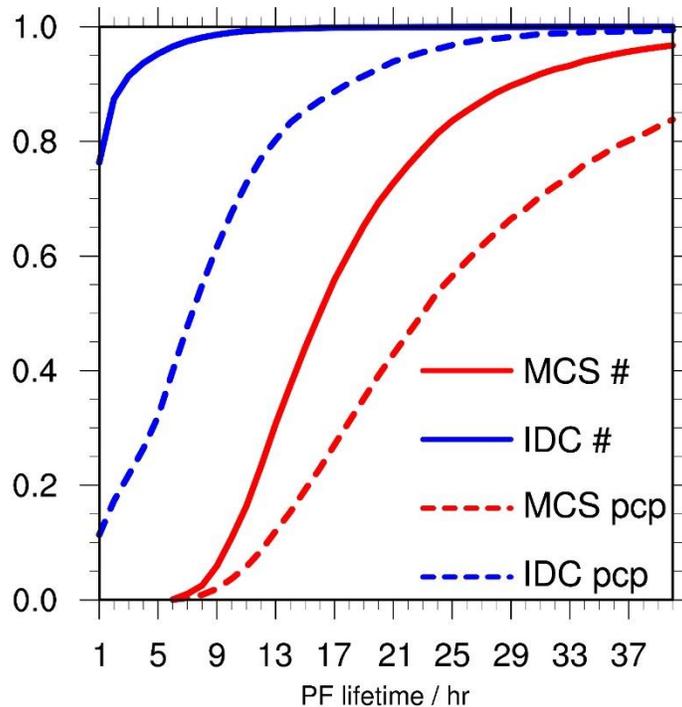

624 Figure A11 shows the fractions of available Gridrad reflectivity data from 2004 to 2017
625 between 1 km and 12 km ASL. The fractions are relatively high over the majority of the
626 troposphere except for 1 km ASL. Based on the criteria of the SL3D algorithm, Z_H at 1 km is
627 rarely used and can be easily substituted by Z_H at 2 km. Generally, Gridrad has good spatial
628 coverage during the period with most grid cells east of the Rocky Mountains having fractions >
629 90% between 2 and 9 km and 80% between 10 and 12 km. The completeness of the Gridrad
630 dataset is relatively lower compared to the satellite T_b and Stage IV precipitation datasets, and
631 Gridrad Z_H is a crucial variable in the SL3D classification and MCS/IDC identification.
632 Therefore, the missing data of Gridrad Z_H should have some impacts on our data product.
633 However, as an advanced long-term high-resolution 3-D radar reflectivity dataset, Gridrad is
634 valuable for constructing a climatological MCS/IDC data product.

635 4.3 Temporal resolution limitation of the source datasets

636 As we discussed in Section 3.2.3, the diurnal cycles of NC precipitation show some
637 possible aliasing from IDC precipitation. Some weak IDC events are so short that the hourly
638 data cannot properly capture their occurrence, especially for Gridrad Z_H , which only includes
639 reflectivities within ± 3.8 minutes of each hour. We calculate the cumulative distribution
640 functions of PF-based lifetimes for MCS and IDC events and their associated precipitation in
641 the data product for 2004 – 2017, as shown in Figure 10. About 75% of IDC events have a PF-
642 based lifetime of 1 hour. Therefore, it is almost certain that we miss some IDC events shorter
643 than 1 hour in the data product. Here we give an estimate of the probability p that a given IDC
644 event with a convective signal duration of x minutes is detected by radar, as expressed below:

$$645 \quad p = \frac{2 \times 3.8}{60 - x} \quad (1)$$

646 where the numerator is the time window of Gridrad observation in each hour, and x is the
647 duration of the IDC event. The detection probability is only about 25% when $x = 30$ minutes.
648 To obtain a detection probability of 50%, we require $x \geq 45$ minutes. Hence, we cannot assess
649 the distribution of IDC convective signals with durations less than 1 hour using the currently
650 available datasets. Higher-resolution datasets, such as individual NEXRAD radar data, which
651 typically has an update cycle of 4-5 min, are necessary to derive the information. However, as
652 shown in Figure 10, we find that precipitation from IDC events with a 1-hour PF lifetime only
653 accounts for about 10% of the total IDC precipitation. Therefore, IDC events with PF lifetimes
654 less than 1 hour should have a relatively small impact on precipitation.

655 **Figure 10.** Cumulative distribution functions of PF-based lifetimes for MCS and IDC events
 656 and their associated precipitation in the data product domain for 2004 – 2017. The red solid line
 657 is for the number of MCSs, the red dash line for MCS associated precipitation, the blue solid
 658 line for the number of IDC events, and the blue dash line for IDC associated precipitation.
 659

660 4.4 The impact of MCS and IDC definition criteria

661 The separation between MCSs and long-lasting IDC events is somewhat fuzzy (Feng et al.,
 662 2019; Geerts et al., 2017; Haberlie and Ashley, 2019; Pinto et al., 2015; Prein et al., 2017).
 663 Here, we briefly examine the impact of different MCS/IDC definition criteria on the data
 664 product. We change the definition of MCSs to relax the CCS and PF size and duration
 665 thresholds. Specifically, the second and third criteria listed in Section 2.2.2 are modified as
 666 follows: 2) CCS areas associated with the track surpass 40,000 km² for more than 4 continuous
 667 hours; 3) PF major axis length exceeding 80 km and intense convective cell areas ≥ 16 km²
 668 exist for more than 3 consecutive hours. And we also require that each merge/split-track
 669 associated with MCS/IDC events must have a CCS-based lifetime of no more than 3 hours. We
 670 keep the definition of IDC the same as described in Section 2.2.2, which is a limit for IDC that
 671 we can identify based on the source datasets.

672 By using the new definition, as expected, the lifetimes and spatial coverages of MCSs are
673 reduced, and those of IDC change little because most IDC events cannot satisfy the new MCS
674 criteria (Tables 1 and A5). The annual number of MCSs identified in 2004 – 2017 increases
675 from 454 to 857. The number increases from 122 to 207 in spring, 212 to 434 in summer, 83 to
676 151 in autumn, and 37 to 62 in winter. As PF-based lifetimes of MCS/IDC events in summer
677 are the shortest (Table 1), the new definition has the most significant impact in summer. The
678 annual number of IDC decreases from 45,346 to 45,225. Reducing the merge/split lifetime limit
679 retains more independent IDC events, which is the reason why the decrease in the number of
680 IDC events is smaller than the increase in the number of MCSs. Annual mean MCS
681 precipitation east of the Rocky Mountains increases from 313 mm to 353 mm, while IDC
682 precipitation decreases from 170 mm to 130 mm. The fraction of MCS precipitation only
683 increases by 6% (from 45% to 51%), compared to the almost doubling of MCS number (from
684 454 to 857), suggesting the MCS definition in the original data product is capable of capturing
685 most of the important MCSs with heavy precipitation. Similar to MCS numbers, summer has
686 the most increase in MCS precipitation amount, from 100 mm to 119 mm. And annual mean
687 MCS and IDC precipitation intensities decrease slightly as MCS precipitation intensities are
688 somewhat larger than IDC in most regions (Tables A3, A4, A6, and A7). We summarize the
689 regional precipitation statistics of the NGP, SGP, SE, and NE based on the new definition in
690 Tables A6 and A7.

691 Although the new definition changes the absolute values of MCS/IDC characteristics, the
692 contrast between MCS and IDC events is still present. The new definition has small impacts on
693 the spatial distribution patterns of MCS/IDC precipitation. And NC precipitation characteristics
694 are almost the same as before. Therefore, our original definition captures the essential
695 characteristics of MCS and IDC events. In addition, the original data product is complete and

696 flexible. We store all criteria variables of MCS/IDC events in the data product. Users can easily
697 change the definition of MCSs and switch between tracks that are attributed to MCS and IDC
698 without re-running the FLEXTRKR algorithm. There is no need to change the “track” and
699 “merge” lifetime criterion as we do above because they have little impact on the climatological
700 characteristics of MCS and IDC events.

701 4.5 Recommendations for the usage of the MCS/IDC data product

702 Considering the limitations and uncertainties mentioned above, we generally recommend
703 using the data product for observational analyses and model evaluations of convection statistics
704 and characteristics over relatively long periods such as a month, a season, or longer to fully take
705 advantage of the long term dataset, although analysis of individual weather events is also
706 possible as supported by the hourly temporal resolution of the data product. In addition, since
707 the completeness and quality of the source radar dataset degrade dramatically beyond the US
708 border and over the Rocky Mountains (Figure A11), we recommend the usage of the data
709 product within the CONUS east of the Rocky Mountains to alleviate the impact of the
710 termination of MCS/IDC tracks due to poor radar coverage and missing radar data beyond their
711 maximum scan range.

712 Detailed investigation of a short period or a specific MCS/IDC event is acceptable, but
713 cautions should be taken when encountering missing data around the track during the period.
714 Due to the complexity of the algorithms used to develop the data product, it is difficult to
715 quantify the impact of missing data on the MCS/IDC track. Therefore, we do not recommend
716 examining a specific MCS/IDC track if there are too many missing data (precipitation, T_b , or
717 Z_H) along the track. Users planning to apply the data product for a specific case study should
718 examine the availability of the source data first, which are also stored in the data product except

719 for 3-D Z_H due to the large data volume. Users can access the original 3-D Z_H at
720 <https://rda.ucar.edu/datasets/ds841.0/> (Table A1).

721 Lastly, although our sensitivity test in Section 4.4 shows that precipitation characteristics
722 are similar between two different sets of MCS/IDC definition criteria, we still recommend users
723 conduct further sensitivity tests and examine the impact of different definition criteria on the
724 results if the data product is applied to other studies, such as the effects of MCS and IDC events
725 on atmospheric circulation, environmental conditions associated with the initiation and
726 evolution of MCS and IDC events, and MCS/IDC associated weather hazards.

727 **5 Data availability**

728 The high-resolution (4 km hourly) MCS/IDC data product and the corresponding user
729 guide document are available at <http://dx.doi.org/10.25584/1632005> (Li et al., 2020). The
730 original format of the data files is NetCDF-4, and we archive them as compressed files for each
731 year so that the data product is easily accessible. The user guide contains a brief explanation
732 about the approach to develop the data product and a detailed description of the data file content
733 to help users understand the data product.

734 **6 Conclusions**

735 Here we present a unified high-resolution (4 km, hourly) data product that describes the
736 spatiotemporal characteristics of MCS and IDC events from 2004 to 2017 east of the Rocky
737 Mountains over the CONUS. We produce the data product by applying an updated FLEXTRKR
738 algorithm to the NCEP/CPM L3 4 km Global Merged IR V1 T_b dataset, ERA5 melting level
739 heights, the 3-D Gridrad radar reflectivity dataset, and the Stage IV precipitation dataset.
740 Climatological features of the MCS and IDC events from the data product are compared, with a

741 focus on their precipitation characteristics. Consistent with our definitions of MCSs and IDC in
742 the FLEXTRKR algorithm, we find that MCSs have much broader spatial coverage and longer
743 duration than IDC events. While there are many more frequent IDC occurrences than MCSs,
744 the mean convective intensities of IDC events are comparable to those of MCSs. MCS and IDC
745 events both contribute significantly to precipitation east of the Rocky Mountains but with
746 distinct spatiotemporal variabilities. MCS precipitation affects most regions of the eastern US in
747 all seasons, especially in spring and summer. The MCS precipitation center migrates
748 northwards from Arkansas in spring to northern Missouri and Iowa in summer, followed by a
749 southward migration to Louisiana in autumn, and finally to Mississippi and Alabama in the
750 Southeast in winter. IDC precipitation mostly concentrates in the Southeast in summer. IDC
751 precipitation shows a significant diurnal cycle in summer months with a peak around 16:00 –
752 17:00 Local Time over all regions east of the Rocky Mountains. In contrast, MCS precipitation
753 peaks during nighttime in spring and summer for most regions except for the Southeast, where
754 MCS precipitation peaks in the late afternoon in summer, similar to IDC precipitation. Lastly,
755 we analyze the potential uncertainties of the data product and the sensitivity of the dataset to
756 MCS definitions and give our recommendations for the usage of the data product. The data
757 product will be useful for investigating the atmospheric environments and physical processes
758 associated with convective systems, quantifying the impacts of convection on hydrology,
759 atmospheric chemistry, severe weather hazards, and other aspects of the energy, water, and
760 biogeochemical cycles, and improving the representation of convective processes in weather
761 and climate models.

Table A2. The classification criteria of the Storm Labeling in Three Dimensions (SL3D) algorithm in this study

SL3D category	Criteria
convective	$Z_H^1 = 25$ dBZ echo-top height ≥ 10 km; or $Z_H \geq 45$ dBZ above $(Z_{\text{melt}}^2 + 1)$ km; or Z_H peakedness ³ exceeding thresholds ⁴ in at least 30% of the echo column between surface and 9 km. After the above filtering, exclude isolated convective grid points. Finally, grid points that have $Z_{\text{Hmax}}^5 \geq 25$ dBZ and are immediately adjacent to other convective grid points are classified as convective.
precipitating stratiform	$Z_H \geq 20$ dBZ at 3 km; or $Z_H \geq 10$ dBZ at 1 km or 2 km
non-precipitating stratiform	no echo or $Z_H < 20$ dBZ at 3 km, and echo presents above 3 km. If no echo at 3 km – 5 km, but echo presents above 5 km, classified as an anvil.
anvil	No echo at 3 km – 5 km, but echo presents above 5 km
convective updraft	convective grid points satisfy: (1) $Z_{\text{Hmax}} \geq 40$ dBZ, and (2) $\frac{\partial Z_H}{\partial z} \geq 8$ dBZ km^{-1} with echoes in at least six of eight horizontally adjacent grid volumes presents between the surface and 7 km.

766

¹ Z_H : logarithmic radar reflectivity.

767

² Z_{melt} : melting level height. If temperatures at different vertical levels within a grid column are all below zero, there is no melting level. In this

768

situation, we set $Z_{\text{melt}} = -2$.

769

³ Peakedness is the difference between the Z_H of the grid point being evaluated and the median Z_H of a horizontal 12-km radius around the point.

770

$${}^4 \text{ threshold} = \max \left(4.0 \text{ dBZ}, 10.0 - \frac{Z_H^2}{337.5} \text{ dBZ} \right).$$

771

⁵ Z_{Hmax} denotes column max reflectivity.

772

 804 **Figure A5.** Annual mean monthly diurnal cycles of initiated MCS (left panel) and IDC (right
 805 panel) numbers in the data product domain for 2004 – 2017. Here, we define that an MCS or
 806 IDC event initiates when the first PF appears. Therefore, we can derive the initiated time of all
 807 MCS and IDC events, which is the basis of this figure. For example, on average, more than 7
 808 MCSs initiated at 14:00 Local Time every June between 2004 and 2017.
 809

810 **Figure A6.** Distributions of the fractions of different types of precipitation in each season. Here, precipitation refers to annual
 811 mean seasonal amounts for 2004 – 2017. We exclude hourly data with precipitation $\leq 1 \text{ mm h}^{-1}$ in the calculation. The first row
 812 is for total precipitation, the second for MCS precipitation, the third for IDC precipitation, and the fourth for NC precipitation.
 813 The first column shows spring precipitation, the second for summer, the third for autumn, and the fourth for winter.
 814
 815

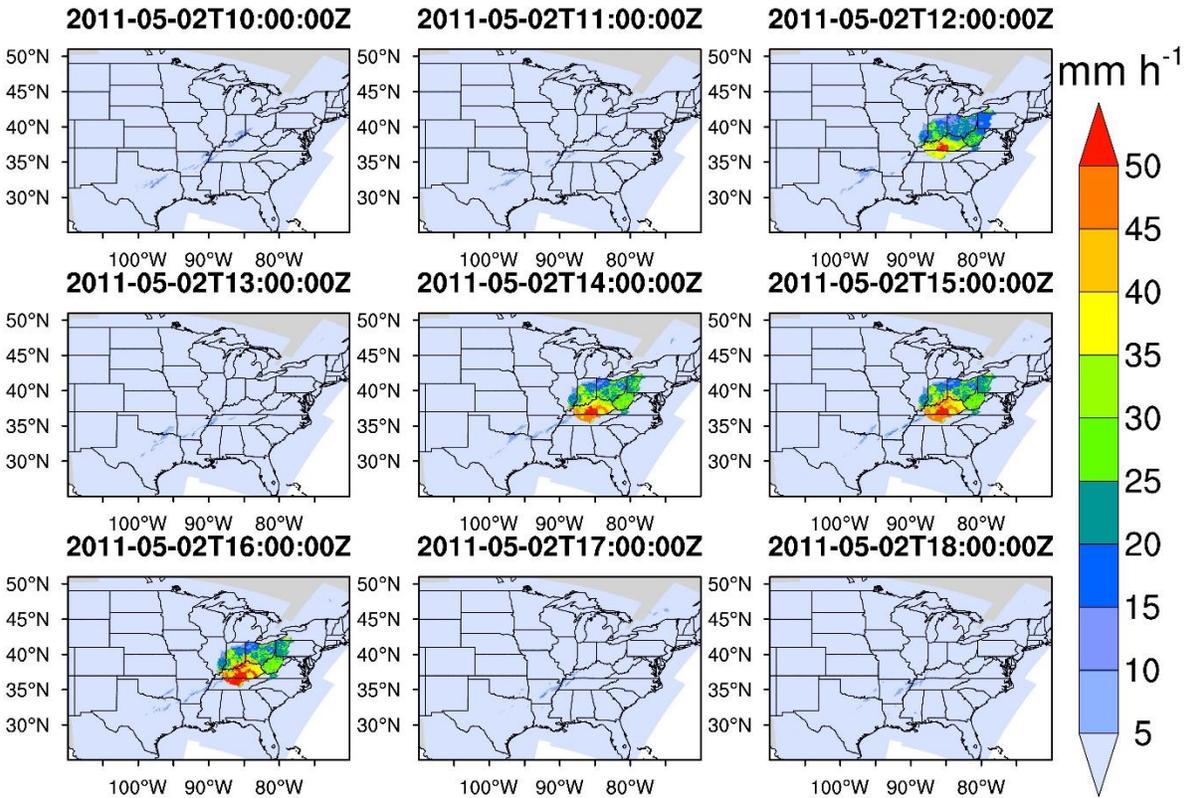

816 **Figure A7.** Distributions of annual mean seasonal precipitation intensities for different types of precipitation for 2004 – 2017.
 817 The first row is for total precipitation, the second for MCS precipitation, the third for IDC precipitation, and the fourth for NC
 818 precipitation. The first column shows spring precipitation, the second for summer, the third for autumn, and the fourth for
 819 winter. We exclude hourly data with precipitation $\leq 1 \text{ mm h}^{-1}$ in the calculation.
 820

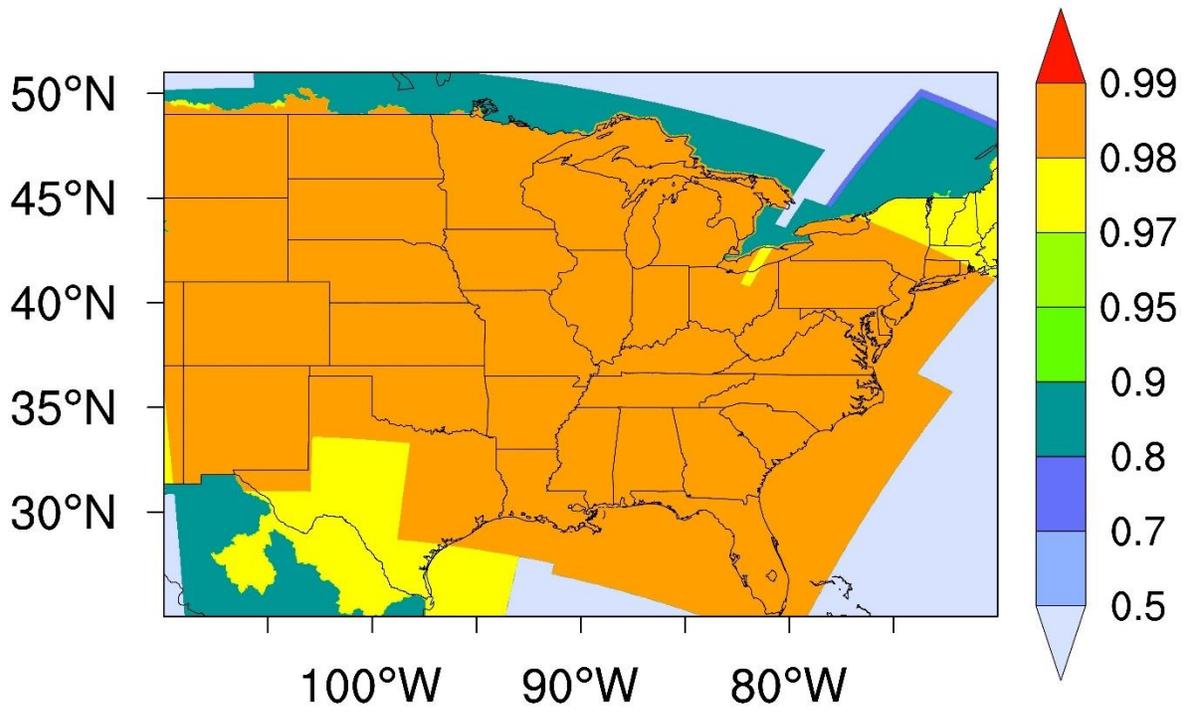

821
822
823
824
825

Figure A8. Monthly mean diurnal cycles of precipitation intensities for MCSs (a, d, g, j), IDC (b, e, h, k), and NC (c, f, i, l) in the NGP (a, b, c), SGP (d, e, f), SE (g, h, i), and NE (j, k, l) during 2004 – 2017.

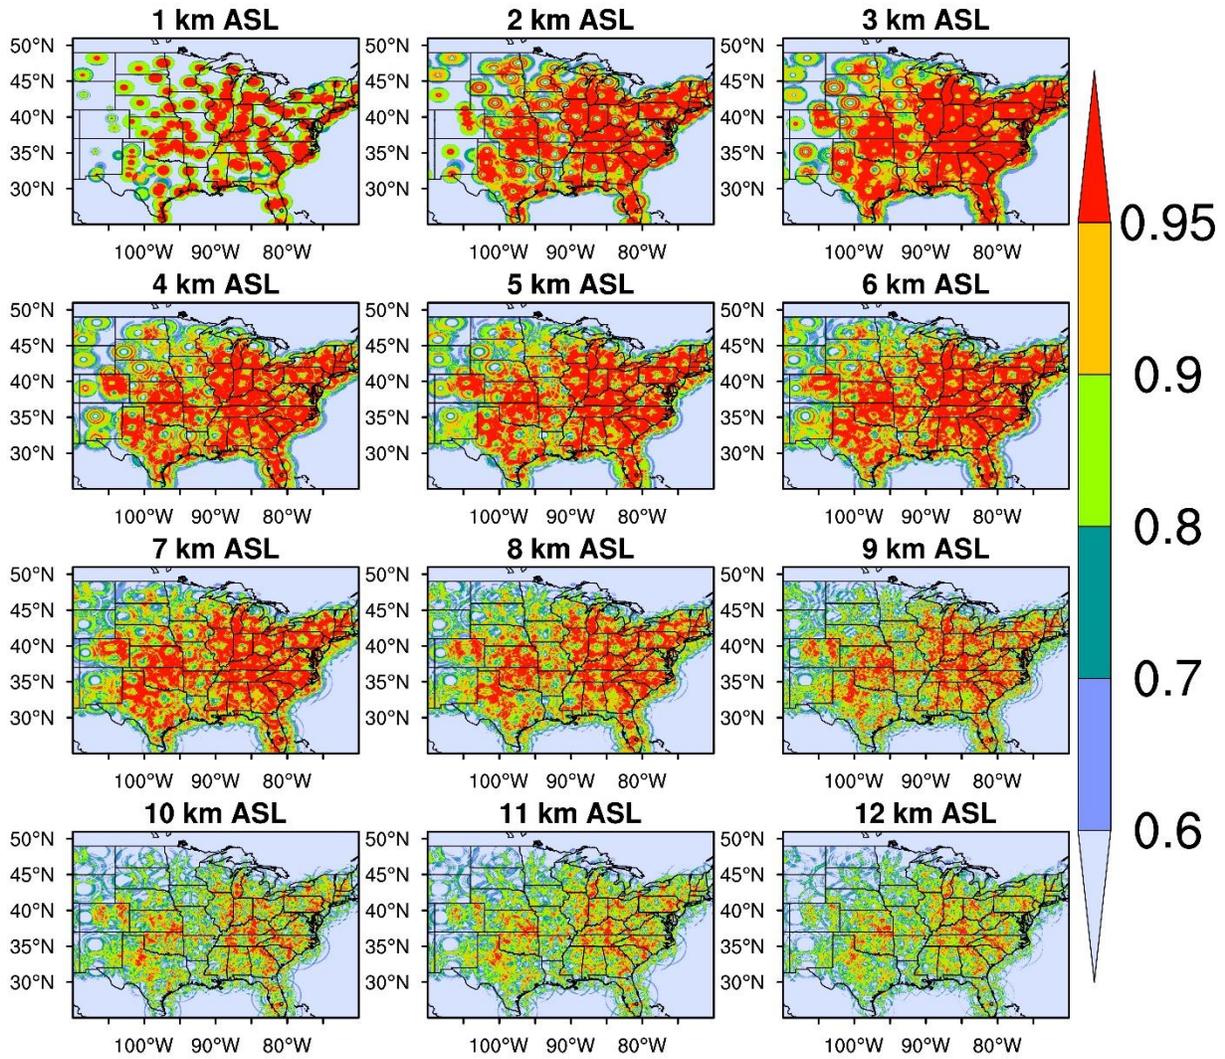

826
 827
 828
 829
 830
 831

Figure A9. An example of Stage IV erroneous precipitation. Stage IV shows a large area of intense precipitation suddenly appearing at 2011-05-02T12:00:00Z, which then unexpectedly disappears at 13:00:00Z, comes back abruptly at 14:00:00Z, and finally goes away immediately at 17:00:00Z.

832
 833
 834
 835
 836

Figure A10. Distribution of the fraction of valid Stage IV precipitation data for 2004 – 2017. Here, “valid” means that precipitation data are available and reasonable. The erroneous precipitation discussed in Section 4.1 is unreasonable and invalid.

837
 838 **Figure A11.** Distributions of the fractions of available radar reflectivity data for 2004 – 2017 at
 839 different vertical levels. As long as radars scan a grid cell, we think of it as “available” even
 840 though there is no echo.

841 **Author contributions**

842 JL and ZF updated the FLEXTRKR algorithm and prepared the source datasets. JL ran the SL3D
843 and updated FLEXTRKR algorithms for 2004 – 2017. JL collected and archived the MCS/IDC
844 data product and did the analyses. JL led the writing of the manuscript with input from ZF, YQ,
845 and LRL. YQ and LRL guided the development of the data product. JL, ZF, YQ, and LRL
846 reviewed the manuscript.

847 **Competing interests**

848 The authors declare that they have no conflict of interest.

849 **Acknowledgments**

850 This research was supported by the US Department of Energy Office of Science Biological and
851 Environmental Research as part of the Regional and Global Modeling and Analysis (RGMA)
852 program area through the Integrated Coastal Modeling (ICoM) project. LRL and ZF were also
853 partly supported by the Water Cycle and Climate Extremes Modeling (WACCEM) Scientific
854 Focus Area funded by RGMA. The research used computational resources from the National
855 Energy Research Scientific Computing Center (NERSC), a DOE User Facility supported by the
856 Office of Science under Contract DE-AC02-05CH11231. PNNL is operated for DOE by Battelle
857 Memorial Institute under Contract DE-AC05-76RL01830. We thank Dr. Cameron R. Homeyer
858 from the University of Oklahoma for helping us understand the Gridrad dataset and Dr. Jingyu
859 Wang from PNNL for identifying the existence of erroneous Stage IV precipitation. We obtain
860 the NCEP/CPM L3 half-hourly 4 km Global Merged IR V1 brightness temperature dataset from
861 https://disc.gsfc.nasa.gov/datasets/GPM_MERGIR_1/summary (last access: Dec 28, 2019). The

862 3D Gridrad dataset is from <https://rda.ucar.edu/datasets/ds841.0/> (last access: Jan 2, 2020). We
863 download hourly Stage IV precipitation data from <https://rda.ucar.edu/datasets/ds507.5/> (last
864 access: Dec 28, 2019), and the ERA5 melting level height data was downloaded from
865 <https://doi.org/10.24381/cds.adbb2d47> (last access: Jan 24, 2020).
