Abstract: Probabilistic methods are very useful to estimate the uncertainty in spatial variability in meteorological conditions-fields (e.g., the uncertainty in spatial patterns of precipitation and temperature across large domains). In ensemble probabilistic methods, "equally plausible" ensemble members are used to approximate the probability distribution, hence the uncertainty, of a spatially distributed meteorological variable conditioned on the available information. The ensemble members can be used to evaluate the impact of the uncertainties in spatial meteorological fields for a myriad of applications. This study develops the Ensemble Meteorological Dataset for North America (EMDNA). EMDNA has 100 ensemble members with daily precipitation amount, mean daily temperature, and daily temperature range at 0.1° spatial resolution (approx. 10-km grids) from 1979 to 2018, derived from a fusion of station observations and reanalysis model outputs. The station data used in EMDNA are from a serially complete dataset for North America (SCDNA) that fills gaps in precipitation and temperature measurements using multiple strategies. Outputs from three reanalysis products are regridded, corrected, and merged using the Bayesian Model Averaging. Optimal Interpolation (OI) is used to merge station- and reanalysis-based estimates. EMDNA estimates are generated based using spatiotemporally correlated random fields on to sample from the OI estimates and spatiotemporally correlated random fields. Evaluation results show that (1) the merged reanalysis estimates outperform raw reanalysis estimates, particularly in high latitudes and mountainous regions; (2) the OI estimates are more accurate than the reanalysis and station-based regression estimates, with the most notable improvements for precipitation occurring evident in sparsely gauged regions; and (3) EMDNA estimates exhibit good performance according to the diagrams and metrics used for probabilistic evaluation. We also discuss the limitations of the current framework and highlight that persistent efforts arefurther research is needed to further develop probabilistic methods and improve ensemble meteorological datasets. Overall, EMDNA is expected to be useful for hydrological and meteorological applications

- 35 in North America. The whole entire dataset and a teaser dataset (a small subset of EMDNA for easy download and
- preview) are available at https://doi.org/10.20383/101.0275 (Tang et al., 2020a).

Precipitation and temperature data are fundamental <u>meteorological inputs variables</u> for a wide variety of geoscientific and operational applications benefitting society (Eischeid et al., 2000; Trenberth et al., 2003; Wu et al., 2014; Yin et al., 2018). Accurately estimating spatial meteorological fields is still challenging despite the availability of many measurement/<u>estimation</u> approaches (e.g., meteorological stations, weather radars, and satellite sensors) and <u>the availability of many</u> atmospheric models (Kirstetter et al., 2015; Sun et al., 2018; Hu et al., 2019; Newman et al., 2019a). There is consequently substantial uncertainty in analyses of spatially distributed meteorological variables.

The uncertainty in spatial meteorological estimates depends on both the measurements available and the climate of the region of study. Whilst meteorological stations provide the most reliable observations at the point scale, spatial meteorological estimates based on station data can be degraded by uncertain because of both the sparseity of station networks in remote regions and by because of measurement errors caused by factors such as evaporation/wetting loss and under-catch of precipitation (Sevruk, 1984; Goodison et al., 1998; Nešpor and Sevruk, 1999; Yang et al., 2005; Scaff et al., 2015; Kochendorfer et al., 2018). Interpolating station data to a regular grid can introduce additional uncertainties, especially in regions where there are strong spatial gradients in meteorological fields due to factors such as method choices and topographic variations. The accuracy of precipitation estimated from ground radars is affected by factors such as beam blockage, signal attenuation, ground clutter, and uncertainties in the representativeness of radar variables to surface rainfall reflectivity rainfall relationships (Dinku et al., 2002; Kirstetter et al., 2015). Moreover, the spatial and temporal coverage of ground radars is limited to large populated areas in most regions of the world. Satellite sensors provide quasi-global estimates of meteorological variables, but their utility can be limited by short sampling periods with insufficient coverage and return frequency, data latency, indirect measurements, imperfect retrieval algorithms, and instrument limitations (Adler et al., 2017; Tang et al., 2016, 2020b). Reanalysis models, which provide long-term global simulations, also contain biases and uncertainties caused by the imperfect model representations of physical processes, observational constraints, and the model resolution, and model parameterization (Donat et al., 2014; Parker, 2016).

In recent years, numerous deterministic gridded precipitation and temperature datasets based on observed or simulated data from single or multiple sources have become <u>publicly</u> available to the <u>public</u> (Maurer et al., 2002; Huffman et al., 2007; Mahfouf et al., 2007; Daly et al., 2008; Di Luzio et al., 2008; Haylock et al., 2008; Livneh et al., 2013; Weedon et al., 2014; Fick and Hijmans, 2017; Beck et al., 2019; Ma et al., 2020; Harris et al., 2020). Since the uncertainties vary in space and time, deterministic products do not always agree with each other (Donat et al., 2014; Henn et al., 2018; Sun et al., 2018; Newman et al., 2019a; Tang et al., 2020b). The uncertainties can be propagated to applications such as hydrological modeling and climate analysis (Clark et al., 2006; Hong et al., 2006; Slater and Clark, 2006; Mears et al., 2011; Rodell et al., 2015; Aalto et al., 2016). Proper understanding of the uncertainties can benefit the objective application of meteorological analyses and further improve existing products, yet few gridded datasets provide such uncertainty estimates (Cornes et al., 2018; Frei and Isotta, 2019).

Probabilistic datasets now can provide alternatives to deterministic datasets for quantitative precipitation and temperature estimation and have advantages in estimating uncertainties and representing extremes (Kirstetter et al., 2015; Mendoza et al., 2017; Frei and Isotta, 2019). Recently, several ensemble meteorological datasets have become available. For example, Morice et al. (2012) develop the observation-based HadCRUT4 global temperature datasets with 100 members. Caillouet et al. (2019) develop the Spatially COherent Probabilistic Extended Climate dataset (SCOPE Climate) with 25 members in France. Newman et al. (2015, 2019b, 2020) continually extend the probabilistic estimation methodology proposed by Clark and Slater (2006), and produce ensemble precipitation and temperature datasets in the contiguous USA (CONUS), the Hawaii Islands, and Alaska and Yukon, respectively. Moreover, several widely used deterministic datasets now have ensemble versions in view of the advantages of probabilistic estimates. Cornes et al. (2018) developed the ensemble version (100 members) of the Haylock et al. (2008) Europe-wide E-OBS temperature and precipitation datasets. Khedhaouiria et al. (2020) developed the experimental High-Resolution Ensemble Precipitation Analysis (HREPA) for Canada and the northern part of the CONUS with 24 members, which can be regarded as an experimental ensemble version of the Canadian Precipitation Analysis (CaPA; Mahfouf et al., 2007; Fortin et al., 2015).

- Our objective is to develop an Ensemble Meteorological Dataset for North America (EMDNA) from 1979 to 2018.
- 86 To improve the quality of estimates in sparsely gauged regions, station data and reanalysis outputs are merged to
- 87 generate gridded precipitation and temperature estimates. Then, ensemble estimates are produced using the
- 88 probabilistic method described by Clark and Slater (2006) and Newman et al. (2015, 2019b, 2020). EMDNA has 100
- 89 members and contains daily precipitation amount, mean daily temperature (Tmean), and daily temperature range
- 90 (Trange) at 0.1° spatial resolution. Minimum and maximum temperature can be calculated from Tmean and Trange.
- 91 It is expected that the EMDNA will be useful for a variety of applications in North America.

2. Datasets

Station observations are often havesubject to temporal discontinuities caused by missing values and short record lengths_(Kemp et al., 1983). This study uses station precipitation and minimum/maximum temperature data from the Serially Complete Dataset for North America_(SCDNA; (Tang et al., 2020c), which is open-access on Zenodo (https://doi.org/10.5281/zenodo.3735533; Access Date: July 25, 2020). Serially complete datasets equild-improve the quality of spatial interpolation estimates compared to raw station observations with data gaps (Longman et al., 2020; Tang et al., 2021). Thean and Trange are calculated from minimum and maximum temperature data. In SCDNA, raw measurements undergo strict quality control checks, and data gaps are filled by combining estimates from multiple strategies (including quantile mapping, spatial interpolation, machine learning, and multi-strategy merging). SCDNA uses reanalysis estimates as the auxiliary data to ensure temporal completeness in sparsely gauged regions. The production of SCDNA has nine steps: (1) matching reanalysis estimates and station data, (2) selecting qualified neighboring stations, (3) building empirical cumulative density functions (CDFs), (4) estimation based on 16 strategies for each day of year, (5) independent validation, (6) merging estimates from the 16 strategies, (7), climatological bias correction, (8) evaluation of SCDNA, and (9) final quality control (Tang et al., 2020c). -SCDNA covers the period

from 1979 to 2018 and has 24₂615 precipitation stations and 19₂579 temperature stations. We select precipitation and temperature because they are used in many hydrometeorological studies and are measured by a large number of meteorological stations, while other variables (e.g., humidity and wind speed) are only measured by a much smaller collection of stations.

Station-based gridded meteorological estimates usually rely on a certain number of neighboring stations surrounding the target grid celllocation. For most regions in CONUS, the search radius to find 20 or 30 neighboring stations (lower and upper limits for station-based gridded estimates in Sect. 3.1) is smaller than 100 km (Fig. 1). For the regions northern north of to 50°N or southern south ofto 20°N, however, the search radius required to find 20 or 30 neighboring stations is much larger, and even exceeds 1,000 km in the Arctic Archipelago. The sparse station network at higher latitudes motivates our decision to optimally combine station data with reanalysis products.

The reanalysis products used in this study include the fifth generation of European Centre for Medium-Range Weather Forecasts (ECMWF) atmospheric reanalyses of the global climate (ERA5; Hersbach et al., 2020), the Modern-Era Retrospective analysis for Research and Applications, Version 2 (MERRA-2; Gelaro et al., 2017), and the Japanese 55-year Reanalysis (JRA-55; Kobayashi et al., 2015). The three widely used products are chosen because of their high spatiotemporal resolutions and suitable time length. The spatial resolutions of ERA5, MERRA-2, and JRA-55 are 0.25°×0.25°, 0.5°×0.625°, and ~55 km, respectively. Their start years are 1979, 1980, and 1958, respectively. Therefore, only ERA5 and JRA-55 are used for 1979 throughout this study. Although reanalysis models assimilate observations from various sources, they differ with station measurements in many aspects (Parker, 2016) and often contain large uncertainties as shown by assessment and multi-source merging studies (e.g., Donat et al., 2014; Lader et al., 2016; Beck et al., 2017, 2019; Tang et al., 2020b). We suppose It is possible The dependence between of reanalysis estimates and on station data may have a negative effect on the merging of reanalysis products (Section 3.2) because station-based weight calculation could be imperfect (e.g., favourable to the reanalysis dataset which assimilates more station data and assigns higher weights to observations could be given higher weight). The potential dependence, however, is not considered in this study Thereby, the possible dependence between reanalysis estimates and station data-because of the limited understanding of the dependence between reanalysis estimates and station observationsis not considered when merging them in this study. Moreover, none of the reanalysis datasets assimilate precipitation data from stations.

The elevation data are sourced from the 3 arc-second resolution Multi-Error-Removed Improved-Terrain digital elevation model (MERIT DEM; Yamazaki et al., 2017).

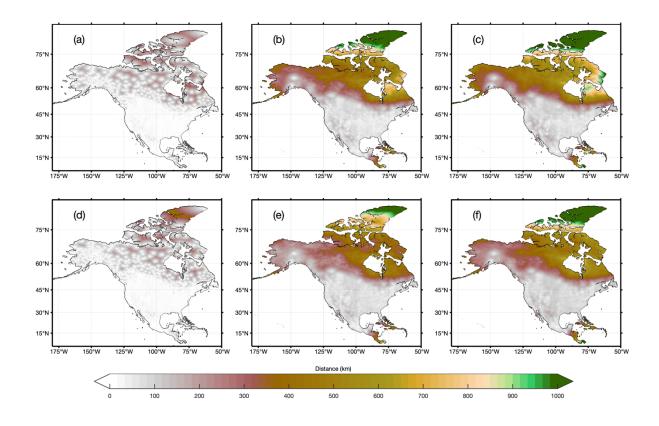

Figure 1. The color of each 0.1° grid indicates the radial radius to find (a) one, (b) 20, and (c) 30 neighboring stations for precipitation (a-c) and temperature (d-f).

3. Methodology

The estimate of a variable at a specific location and time step can be regarded as a random value following a probability distribution. The probability density functions (PDFs) of variables such as the Tmean and Trange, can be approximated using the normal distribution. Their value x for the a target location and time step is expressed as:

$$x \sim N(\mu, \sigma^2) \tag{1}$$

where μ is the mean value and σ is the standard deviation. The <u>pP</u>robabilistic estimat<u>esion</u> of Tmean <u>and or</u> Trange can be realized by sampling from this distribution. In a spatial meteorological dataset, the distribution parameters vary with space and time, and the <u>spatial</u> variability is related to the nature of variables and gridding (interpolation) methods. The performance of gridding methods is critical because accurate estimation of μ can reduce systematic bias and smaller σ means narrower spread.

Precipitation is different from Tmean and Trange because it can be intermittent from local to synoptic scales and its distribution is both highly skewed and bounded at zero. Following Papalexiou (2018) and Newman et al. (2019b), the cumulative density function (CDF) CDF of precipitation can be expressed as below:

$$F_X(x) = (1 - p_0)F_{X|X>0}(x) + p_0, \text{ for } x \ge 0$$
(2)

where $F_X(x)$ is the CDF for $x \ge 0$, $F_{X|X>0}(x)$ is the CDF for x > 0, and p_0 is the probability of zero precipitation. The probability of precipitation (PoP) is $1 - p_0$. The CDF $F_{X|X>0}(x)$ is often approximated using the normal distribution after applying suitable transformation functions to observed precipitation. Clark and Slater (2006) perform the normal quantile transformation using an empirical CDF from station observations. Newman et al. (2015) apply a power-law transformation. Newman et al. (2019b) adopts the Box-Cox transformation, that is,

$$x' = \frac{x^{\lambda} - 1}{\lambda} \tag{3}$$

where λ is set to 1/3 following Newman et al. (2019b) and Fortin et al. (2015). Eq. (1) applies to x', enabling the probabilistic estimation of precipitation. Unlike Newman et al. (2019b) that uses transformed precipitation throughout the production, this study only uses Box-Cox transformation when the assumption of normality is necessary (Sect. 3.2.4 and 3.3) to reduce the error introduced by the back transformation. The limitations and alternative choices of precipitation transformation are discussed in Sect. 5.2.

In summary, seven space- and time-varying parameters (μ and σ for three variables and PoP) should be obtained to realize probabilistic estimation. Our method to develop probabilistic meteorological estimates is summarized in Fig. 2a. We apply four main steps to produce EMDNA: (1) station-based regression estimates (Sect. 3.1), (2) the regridding, downscaling, bias correction and merging of three reanalysis products (Sect. 3.2), (3) optimal interpolation-based merging of reanalysis and station-based regression outputs, and the bias correction of the resulting precipitation estimates (Sect. 3.3), and (4) the production of probabilistic estimates in the form of spatial meteorological ensembles (Sect. 3.4).

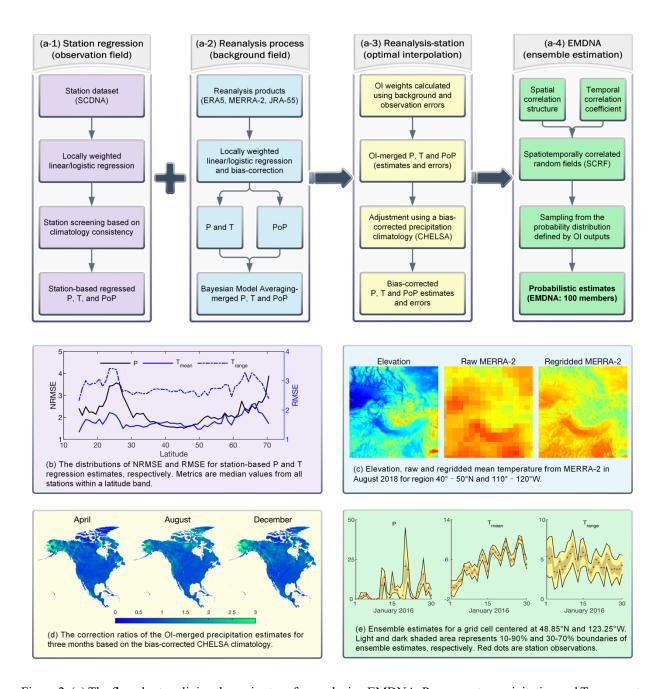

Figure 2. (a) The flowchart outlining the main steps for producing EMDNA. P represents precipitation and T represents temperature. (b-e) demonstrate output examples from (a-1 to -4), respectively. (b) Latitudinal distribution of the root mean square error (RMSE) for temperature and normalized RMSE (NRMSE) for precipitation (Sect. 3.1). (c) Example showing the mean temperature of MERRA-2 before and after regridding (Sect. 3.2). (d) The correction ratios calculated using precipitation climatology from the bias-corrected CHELSA (Sect. 3.3). (e) Example of the ensemble-based distributions of precipitation and temperature estimates from EMDNA (Sect. 3.4).

3.1 Regression estimates from station data

Clark and Slater (2006) and Newman et al. (2015, 2019b) use locally weighted linear regression and logistic regression to obtain gridded precipitation and temperature and gridded precipitation estimates which are used as parameters in Eq. (1). However, for high-latitude regions in North America where stations are scarce (Fig.1), such gridded estimates based only on station data could contain large uncertainties (Fig. 2b) due to the long distances needed to assemble a sufficient sample of stations to form the regressions. This study uses optimal interpolation (OI) to merge data from stations and reanalysis models. In this section, we only obtain regression estimates and their errors at the locations of stations, which are used as inputs to OI in Sect. 3.3.

3.1.1 Locally weighted linear regression

Daily precipitation amount, Tmean and Trange are estimated for all stations based on the locally weighted linear regression (also known as the geographically weighted regression). Let x_o be the station observation for variable X (precipitation, Tmean, and Trange), the regression estimate \hat{x} for the target point and time step is obtained as below:

$$x_o = \hat{x} + \varepsilon = \beta_0 + \sum_{i=1}^n A_i \beta_i + \varepsilon \tag{4}$$

where A_i is the *i*th time-invariant <u>topographic</u> attribute (or predictor variables), β_0 and β_i are regression coefficients estimated using ordinary least squares, and ε is the residual (or error term). The <u>topographic</u> attributes are latitude, longitude, and elevation for Tmean and Trange. For precipitation, two more <u>topographic</u> attributes (west-east and south-north slopes) are used to account for windward and leeward slope precipitation differences. An isotropic Gaussian low-pass filter is used to smooth DEM before calculating slopes, which can reduce the influence of noise in a high-resolution DEM on the large-scale topographic effect of precipitation (Newman et al., 2015). Ideally the scale of this smoothing reflects the scale at which terrain most directly influences precipitation or temperature spatial patterns; in this case the filter bandwidth is 180 km.

For a target station point, \hat{x} is obtained based on data from neighboring stations. Newman et al. (2015, 2019b) used 30 neighboring stations, without controlling for maximum station distance. The very low station density in high-latitude regions makes this configuration infeasible, hence this study adopts a relatively flexible criterion for selecting neighboring stations: (1) finding at most 30 stations within a fixed search radius (400 km), and (2) if fewer than 20 stations are found, extending the search radius until 20 stations are found. The least number lower threshold is set to 20 to ensure that linear/logistic regression is robust. To incorporate local dependence, a tricube weighting function is used to calculate the weight $w_{i,j}$ between the target station i and the neighboring station j.

$$w_{i,j} = \left[1 - \left(\frac{d_{i,j}}{d_{max}}\right)^3\right]^3 \tag{5}$$

where $d_{i,j}$ is the distance between i and j, and d_{max} depends on the maximum distance $(d_{i,j}^{max})$ between i and all its neighboring stations. If $d_{i,j}^{max}$ is smaller than 100 km, d_{max} is set to 100 km; otherwise, d_{max} is set to $d_{i,j}^{max} + 1$ km

- 204 (Newman et al., 2015, 2019b). The cubic weight function is smoother compared to functions such as exponential
 205 functions and inverse distance functions, indicating that $w_{i,j}$ degrades with distance in a relatively slow way which
 206 generally leads to smooth spatial variations of variables. The comparison of different weight functions could be a
- 207 <u>direction for future studyresearch-direction.</u> Regression coefficients are estimated by weighted least squares method
- 208 (described in in-Appendix A).
- We found that a small number of observations stations show a climatology that is notably statistically different from
- surrounding stations, which could cause an adverse effect on gridded estimates, particularly in sparsely gauged regions.
- 211 Strategies are designed to identify and exclude such stations are summarized in (Appendix B).

212 3.1.2 Locally weighted logistic regression

- PoP is estimated using the locally weighted logistic regression by fitting binary precipitation occurrence to spatial
- 214 topographic attributes:

$$PoP = \frac{1}{1 + \exp(-\beta_0 + \sum_{i=1}^{n} A_i \beta_i)}$$
 (6)

- The topographic attributes (A_i) are the same as those used by precipitation regression. Appendix A describes the
- 216 <u>method to estimate rRegression coefficients are estimated in Appendix A.</u>
- The errors of precipitation, temperature, and PoP estimates for all stations are calculated as the difference between
- regression estimates and station observations using the leave-one-out cross-validation procedure (also known as the
- 219 <u>jackknife procedure</u>). The leave-one-out evaluation could be affected by the distributions of stations in some cases.
- For example, two stations with very close distance may both show very high accuracy in the leave-one-out evaluation,
- which is actually (this is a problem for all station-based evaluation methods).

222 3.2 Regridding, correction, and merging of reanalysis datasets

- 223 The three reanalysis datasets (ERA5, MERRA-2, and JRA-55) have different spatial resolutions and contain
- systematic biases. In this section, we discuss steps taken to (1) re-grid all reanalysis datasets to the resolution of
- EMDNA (0.1°)_{5\(\beta\)} (2) perform a correction to remove the systematic bias in original estimates\(\beta\), and (3) merge the three
- reanalysis datasets to produce a background field that improves over any individual reanalysis dataset, in support of
- the reanalysis-station merging described in Sect. 3.3.

3.2.1 Regridding of reanalysis datasets

- Precipitation, Tmean, and Trange are regridded to 0.1° using locally weighted regression (Fig. 2c). Latitude, longitude,
- and elevation are used as predictor variables for simplicity. Precipitation or temperature lapse rates are implicitly
- considered by involving elevation in the regression. Raw reanalysis data from a 5 × 5 space window (i.e., 25 coarse-
- resolution grids) centered by the 0.1° target grid are used to perform the regression. Each grid is represented using its

center point. This regridding method has been proven effective in previous studies (Xu et al., 2015; Duan and Li, 2016; Lu et al., 2020). Reanalysis estimates are also regressed to the locations of all stations to facilitate evaluation and weight estimation in the following steps, which can avoid the scale mismatch caused by using point-scale observations to evaluate 0.1° gridded estimates (Tang et al., 2018a).

We also tested other regridding methods such as the nearest neighbor, bilinear interpolation, and temperature lapse rate-based downscaling (Tang et al., 2018b). Results (not shown) indicated that their performance is generally inferior to the locally weighted regression with respect to several accuracy metrics.

3.2.2 Probability of precipitation estimation

Reanalysis precipitation can exhibit large biases in the number of wet days because the models often generate many light precipitation events. To overcome this limitation, we designed two methods for determining the occurrence of reanalysis precipitation. The first is to use positive thresholds to determine precipitation occurrence. The threshold was estimated in two ways, namely by forcing reanalysis precipitation (1) to have the same number of wet days with station data, or (2) to achieve the highest critical success index (CSI). Gridded thresholds can be obtained through interpolation and used to discriminate between precipitation events or non-events. However, this method can only obtain binary occurrence instead of continuous PoP between zero and one. The second method is based on univariate logistic regression. The amount of reanalysis precipitation is used as the predictor and the binary occurrence from station data is used as the predictand. The logistic regression is implemented for each reanalysis product in the same way as Sect. 3.1.2. The comparison between the threshold-based method and the logistic regression-based method shows the latter achieves higher accuracy. Therefore, we adopt the univariate logistic regression to estimate PoP for each reanalysis product in this study. The possible bias caused by station measurements is not considered.

3.2.3 Bias correction of reanalysis datasets

Considering reanalysis products <u>usually</u> contain systematic bias<u>es</u> (Clark and Hay, 2004; Mooney et al., 2011; Beck et al., 2017; Tang et al., 2018b, 2020b), the linear scaling method (also known as multiplicative/additive correction factor; Teutschbein and Seibert, 2012) is used to correct reanalysis precipitation, Tmean, and Trange estimates. Reanalysis PoP is not corrected because station information has been incorporated in the logistic regression. Let x_r be the reanalysis estimate for variable X, the corrected estimate for a target grid/point i is calculated as:

$$x_{r,i}^{*} = \begin{cases} x_{r,i} + \frac{\sum_{j=1}^{m} w_{i,j} (\bar{x}_{o,j} - \bar{x}_{r,j})}{\sum_{j=1}^{m} w_{i,j}} & \text{additive correction} \\ x_{r,i}^{*} = \begin{cases} \frac{\sum_{j=1}^{m} w_{i,j} \frac{\bar{x}_{o,j}}{\bar{x}_{r,j}}}{\sum_{j=1}^{m} w_{i,j}} & \text{multiplicative correction} \end{cases}$$

$$(7)$$

where $x_{r,i}^*$ is the corrected reanalysis estimate, $w_{i,j}$ is the distance-based weight (Eq. (5)), and $\bar{x}_{o,j}$ and $\bar{x}_{r,j}$ are the climatological mean for each month (e.g., all January from 1979 to 2018) from station observations and reanalysis

estimates for the *j*th neighboring station, respectively. The additive correction is used for Tmean and Trange, and the multiplicative correction is used for precipitation. The number of neighboring stations (*m*) is set to 10, which is smaller than that used for linear or logistic regression (Sect. 3.1) but should be enough for bias correction. The upper bound of $\frac{\bar{x}_{0,j}}{\bar{x}_{r,j}}$ is set to 10 to avoid over-correction in some cases (Hempel et al., 2013).

Linear scaling can also be performed at monthly (Arias-Hidalgo et al., 2013; Herrnegger et al., 2018; Willkofer et al., 2018) or daily (Vila et al., 2009; Habib et al., 2014) time scales by replacing $\bar{x}_{o,j}$ and $\bar{x}_{r,j}$ by the monthly mean (e.g., January in one year) or daily values. We compared the performance of corrections at different scales and found that monthly- or daily-scale corrections acquire more accurate estimates than the climatological correction. The climatological correction was adopted because (1) it preserves the absolute/relative trends better than daily or monthly corrections, and (2) the OI merging (Sect. 3.3) adjusts daily variability of estimates, which compensates for the limitation of climatological correction and makes daily/monthly-scale correction unnecessary.

Quantile mapping is another widely used correction method (Wood et al., 2004; Cannon et al., 2015). We compared quantile mapping and linear scaling and found that they are similar in statistical accuracy, while quantile mapping achieves better probability distributions with much smaller Hellinger distance (Hellinger, 1909) which is a metric used to quantify the similarity between estimated and observed probability distributions. Nevertheless, quantile mapping could result in spatial smoothing of precipitation and temperature, particularly in high-latitude regions where stations are few. For example, Ellesmere Island, the northernmost island of the Canadian Arctic Archipelago, usually shows lower temperature in inland regions due to orographic uplift of air parcels/clouds. However, quantile mapping will erase this gradient because reanalysis grids for this island are corrected based on almost the same reference stations on the coast. To ensure the authenticity of spatial distributions, quantile mapping is not used in this study.

3.2.4 Merging of reanalysis datasets

The three reanalysis products are merged using the Bayesian Model Averaging (BMA, Hoeting et al., 1999), which has proved to be effective in fusing multi-source datasets (Chen et al., 2015; Ma et al., 2018a, b). According to the law of total probability, the PDF of the BMA estimate can be written as:

$$p(E) = \sum_{r=1}^{3} p(E|x_r^*, x_o) \cdot p(x_r^*|x_o)$$
 (8)

where E is the ensemble estimate, x_r^* (r=1, 2, 3) is the bias-corrected estimate from three reanalysis products, $p(E|x_r^*, x_o)$ is the predicted PDF based only on a specific reanalysis product, and $p(x_r^*|x_o)$ is the posterior probability of reanalysis products given the station observation x_o . The posterior probability $p(x_r^*|x_o)$ can be identified as the fractional BMA weight w_r with $\sum_{r=1}^3 w_r = 1$. BMA prediction can be written as the weighted sum of individual reanalysis products.

For Tmean and Trange, $p(E|x_r^*, x_o)$ can be regarded as the normal distribution $g(E|\theta_r)$ defined by the parameter $\theta_r = \{\mu_r, \sigma_r^2\}$, where μ_r is the mean and σ_r^2 is the variance (Duan and Phillips, 2010). For precipitation, if we apply Box-Cox transformation (Eq. (3)) to positive events (>0) and exclude zero events, its distribution is approximately normal, and $p(E|x_r^*, x_o)$ can be represented using $g(E|\theta_r)$. Therefore, Eq. (8) can be written as:

$$p(E) = \sum_{r=1}^{3} w_r \cdot g(E|\theta_r)$$
 (9)

- There are different approaches to infer w_r and θ_r (Schepen and Wang, 2015). This study uses the log-likelihood function to estimate the parameters (Duan and Phillips, 2010; Chen et al., 2015; Ma et al., 2018b). The Expectation-Maximization algorithm (Raftery et al., 2005) can be applied to estimate parameters by maximizing the likelihood function. BMA weights are obtained for all stations and each month. Gridded weights are obtained using the inverse distance weighting interpolation.
- 300 Merging multiple datasets could affect the probability distributions and extreme characteristics of original datasets.
- This is not a major concern because the merged reanalysis data are further adjusted by station data in OI merging (Sect.
- 302 3.3), a later step in the EMDNA process. Also, the probabilistic estimation of ensemble members (Sect. 3.4) has a
- large effect on estimates of extreme events.
- Gridded errors of BMA-merged estimates are necessary to enable optimal interpolation (Sect. 3.3). The error estimation is realized using a two-layer cross-validation (Appendix C).

3.3 Optimal Interpolation-based merging of reanalysis and station data

307 **3.3.1 Optimal Interpolation**

306

314

315316

317

318

OI has proven to be effective in merging multiple datasets (Sinclair and Pegram, 2005; Xie and Xiong, 2011) and has been applied in operational products such as CaPA (Mahfouf et al., 2007; Fortin et al., 2015) and the China Merged Precipitation Analysis (CMPA, Shen et al., 2014, 2018). Let x_A be the OI analysis estimate. The OI analysis estimate $(x_{A,i})$ for a target grid/point i and time step is obtained by adding an increment to the first guess of the background $(x_{B,i})$. The increment is a weighted sum of the difference between observation and background values at neighboring stations.

$$x_{A,i} = x_{B,i} + \sum_{j=1}^{m} w_j (x_{O,j} - x_{B,j})$$
(10)

where $x_{0,j}$, $x_{B,j}$, and w_j are the observed value (subscript O), background value (subscript B), and weight for the jth neighboring station. Let x_T be the true value, the errors of observed and background values are $\varepsilon_{O,j} = x_{O,j} - x_{T,j}$ and $\varepsilon_{B,j} = x_{B,j} - x_{T,j}$ (or $\varepsilon_{B,i} = x_{B,i} - x_{T,i}$), respectively. Assuming that (1) the observation and background errors are unbiased with an expectation of zero and (2) there is no correlation between background and observation errors, the weights that minimize the variance of the analysis errors can be obtained by solving:

 $\mathbf{w}(\mathbf{R} + \mathbf{B}) = \mathbf{b} \tag{11}$

where **w** is the vector of w_j (j = 1, 2, ..., m), **R** and **B** are $m \times m$ covariance matrices of $\varepsilon_{0,j}$ and $\varepsilon_{B,j}$, respectively, and **b** is the $m \times 1$ vector of covariance between $\varepsilon_{B,i}$ and $\varepsilon_{B,j}$. The background provided by reanalysis models assimilates observations in the production and is corrected in a way using station data (described in Sect. 3.2.3), which may affect the soundness of the second assumption. The effect of this slight violation, however, is rather small according to our results and previous studies (Xie and Xiong, 2011; Shen et al., 2014b, 2018).

Different approaches can be used to implement OI. For example, Fortin et al. (2015) used raw station observations as x_0 , and assumeds that the background error is a function of error variance and correlation length, and the observation error is a function of error variance. The variances and correlation length are obtained by fitting a theoretical variogram using station observations. Xie and Xiong (2011) and Shen et al. (2014) use station-based gridded estimates as x_0 , and assume that the background error variance is a function of precipitation intensity, the cross-correlation of background errors is a function of distance, and the observation error variance is a function of precipitation intensity and gauge density. The parameters of those functions are estimated based on station data in densely gauged regions.

In this study, we adopt a novel design that calculates weights based on error estimation, a feature that is enabled by the probabilistic nature of the observational dataset. Regression estimates and their errors at station points (Sect. 3.1) are used as x_0 and ε_0 , respectively. BMA-merged reanalysis estimates and their errors (Sect. 3.2) are used as x_B and ε_B , respectively. We do not use gridded regression estimates because (1) $x_{0,j} - x_{B,j}$ will show weak variation if neighboring stations are replaced by neighboring grids, and (2) estimates of weights \mathbf{w} could be unrealistic because of the spatial smoothing of interpolated regression errors. The advantages of this design are (1) weights and inputs closely match each other and (2) weights in sparsely gauged regions are not determined by parameters fitted in densely gauged regions. In regions with few stations, the errors of regression estimates could be larger than reanalysis estimates, resulting in a smaller contribution from regression estimates and a larger contribution from reanalysis estimates, which is the complementary effect we expect by involving reanalysis datasets in EMDNA.

The Box-Cox transformation is applied to precipitation estimates. Then, precipitation, PoP, Tmean, and Trange estimates provided by OI are used as μ and PoP required for generating meteorological ensembles.

3.3.2 Error of OI-merged estimates

Variance is a necessary parameter to enable ensemble estimation. The variance σ^2 is represented using the mean squared error of OI estimates in this study. First, the error of OI analysis estimates ($\varepsilon_A = x_A - x_o$) is obtained for all stations using the leave-one-out strategy. Then, the σ_i^2 for the *i*th grid is obtained as a weighted sum of squared errors from neighboring stations:

$$\sigma_i^2 = \frac{\sum_{j=1}^m w_{i,j} (\varepsilon_{A,j})^2}{\sum_{j=1}^m w_{i,j}}$$
(12)

where $\varepsilon_{A,j}$ is the difference between the station observation and OI estimate at the *j*th neighboring station, and $w_{i,j}$ is the weight (Eq. (5)).

3.3.3 Correction of precipitation under-catch

Considering station precipitation data usually contain measurement errors such as wind-induced under-catch particularly in high-latitude and mountainous regions, OI-merged precipitation is further adjusted using thee Precipitation Bias Correction (PBCOR) datasetthe bias corrected precipitation climatology produced by Beck et al. (2020). The This PBCOR climatology infers the long-term precipitation (without rain-snow separation) using a Budyko curve and streamflow observations collected from seven national and international sources, among which the Global Runoff Data Centre (GRDC), the U.S. Geological Survey (USGS), and the Water Survey of Canada Hydrometric Data (HYDAT) are data sources in North America. The streamflow stations are scarce in high latitude regions and absent in Greenland... Three corrected datasets are provided, including WorldClim, version 2 (WorldClim V2; Fick and Hijmans, 2017), the Climate Hazards Group Precipitation Climatology, version 1 (CHPclim V1; Funk et al., 2015) and Climatologies at High Resolution for the Earth's Land Surface Areas, version 1.2 (CHELSA V1.2; Karger et al., 2017). The water balance-based method of Beck et al. (2020) considers all measurement errors (e.g., under-catch and wetting/evaporation loss) as a whole and under-catch is the major error source in many regions. Note that the rain gauge catch error includes both under-catch an (Hempel et al., 2013)d over-catch. The potential overcatch could be caused by splash of rain or blow snow collected on the wind shield (Folland, 1988; Zhang et al., 2019). Since over-catch is less common compared to under-catch and the PBCOR dataset does not consider over-catch, the bias correction in this study only addresses the under-catch problem. Moreover, the water balance estimates of precipitation under-catch do not consider non-contributing areas of river basins (e.g., endorheic sub-catchments), which are common in the Canadian Prairies and the northern Great Plains in the USA.

Although the three datasets show similar precipitation distributions after bias correction, CHELSA V1.2 is used because its period (1979–2013) is most similar to our study period (1979–2018). The correction of OI-merged precipitation is performed in two steps: (1) the ratio between bias-corrected CHELSA V1.2 and OI-merged long-term monthly precipitation is calculated at the 0.1° resolution during 1979–2013, and (2) daily OI-merged precipitation estimates during 1979–2018 are scaled using the corresponding monthly ratio map. The bias correction notably increases precipitation in northern Canada and Alaska (Fig. 2d) where precipitation—under-catch of precipitation—is often largesignificant due to the large proportion of snowfall. The uncertainties of gridded estimates are typically larger in high-latitude sparsely gauged regions and topographically elevated regions, which is partly related to the increased proportion of snowfall and hence larger gauge catch errors.

3.4 Ensemble generation

378

379 3.4.1 Spatiotemporally correlated random fields

- Spatially correlated random fields (SCRFs) are used to sample from the probability distributions of precipitation and
- 381 temperature. The SCRFs are produced using the following three steps. First, the spatial correlation structure is
- generated based on an exponential correlation function:

$$c_{i,j} = \exp\left(-\frac{d_{i,j}}{C_{len}}\right) \tag{13}$$

- where $d_{i,j}$ is the distance between grids i and j, and C_{len} is the spatial correlation length determined for each
- 384 climatological month based on regression using station data for precipitation, Tmean, and Trange, separately. The
- 385 spatial correlation structure is generated using the conditional distribution approach. Every point is conditioned on
- previously generated points which are determined using a nested simulation strategy to improve the calculation
- 387 efficiency (Clark and Slater, 2006).
- Second, the spatially correlated random field (\mathbf{R}_t) for the tth time step is generated by sampling from the normal
- distribution with the mean value and standard deviation depending on the random numbers of previously generated
- 390 grids (Clark and Slater, 2006).
- Third, the SCRF is generated by incorporating spatial and temporal correlation relationships. Let ρ_{TM} and ρ_{TR} be the
- lag-1 auto-correlation for Tmean and Trange, respectively, ρ_{CR} be the cross-correlation between Trange and
- precipitation, $\mathbf{R}_{t-1,TM}$, $\mathbf{R}_{t-1,TR}$ and $\mathbf{R}_{t-1,PR}$ be the SCRF for the (t-1)th time step for Tmean, Trange, and precipitation,
- respectively, the SCRF for th time step following (Newman et al., 2015) is written as:

$$\begin{cases} \mathbf{R}_{t,TM} = \rho_{TM} \mathbf{R}_{t-1,TM} + \sqrt{1 - \rho_{TM}^2} \mathbf{R}_{t-1,TM} \\ \mathbf{R}_{t,TR} = \rho_{TR} \mathbf{R}_{t-1,TR} + \sqrt{1 - \rho_{TR}^2} \mathbf{R}_{t-1,TR} \\ \mathbf{R}_{t,PR} = \rho_{CR} \mathbf{R}_{t-1,TR} + \sqrt{1 - \rho_{CR}^2} \mathbf{R}_{t-1,PR} \end{cases}$$
(14)

3.4.2 Probabilistic estimation

- Probabilistic estimates are produced using the probability distribution $N(\mu, \sigma^2)$ in Eq. (1) and **R** in Eq. (14). For
- Trmean and Trange, the SCRF (\mathbf{R}_{TM} and \mathbf{R}_{TR}) is directly used as the standard normal deviate (\mathbf{R}_{X}). The estimate (x_{e})
- for the ensemble member e is written as:

$$x_e = \mu + R_X \cdot \sigma \tag{15}$$

399 For precipitation, an additional step is to judge whether an event occurs or not according to OI-merged PoP and the 400 estimated probability from the SCRF. Let $F_N(x)$ be the CDF of the standard normal distribution, $F_N(R_{PR})$ is the cumulative probability corresponding to the random number R_{PR} . If $F_N(R_{PR})$ is larger than p_0 , the scaled cumulative 402 probability of precipitation (p_{cs}) is calculated as:

$$p_{cs} = \frac{F_N(R_{PR}) - p_0}{1 - p_0} \tag{16}$$

403 The probabilistic estimate for precipitation can be expressed as:

$$x_{e} = \begin{cases} 0 & if & F_{N}(R_{PR}) \leq p_{0} \\ \mu + F_{N}^{-1}(p_{cs}) \cdot \sigma & if & F_{N}(R_{PR}) > p_{0} \end{cases}$$
 (17)

3.5 Evaluation of probabilistic estimates

- 405 Independent stations that are not used in SCDNA are used to evaluate EMDNA because the leave-one-out strategy is 406 too time-consuming for to evaluateing probabilistic estimates. GHCN-D stations with precipitation or temperature 407 records less than eight years are extracted because SCDNA restricts attention to stations with at least eight-year records. In total, 15,018 precipitation stations and 2,455 temperature stations are available for independent testing. 408
- 409 The Brier skill score (BSS; Brier, 1950) is used to evaluate probabilistic precipitation estimates. The continuous ranked 410 probability skill score (CRPSS) is used to evaluate probabilistic temperature estimates. Their definitions are described

411 in Appendix D.

421

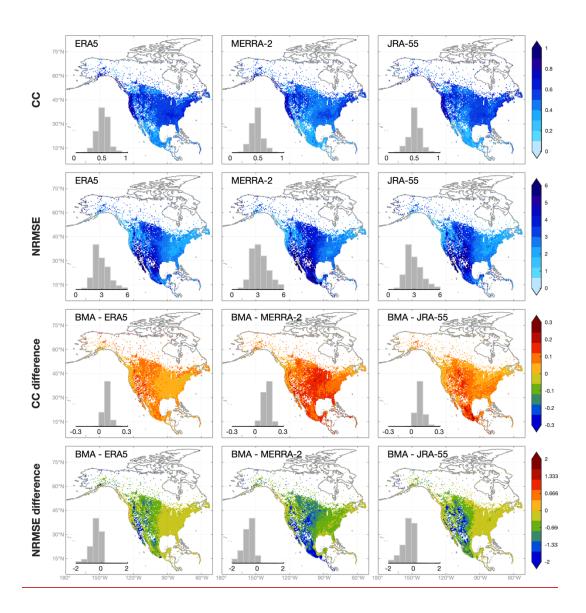

424

Furthermore, the reliability and discrimination diagrams are used to assess the behavior of probabilistic precipitation estimates. The reliability diagram shows the conditional probability of an observed event (precipitation above a threshold) given the probability of probabilistic precipitation estimates. In a reliability diagram, a perfect match has all points located on the 1-1 line. The discrimination diagram shows the PDF of probabilistic precipitation estimates for different observed categories. For precipitation, two categories are defined: events or non-events, i.e., observed precipitation above or below a threshold. The difference between PDF curves of events or non-events represents the degree of discrimination. Larger discrimination is preferred. The PDF for non-event/event should be maximized at the probability of zero/one.

4. Results

4.1 Comparison between raw and merged reanalysis estimates

422 The three raw reanalysis estimates are regridded, corrected for bias, and merged. In this section, we directly compare 423 raw and BMA-merged estimates. The evaluation is performed for all stations using the two-layer cross-validation strategy. The correlation coefficient (CC), and root mean square error (RMSE), and normalized RMSE (NRMSE) are 425 used as evaluation metrics. RMSE is sued for Tmean, and NRMSE is used for precipitation and Trange to remove 426 patterns caused by climatology. 427 For precipitation, the three reanalysis products show the highest CC in CONUS and the lowest CC in Mexico (Fig. 3). 428 The slight spatial discontinuity of CC along the Canada-USA border and the USA-Mexico border (Fig. 3 and 6) is 429 caused by the inconsistent reporting time of stations. Daily precipitation from reanalysis products is accumulated from 430 0 to 24 UTC, while stations from different countries or regions usually have different UTC accumulation periods (Beck et al., 2019; Tang et al., 2020a). The distributions of RMSE agrees with those of precipitation amounts with 431 432 higher values in the southern corner and west coast of North America and western CONUSNRMSE is higher in central 433 CONUS and Mexico compared to other regions. Overall, ERA5 outperforms MERRA-2 followed by JRA-55. 434 BMA-merged precipitation estimates show higher accuracy than all reanalysis products (Fig. 3). For ERA5 and JRA-55, The improvement of CC and NRMSE is the most evident in the Rocky Mountains, while for MERRA-2, the 435 436 largest improvement is also obvious occurs in central CONUS. ERA5 is the closest to BMA estimates concerning CC 437 and NRMSE. The improvement of BMA estimates against ERA5 is more prominent in the high-latitude regions. 438 Specifically, the mean CC increases by 0.05 and 0.07 in regions southern and northern to 55°N, respectively. The 439 corresponding decrease of mean NRMSE is 0.150.72 and 0.210.89 mm/d, respectively.

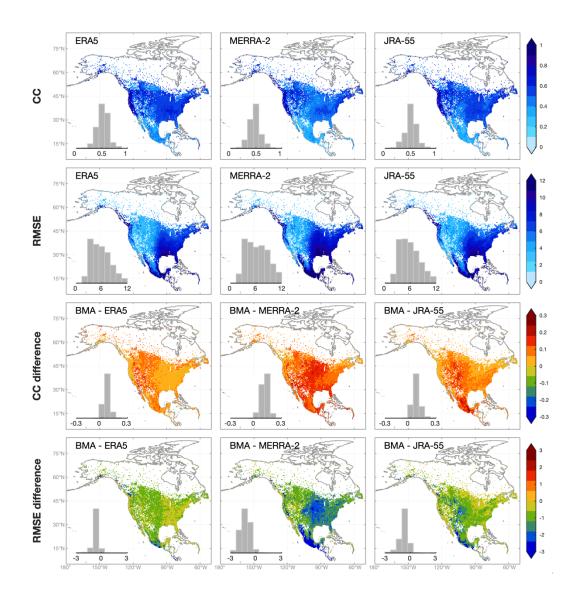

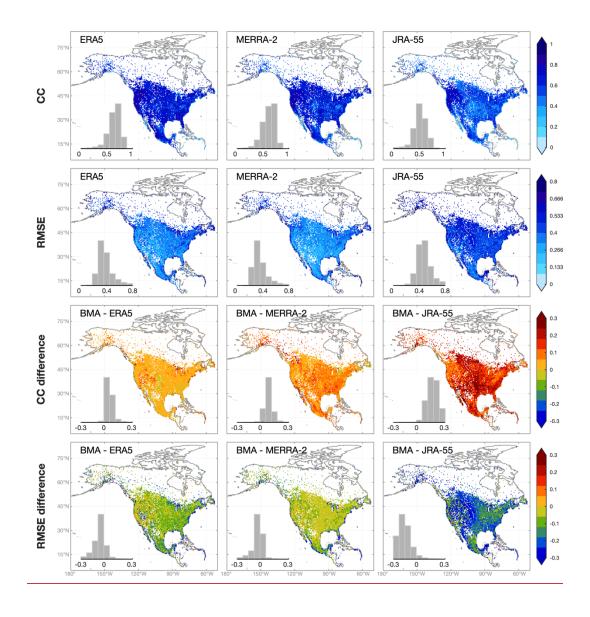

Figure 3. The spatial distributions and histograms of CC (the first row) and NRMSE (the second row) based on raw reanalysis precipitation estimates (ERA5, MERRA-2, and JRA-55). The improvement of BMA-merged estimates against raw reanalysis estimates is shown in the third and fourth rows. The maps are at the The grid resolution is 0.5° resolution, and the value of Per each 0.5° grid point; the is the median metric of median value of all stations located within the grid is shown.

The CC of reanalysis Tmean estimates is close to one in most regions of North America (Fig. 4) and still above 0.9 in Mexico where the CC is the lowest. According to RMSE, Tmean estimates have the largest error in western North America because coarse-resolution raw reanalysis estimates cannot reproduce the variability of temperature caused by elevation variations. The rank of three reanalysis products for Tmean is the same as that for precipitation with ERA5 being the best one. BMA estimates show higher CC than reanalysis products particularly in Mexico, while the improvement of RMSE is the most notable in the Rocky Mountains. For a few stations, the RMSE of BMA estimates

- is slightly worse than raw reanalysis estimates (Fig. 4) because the downscaling of reanalysis temperature could occasionally magnify the error in low-altitude regions (Tang et al., 2018b).
- For Trange, BMA estimates show much larger improvement than Tmean, while the differences of CC and NRMSE are relatively evenly distributed (Fig. 5). The improvement of BMA estimates against JRA-55 estimates is especially
- large. In general, BMA is effective in improving the accuracy of reanalysis precipitation and temperature estimates.

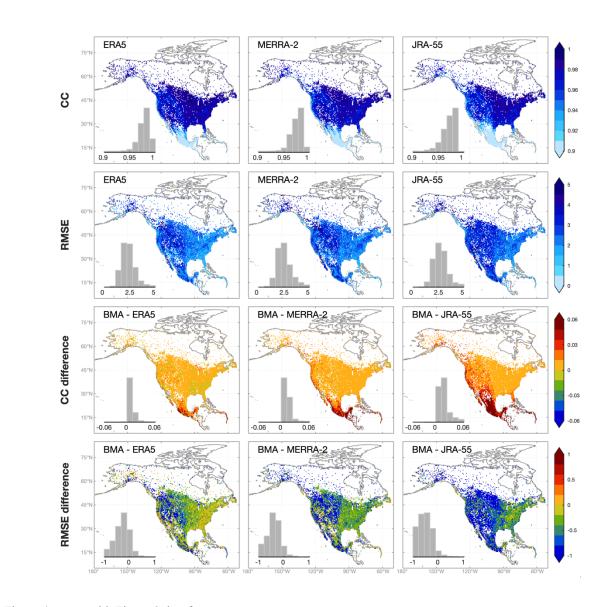

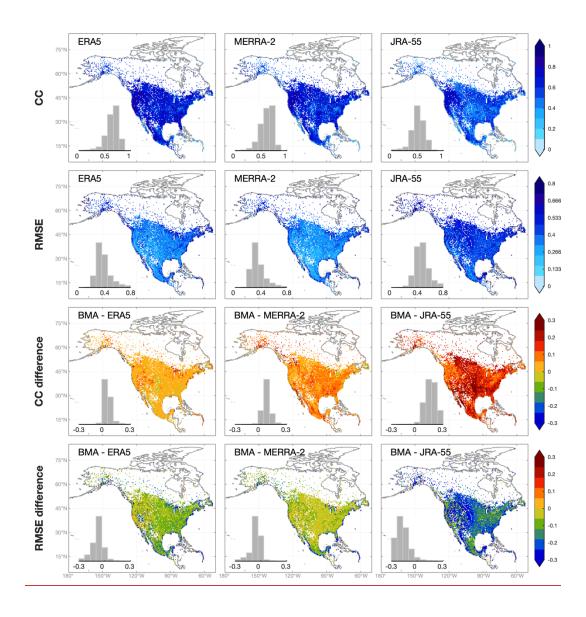

Figure 4. Same with Figure 3, but for mean temperature.

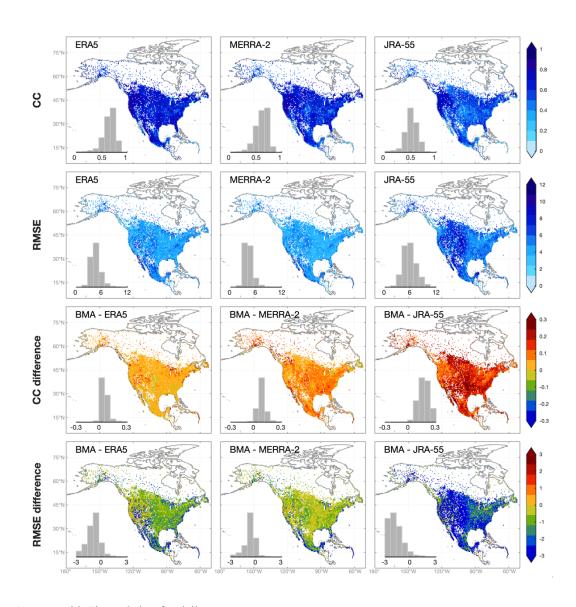

Figure 5. Same with Figure 3, but for daily temperature range.

4.2 The performance of optimal interpolation

Optimal interpolation is used to combine station-based estimates with reanalysis estimates. The performance of OI-merged precipitation and temperature estimates is compared to the background (BMA-merged reanalysis estimates; Fig. 6) and observation (station-based regression estimates; Fig. 7) inputs. To better show the spatial variations of the improvement of OI estimates, RMSE for precipitation and Trange is normalized using the mean value (termed as NRMSE), while Tmean is evaluated using RMSE.

Overall, OI estimates are more accurate than merged reanalysis or station regression estimates for all variables across North America. Comparing OI estimates to reanalysis estimates, for precipitation, Tmean, and Trange, the mean CC is improved by 0.24, 0.02, and 0.15, respectively, and the mean RMSE is reduced by 1.88 mm/d, 0.52°C, and 0.87°C,

respectively. The improvement of OI estimates against station estimates is smaller with the mean CC increasing by 0.06, 0.01 and 0.05, and the mean RMSE decreasing by 0.56 mm/d, 0.18°C, and 0.29°C for precipitation, Tmean, and Trange, respectively.

 OI can utilize the complementarity between station and reanalysis estimates. For example, according to CC, the improvement of OI estimates against reanalysis estimates is larger in the eastern than the western CONUS, while the improvement against station estimates is larger in western than eastern CONUS. This means that although station estimates generally show higher accuracy than reanalysis estimates, station estimates face more severe quality degradation in mountainous regions. Moreover, the latitudinal curves of CC and NRMSE in Fig. 6 and 7 indicate that the improvement of OI estimates against reanalysis estimates decreases as the latitude increases from southern CONUS to northern Canada, while the improvement against station estimates shows a reverse trend.

For Tmean, the CC improvement for OI estimates is the largest in Mexico and decreases from low to high latitudes, while based on RMSE, the improvement increases with latitude. For Trange, the latitudinal variation exhibits a similar pattern with precipitation for regions north of 50°N, with larger/smaller improvement in higher latitudes against station/reanalysis estimates. For regions south of 50°N, the improvement of CC and NRMSE against station estimates shows different trends.

The latitudinal variations in Fig. 6 and 7 are related to station densities (Fig. 8). Station-based estimates often have lower accuracy in regions with scarce stations (i.e., high-latitude North America), while reanalysis estimates could have less dependence on station densities due to the compensation of physically-based models. Therefore, For precipitation, the improvement of OI estimates against regression estimates increases with the distance according to both CC and NRMSE, while the improvement against reanalysis estimates shows an inverse trend (Fig. 8). The shaded area figure within Fig. 8 shows that most stations can find the 20 neighboring stations within the search radius of 20-100 km. However, as the distance increases beyond 200 km, the number of stations becomes very small while the number of grids is still large. For Tmean, the trend with distance is not obvious probably because it is usually easier to interpolate Tmean observations due to its strong linkage with elevation and latitude. For Trange, the improvement against reanalysis and station estimates both increases with the distance. The results show that OI merging is particularly useful in sparsely gauged regions.

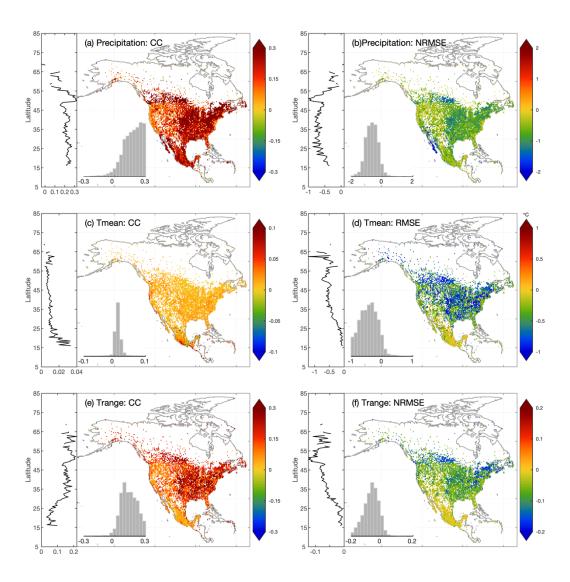

Figure 6. The differences of (a) CC and (b) NRMSE (normalized RMSE) between OI-merged precipitation estimates and BMA-merged reanalysis precipitation estimates. The latitudinal distributions of metrics are attached on the left side, showing the median value for 0.5° latitude bands. (c-d) are the same with (a-b) but for mean temperature and RMSE is not normalized. (e-f) are the same with (a-b) but for daily temperature range.

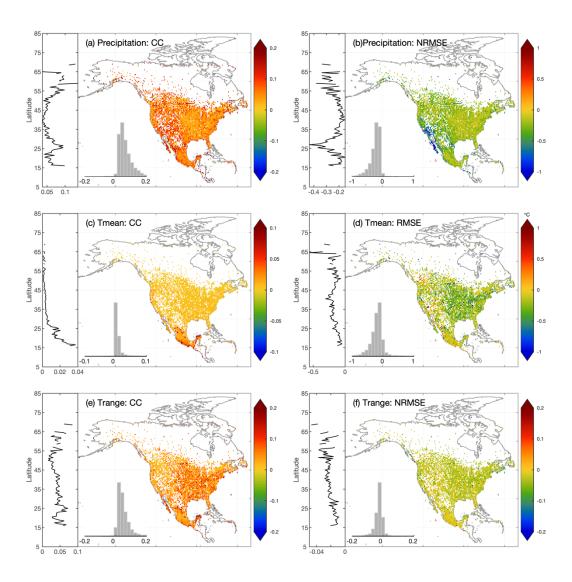

Figure 7. Similar with Figure 6, but the differences are between OI-merged precipitation estimates and station-based regression precipitation estimates.

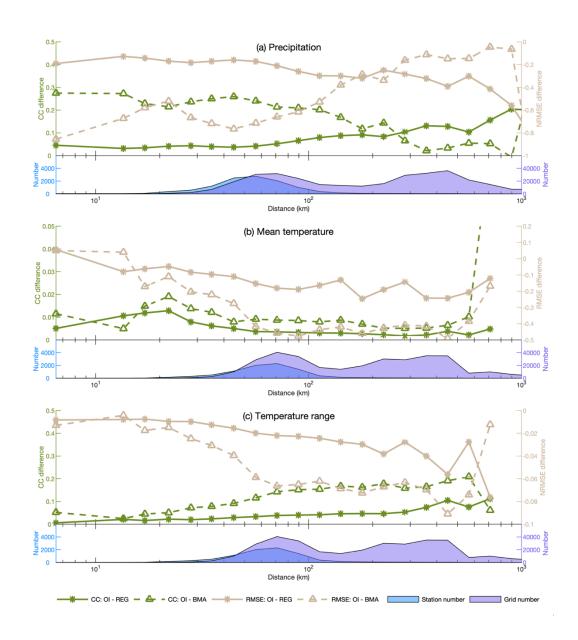

Figure 8. The improvement of OI-based station reanalysis merged estimates against station-based regression (REG) and BMA-merged reanalysis (BMA). The logarithmic X-axis shows the distance between the target station/grid and its 20th distant neighboring station. A larger distance represents a lower station density. The shaded area chart shows the numbers of stations and grid points corresponding to the same distance, which is the same for mean temperature and temperature range.

4.3 Evaluation of probabilistic estimates

The distributions of the OI and ensemble precipitation, Tmean, and Trange estimates in June 2016 are shown in Fig. 89. Compared with OI precipitation estimates, ensemble precipitation estimates show generally consistent but less smooth distributions because of the relatively short spatial correlation length in the warm season. For Tmean and

Trange, OI and ensemble estimates show very similar spatial distributions. Precipitation shows the largest standard deviation, while Tmean shows the smallest, because the standard deviation is determined by the errors of OI estimates.

The PoP from station observations and ensemble estimates is compared based on stations with at least 5-year-long records from 1979 to 2018 (Fig. 910). The comparison cannot represent climatological PoP (Newman et al., 2019b) due to short time length of independent stations (Sect. 3.5). Overall, EMDNA estimates show similar PoP distributions with station observations. The PoP in Canada is slightly overestimated because (1) the quality of EMDNA is lower in regions with fewer stations and (2) point-scale station observations could underestimate the PoP at a larger scale (e.g., 0.1° grids) as shown by Tang et al. (2018a).

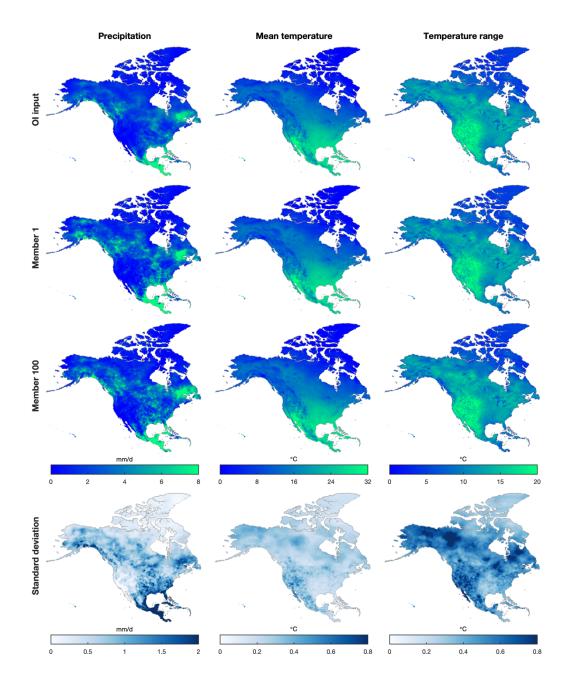

Figure <u>89</u>. The distributions of average values from precipitation (the first column), mean daily temperature (the second column), and daily temperature range (the third column) averaged over the period 1-30 June 2016. The first to third rows represent estimates from OI-merged inputs, ensemble member 1, and ensemble member 100. The fourth row represents the standard deviation of all the 100 members for one month (June 2016).

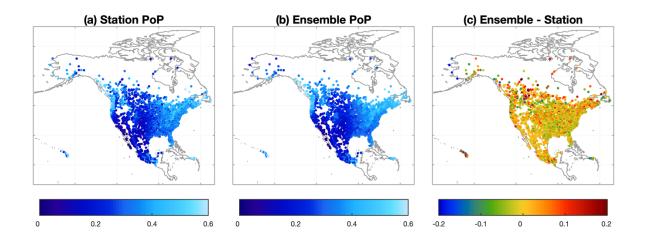

Figure <u>910</u>. The probability of precipitation (PoP) from (a) station observations and (b) concurrent EMDNA ensemble estimates with their differences shown in (c). Stations with at least 5-year-long records from 1979 to 2018 are involved in the comparison.

The discrimination diagram (Fig. 104) shows that ensemble precipitation assigns the highest occurrence frequency at the lowest estimated probability for non-precipitation events, and the performance becomes better as the threshold increases from 0 to 50 mm. For precipitation events, ensemble estimates show the highest frequency at the highest estimated probability for the thresholds of 0, 10, and 25 mm, while as the threshold increases, the frequency curve becomes skewed to the lower estimated probability. This problem is also seen in Clark and Slater (2006) and Newman et al. (2015). Ensemble precipitation shows good reliability for all precipitation thresholds with the points located at or close to the 1-1 line (Fig. 104). At low and high estimated probabilities of occurrence, ensemble precipitation shows slight wet bias. The reliability performance does not show clear dependence with thresholds.

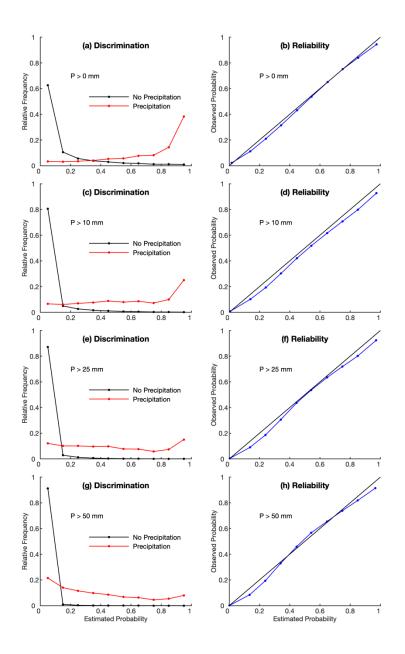

Figure 101. The discrimination and reliability diagrams based on ensemble precipitation estimates. Four rain/no rain thresholds (0, 10, 25, 50 mm) are used.

The BSS for precipitation and CRPSS for Tmean and Trange are shown in Fig. 112. In most cases, ensemble precipitation shows the highest frequency when BSS is above 0.5. As the precipitation threshold increases, the BSS values decrease. The median BSS values are 0.62, 0.54, and 0.46 for the thresholds of 0, 10, and 20 mm/d, respectively. We note that a small number of cases show BSS values smaller than zero, indicating that the ensemble estimated probability is worse than climatological probability. A low BSS value usually occurs in regions where precipitation is hard to estimate (e.g., Rocky Mountains) resulting in inaccurate parameters of Eq. (1).

The BSS for all thresholds shows a clear increasing trend from 1979 to 2018 (Fig. 112b) because the observed precipitation samples from SCDNA increase during this period (Fig. 2 in Tang et al. (2020b)). The increasing trend of BSS is particularly prominent from 2003 to 2009, during which precipitation samples in the USA experience the greatest increase (Tang et al., 2020a). The results show that although infilled station data contribute to higher station densities, observation samples still have a significant effect on gridded data estimation.

Tmean shows high CRPSS for most cases with the frequency peak occurring at ~0.8. The CRPSS of Trange is much lower with the peak occurring at ~0.6. The median CRPSS for Tmean and Trange is 0.74 and 0.51, respectively. Trange shows lower CRPSS probably because the bias direction (i.e., overestimation or underestimation) of daily minimum and maximum temperature could be different, resulting in the larger bias of Trange than Tmean. Analyses show that among stations with negative CRPSS, most are located in Mexico due to the degraded quality of temperature estimates (Sect. 4.1 and 4.2). The long-term variation of CRPSS is not shown because independent temperature stations are insufficient to support validation between 1986 and 2010.

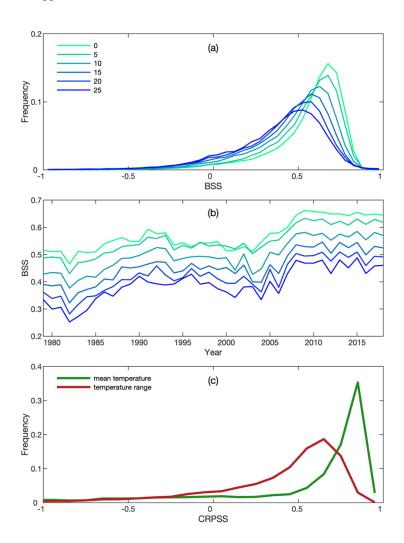

Figure 1<u>1</u>2. (a) The frequency distributions of the Brier Skill Score (BSS) for precipitation corresponding to rain/no rain thresholds from 0 to 25 mm/d. (b) The distributions of BSS for precipitation from 1979 to 2018. For each year, the median value of all stations is used. (c) The frequency distributions of the continuous ranked probability skill score (CRPSS) for daily mean temperature and daily temperature range.

5. Discussion

568

572

- This study presents the framework for producing an ensemble precipitation and temperature dataset over North
- America. Although we have tested multiple choices of methods (Sect. 3) and overall the product shows good
- performance (Sect. 4), the methodology still has limitations that need to be improved through continued efforts.

5.1 Implementation of OI

- OI is used to merge reanalysis outputs and station data. To implement OI-based merging, a critical step is to estimate
- 574 the weights. Previous studies usually adopt empirical error or variogram functions and fit the parameters using station
- observations (e.g., CaPA (Fortin et al., 2015) and CMPA (Shen et al., 2018)); then the parameters are constant for the
- whole study area in the actual application.
- 577 In this study, we proposed a novel design, which uses station-based regression estimates as the observation filed and
- 578 calculates weights by directly solving the weight functions based on observation and background errors. Compared
- 579 with methods that use station data as the observation field, our method is characterized by inferior estimation of the
- 580 observation field but realistic estimation of weights. The close linkage between the observation field and the weights
- 581 could benefit OI estimates but comparing different OI implementations is still meaningful and necessary considering
- that OI has been widely used and is the core algorithm of some operational products.
- 583 Furthermore, regression estimates show worse performance in regions with fewer stations. More advanced
- 584 interpolation methods that can utilize climatology information and comprehensively consider topographic and
- atmospheric conditions (Daly et al., 2008; Newman et al., 2019b; Newman and Clark, 2020) should be examined in
- future studies.

587

5.2 Probabilistic estimation

- Power transformations (e.g., Box-Cox and root/cubic square) with fixed parameters have proven to be useful in
- 589 precipitation estimation and dataset production (Fortin et al., 2015, 2018; Cornes et al., 2018; Khedhaouiria et al.,
- 590 2020; Newman et al., 2020). The Box-Cox transformation with a constant parameter is applied following Fortin et al.
- 591 (2015) and Newman et al. (2019b, 2020). A fixed parameter, however, cannot ensure that transformed precipitation
- is normally distributed everywhere as is desirable.
- We tested a series of additional parametric and non-parametric transformations based on power functions, logarithmic
- functions, or a mix of both, and optimized the parametric transformation functions (including Box-Cox) for every grid

by minimizing the objective function which is the sum of squared L-skewness and L-kurtosis (Papalexiou and Koutsoyiannis, 2013). Theoretically, compared to a Box-Cox transformation with a fixed parameter, the optimized functions can obtain precipitation series closer to the normal distribution which should benefit probabilistic estimation, while the evaluation results show that the Box-Cox transformation with a fixed parameter is better at probabilistic estimation than optimized functions. We suggest there are three reasons for this: (1) the standard deviation in Eq. (1) is obtained by interpolating OI errors (Sect. 3.2.2) from neighboring stations, whereas the optimized transformation parameters could be different at those stations, (2) zero precipitation is excluded during optimization to avoid invalid transformation or optimization, which reduces the number of stations for every time step and thus degrades the quality of the spatial interpolation, and (3) the errors caused by back transformation could be large if the optimized transformation is too powerful. More efforts are needed to resolve this problem.

There are other potential directions for improvement. For example, SCRF is generated from Gaussian distributions, while other choices such as copulas functions (Papalexiou and Serinaldi, 2020) show potential in probabilistic estimation. The spatial correlation length is constant for the whole study area following Newman et al. (2015, 2019b), which may introduce uncertainties for a large domain. Overall, studies related to the production of ensemble meteorological datasets are still insufficient, particularly for large areas. More studies are needed to clarify the critical issues in large-scale probabilistic estimation and explore the effect of parameter/method choices on probabilistic estimates.

- The quality of source data (station observations and reanalysis models) primarily determines the quality of output
- datasets. The density of stations has a critical effect on the accuracy of the observation field and probabilistic estimates.
- While SCDNA collects data from multiple datasets, efforts are ongoing to expand the database by involving station
- sources such as provincial station networks in Canada.
- For reanalysis products, ERA5, MERRA-2, and JRA-55 are regridded using locally weighted linear regression to meet
- the target resolution. There are some choices for future improvement, such as (1) adopting/developing better
- downscaling methods or (2) utilizing outputs from high-resolution re-analysis products or forecasting models such as
- 620 ERA5-Land (Muñoz-Sabater et al., 2021) or the Arctic System Reanalysis (Bromwich et al., 2018) Weather Research
- 621 and Forecasting (WRF) model. For the latter one, a comprehensive assessment of available products is necessary
- 622 before substituting the three reanalysis products used by EMDNA. Moreover, including other data sources such as
- satellite (e.g. (Huffman et al., 2015) GPM IMERG) and weather radar estimates is also an opportunity for regions with
- 624 <u>adequate sample coverage</u>.

5.4 Precipitation under-catch

- Although station precipitation observations are used as the reference in this study, these values are subject to
- measurement errors such as wetting loss, wind-induced under-catch, and trace precipitation. Station temperature
- 628 measurements also contain errors due to microclimate and sensor design(Lin and Hubbard, 2004), which is generally

small and not discussed here. Under-catch of precipitation is particularly severe in high latitudes and mountains due to the stronger wind and frequent snowfall (Sevruk, 1984; Goodison et al., 1998; Nešpor and Sevruk, 1999; Yang et al., 2005; Scaff et al., 2015; Kochendorfer et al., 2018). For example, underestimation of precipitation could be larger than 100% in Alaska (Yang et al., 1998). Bias correction of station precipitation data should consider many factors such as gauge types, precipitation phase, and environmental conditions, which would be very complicated when a large number of sparsely distributed stations are involved over the whole of North America.

The under-catch correction used in this study relies on bias-corrected precipitation climatology produced by Beck et al. (2020), which infers the long-term precipitation using a Budyko curve and streamflow observations. The bias-corrected precipitation climatology, however, is less accurate in northern Canada where streamflow stations are few (Beck et al., 2020). The addition, the streamflow data used by the bias-corrected climatology also contain uncertainties (Hamilton and Moore, 2012; Kiang et al., 2018) related to factors such as streamflow derivation methods (e.g., rate curves) and measurement instruments. In addition, this correction method aims to constrain the total precipitation amount and cannot distinguish between rainfall and snowfall which show different gauge catch performance. Data users can realize rain-snow classification using approaches such as temperature threshold-based methods and reanalysis model-based snowfall proportion. Moreover, as mentioned earlier, the water balance estimates of precipitation under-catch do not consider non-contributing areas of river basins (e.g., endorheie sub-eatchments), which are common in the Canadian Prairies and the northern Great Plains in the USA. Whilst various under-catch correction methods (e.g., Fuchs et al., 2001; Beck et al., 2020; Newman et al., 2020) exist, further studies are needed to compare these solutions considering their effectiveness and availability of input data in a large domain.

- The EMDNA dataset is available at https://doi.org/10.20383/101.0275 (Tang et al., 2020a) in netCDF format.
- 650 Individual ensemble member, ensemble mean, and ensemble spread of precipitation, Tmean, and Trange are provided.
- 651 The total data size is 3.35 TB. Since the 100 members are equally plausible, users can download fewer members if the
- storage space and processing time are limited.
- The deterministic OI estimates of precipitation, PoP, Tmean, and Trange produced in this study are also available in
- 654 netCDF format. The high-quality OI estimates merge reanalysis and station data, which can be useful to applications
- 655 that do not need ensemble forcings. The data sizes are 3.35 TB for the probabilistic part and 40.84 GB for the
- deterministic part, respectively.
- 657 The ensemble mean of the 100 members for Tmean and Trange is similar to deterministic OI estimates. For
- precipitation, the ensemble mean is slightly higher than deterministic OI estimates due to the back transformation. We
- recommend that users select the deterministic dataset instead of the ensemble mean if their applications do not involve
- 660 <u>uncertainty characterization.</u>
- The total data size is 3.35 TB. The total data size is 40.84 GB.

A teaser dataset of probabilistic estimates is provided to facilitate easy preview of EMDNA without downloading the entire dataset. The teaser dataset covers the region from -116.8° to -115.2°W, and 50.7° to 51.9°N, the time from 2014 to 2015, and the ensemble members from 1 to 25. The total data size is smaller than 30 MB. See Appendix E for a brief introduction.

7. Summary and Conclusions

Ensemble meteorological datasets are of great value to hydrological and meteorological studies. Given the lack of a historical ensemble dataset for the entire North America, this study develops EMDNA by integrating multi-source information to overcome the limitation of sparse stations in high-latitude regions. EMDNA contains precipitation, Tmean, and Trange estimates at 0.1° spatial resolution and daily temporal resolution from 1979 to 2018 with 100 members. Multiple methodological choices are examined when determining critical steps in the production of EMDNA. The ultimate framework composes of four main steps: (1) generating station-based interpolation estimates from SCDNA using locally weighted linear/logistic regression, (2) regridding, correction, and merging of reanalysis products (ERA5, MERRA-2, and JRA-55), (3) merging station-reanalysis estimates using OI based on a novel method of OI weight calculation, and correcting precipitation under-catch using the PBCOR dataset, and (4) generating ensemble estimates by sampling from the estimated probability distributions with the perturbations provided by SCRF.

The performance of each step is comprehensively evaluated using multiple methods. The results show that the design of the framework is effective. In short, we find that (1) station-based interpolation estimates are less accurate in regions with sparse stations (e.g., high latitudes) and complex terrain; (2) BMA-merged reanalysis estimates show notable improvement against raw reanalysis estimates, particularly for precipitation and Trange and over high-latitude regions; (3) OI achieves more accurate estimates than interpolation and reanalysis estimates from (1) and (2), respectively, and the complementary effect between reanalysis and interpolation estimates contributes to the large improvement of OI estimates in sparsely gauged regions; and (4) ensemble precipitation estimates show good discrimination and reliability performance for all thresholds, and the BSS values for ensemble precipitation and CRPSS values for ensemble Tmean and Trange are high in most cases. BSS values of ensemble precipitation increase from 1979 to 2018 due to the increase of the number of stations.

Overall, EMDNA (version 1) will be useful for many applications in North America such as regional or continental hydrological modeling. Meanwhile, we recognize that the current framework is not perfect and have provided suggestions on the future directions for large-scale ensemble estimation of meteorological variables. (Sampson et al., 2020) Continuing efforts from the community are needed to promote the development of probabilistic estimation methods and datasets. Development of datasets at higher resolutions (e.g., 1 km and hourly) is also an important direction to enable more sophisticated hydrometeorological studies (e.g., Sampson et al., 2020).

- 694 Author contributions: GT and MC designed the framework of this study. GT collected data, performed the analyses 695 and wrote the paper. MC, SP, AN and AW contributed to the design of the methodology and result evaluation. SP, 696 DB and PW contributed to the evaluation of methodology and results. All authors contributed to data analysis, 697 discussions about the methods and results, and paper improvement.
- 698 Competing interests: The authors declare that they have no conflict of interest.
 - Acknowledgment: The study is funded by the Global Water Futures (GWF) program in Canada. The authors appreciate the extensive efforts from the developers of the ground and reanalysis datasets to make their products available. The authors also thank Federated Research Data Repository (FRDR; https://www.frdr-dfdr.ca; Access Date: September 29, 2020) for publishing our dataset as open access to users.

Appendix A. Regression coefficients

The coefficients for locally weight linear regression are estimated using weighted least square. Given a station i with m neighboring stations, let $\mathbf{A} = [1, A_1, ..., A_n]$ be the $m \times n + 1$ attribute matrix, let $\mathbf{x} = (x_1, x_2, ..., x_m)$ be the station observations from neighboring stations, and let $\mathbf{w}_i = (w_{i,1}, w_{i,2}, ..., w_{i,m})$ be the weight vector with distance-based weights computed from Eq. (5). The regression coefficients $\beta = (\beta_0, \beta_1, ..., \beta_n)$ for Eq. (4) are estimated from the weighted normal equation as

$$\boldsymbol{\beta} = (\mathbf{A}^{\mathrm{T}}\mathbf{W}\mathbf{A})^{-1}\mathbf{A}^{\mathrm{T}}\mathbf{W}\mathbf{x},$$
 A1

- 710 where the $m \times m$ weight matrix $\mathbf{W} = \mathbf{I}_m \mathbf{w}_i$ is a diagonal matrix obtained by multiplying the $m \times m$ identity matrix 711 \mathbf{I}_m with the weight vector \mathbf{w}_i .
- 712 The regression coefficients for logistic regression (Eq. 6) are estimated iteratively as:

$$\boldsymbol{\beta}^{new} = \boldsymbol{\beta}^{old} + (\mathbf{A}^{\mathrm{T}}\mathbf{W}\mathbf{V}\mathbf{A})^{-1}\mathbf{A}^{\mathrm{T}}\mathbf{W}(\mathbf{P}_{0} - \boldsymbol{\pi})$$
 A2

$$\pi = \frac{1}{1 + \exp\left(-\mathbf{A}\boldsymbol{\beta}^{old}\right)}$$
 A3

$$\mathbf{V} = \mathbf{I}_m \boldsymbol{\pi} (1 - \boldsymbol{\pi})$$
 A4

where P_0 is a vector of binary precipitation occurrence for neighboring stations, π is the vector of estimated PoP for 713 neighboring stations, and V is the diagonal variance matrix for PoP. The regression coefficients $\boldsymbol{\beta}^{old}$ are initialized as a vector of ones.

717

734

735

Appendix B. Anomalous stations

- 718 To exclude climatologically anomalous stations, for temperature (Tmean or Trange), we calculate: (1) the absolute
- difference of the climatological mean between the target station and the average value of its 10 neighboring stations
- 720 (referred as Diff-1), and (2) the absolute difference of the climatological mean between station observation and
- regression estimates (referred as Diff-2). A temperature station will be excluded if its Diff-1 is larger than the 95%
- percentile and its Diff-2 larger than the 99% percentile of all stations simultaneously. The threshold of percentiles for
- Diff-1 is lower to better identify some climatologically anomalous stations.
- For precipitation, the ratio (Ratio-1 and Ratio-2) is obtained in the same way with the Diff-1 and Diff-2 of temperature.
- 725 A two-tailed check is used for precipitation compared with the one-tailed check for temperature. A precipitation station
- 726 will be excluded if its Ratio-1 is larger (or smaller) than the 99.9% (1%) percentile and its Ratio-2 larger (or smaller)
- than the 99.9% (1%) percentile simultaneously. This check has more tolerance for heavy precipitation but tries to
- 728 exclude more extremely dry stations.
- As a result, ~1.5% precipitation and temperature stations are rejected, after which algorithms described in Sect. 3.1.1
- 730 and 3.1.2 are re-run. Stations can be anomalous because they are badly operated or simply because they are unique in
- terms of topography or climate. The usage of Diff-2 or Ratio-2 is helpful to avoid excluding unique stations, but for
- cases where the regression is ineffective, the unique stations can still be wrongly excluded. Although the effect on
- final estimates could be rather small, better strategies could be used in future studies.

Appendix C. Error of BMA-merged reanalysis estimates

- The errors of BMA-merged estimates are first estimated for all stations and then interpolated to grids. Considering station observations cannot be used to evaluate merged estimates once they are used in bias correction or BMA weight
- estimation, a two-layer cross-validation strategy is designed. In the first layer, we treat *i* as the target station and find
- its $m(j_1 = 1, 2, ..., m; i \not\in j_1)$ neighboring stations. In the second layer, we treat each j_1 as a target station, and (1)
- find m ($j_2 = 1, 2, ..., m$; $i \notin j_2$) neighboring stations for each j_1 , (2) calculate linear scaling correction factors for all
- j_2 , (3) estimate the correction factor for the target j_1 by interpolating factors at all j_2 stations using inverse distance
- weighting, (4) correct estimates at j_1 using the correction factor, (5) calculate BMA weights of three reanalysis
- products for all j_1 stations, (6) interpolate BMA weights from all j_1 stations to the target station i and merge the three
- reanalysis products for *i*, and (7) calculate the difference between merged reanalysis estimates and station observations
- for i. This two-layer design may seem convoluted but is necessary to ensure that the error estimation is realistic. j_1
- and j_2 could be partly overlapped due to their close locations but should not cause a large effect on the error estimation

747 for i because data for i are only used in (7) in this design. The station-based errors are interpolated to all grids using

748 inverse distance weighting.

756

757

759

760

761762

Appendix D. Metrics for probabilistic evaluation

750 BSS is calculated based on the Brier Score (BS):

$$BSS = 1 - \frac{BS}{BS_{clim}}$$
 D1

BS =
$$\frac{1}{n} \sum_{i=1}^{n} (PoP_{ens} - PoP_{obs})^2$$

where PoP_{ens} is the estimated probability of ensemble precipitation, PoP_{obs} is the observed binary precipitation

occurrence, n is the sample number, and BS_{clim} is the climatological BS by assigning the climatological probability

to all samples. When the two series match the value of BSS will be equal to one.

754 CRPSS is calculated based on the continuous ranked probability skill score (CRPS; Hersbach, 2000):

$$CRPSS = 1 - \frac{CRPS}{CRPS_{clim}}$$
 D3

$$CRPS = \int_{-\infty}^{\infty} (F(x) - H(x \ge x_o))^2 dx$$
 D4

where F(x) is the CDF of the ensemble temperature estimate x, x_0 is the observed temperature, $H(x \ge x_0)$ is the

Heaviside step function with the value being one if the condition $x \ge x_0$ is satisfied and zero if not satisfied, and

CRPS_{clim} is the climatological CPRS. CRPS measures the distance between the CDF of probabilistic estimates and

observations. For a perfect match, the value of CRPSS would be one.

Appendix E. Teaser dataset

The teaser dataset is a subset of EMDNA probabilistic estimates for a small region (-116.8° to -115.2°W, 50.7° to

51.9°N) and a short period (2014 to 2015) with only 25 ensemble members. Users can easily download and preview

the teaser dataset (<30 MB) before downloading the entire EMDNA dataset (~3 TB or ~40 GB) as shown in Sect. 6.

The region covers the Bow River basin above Banff, Canada, which is located in the Canadian Rockies (Figure A1).

The spread of ensemble members in this region could be large due to the complex topography and limited stations.

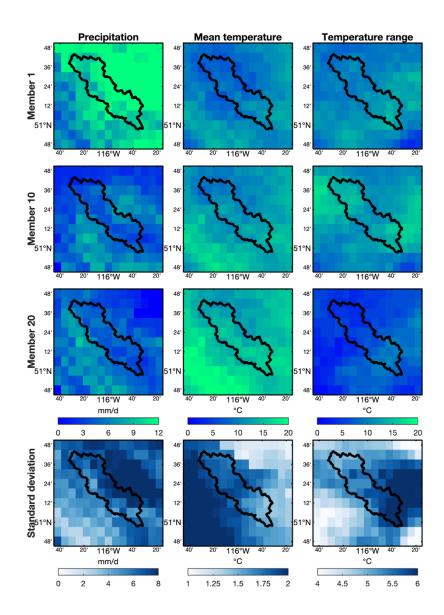

Figure A1. The distributions of daily precipitation (the first column), mean daily temperature (the second column), and daily temperature range (the third column) on 29 June 2015. The first to third rows represent ensemble members 1, 10, and 20, respectively. The fourth row represents the standard deviation of 25 members for this day. The black line outlines the Bow River basin above Banff, Canada.
