Abstract. Gross primary productivity (GPP) quantifies the amount of carbon dioxide (CO₂) fixed by plants through photosynthesis. Although as a key quantity of terrestrial ecosystems, there is a lack of high-spatial-and-temporal-resolution, real-time, and observation-based GPP products. To address this critical gap, here we leverage a state-of-the-art vegetation index, near-infrared reflectance of vegetation (NIR_v), along with accurate photosynthetically active radiation (PAR), to produce a SatelLite Only Photosynthesis Estimation (SLOPE) GPP product in the Contiguous United States (CONUS). Compared to existing GPP products, the proposed SLOPE product is advanced in its spatial resolution (250 m versus > 500 m), temporal resolution (daily versus 8-day), instantaneity (1 day latency versus > 2 weeks latency), and quantitative uncertainty (on a per-pixel and daily basis versus no uncertainty information available). These characteristics are achieved because of several technical innovations employed in this study: (1) SLOPE couples machine learning models with MODIS atmosphere and land products to accurately estimate PAR. (2) SLOPE couples highly efficient and pragmatic gap-filling and filtering algorithms with surface reflectance acquired by both Terra and Aqua MODIS satellites to derive a soil-adjusted NIR_v (SANIR_v) dataset. (3) SLOPE couples a temporal pattern recognition approach with a long-term Crop Data Layer (CDL) product to predict dynamic C4 crop fraction. Through developing a parsimonious model with only two slope parameters, the proposed SLOPE product explains 85% of the spatial and temporal variations in GPP acquired from 49 AmeriFlux eddy covariance sites (324 site-years), with a root-mean-square error (RMSE) of 1.63 gC m⁻² d⁻¹. The median R² over C3 and C4 crop sites reaches 0.87 and 0.94, respectively, indicating great potentials for monitoring crops, in particular bioenergy crops, at the field level. With such a satisfactory performance and its distinct characteristics in spatiotemporal resolution and instantaneity, the proposed SLOPE GPP product is promising for biological and environmental research, carbon cycle research and a broad range of real-time applications at the regional scale. The archived dataset is available at <https://doi.org/10.3334/ORNLDAAC/1786> (Download page: https://daac.ornl.gov/daacdata/cms/SLOPE_GPP_CONUS/data/) (Jiang and Guan, 2020), and the real-time dataset is available upon request.

1 Introduction

Gross primary productivity (GPP) quantifies the amount of carbon dioxide (CO₂) fixed by plants through photosynthesis (Beer et al., 2010; Jung et al., 2017). Because GPP is the largest carbon flux and influences other ecosystem processes such as respiration and transpiration, monitoring GPP is crucial for understanding the global carbon budget and terrestrial ecosystem dynamics (Bonan, 2019; Friedlingstein et al., 2019). In addition, biomass accumulation driven by GPP is the basis for food, feed, wood and fiber production, and therefore monitoring GPP is crucial for human welfare and development (Guan et al., 2016; Ryu et al., 2019).

Over the past two decades, a number of GPP products with different spatial and temporal characteristics have been derived using remote sensing approaches (Xiao et al., 2019). However, since GPP cannot be directly observed at large scales, different models have been developed and used in generating GPP products. Process-based models use a series of nonlinear equations to represent the atmosphere-vegetation-soil system and associated fluxes. For example, a publicly-available global GPP product using process-based models is the Breathing Earth System Simulator (BESS) (Jiang and Ryu, 2016). Machine-learning models upscale site-observed GPP to a larger scale by establishing non-parametric relationships between ground-truth and gridded explanatory variables. The FLUXCOM GPP product is a typical example of this approach (Jung et al., 2019). Semi-empirical approaches utilize equations with a concise physiological meaning (e.g., light use efficiency) that are parameterized with several empirical constraint functions. The MOD17 GPP product (Running et al., 2004), the Vegetation Photosynthesis Model (VPM) GPP product (Zhang et al., 2017), and the Global LAnd Surface Satellite (GLASS) GPP product (Yuan et al., 2010) belong to this category.

With differing principles, assumptions and complexity, existing remote sensing GPP models heavily rely upon inputs with large uncertainties. First, climate forcing, such as temperature, humidity, precipitation and wind speed, are commonly used in these GPP models. However, these meteorological data are not observed but derived from reanalysis approaches and usually have coarse spatial resolution (e.g., > 10 km) and large time lag (e.g., weeks). Second, plant functional types (PFTs) are used to define different parameterization schemes in those models. To date, satellite land cover products are usually characterized by considerably large time lag (> 1 year), relatively low accuracy ($\leq 70\%$) (Yang et al., 2017), and more uncertainties with regards to year-to-year variations (Cai et al., 2014; Li et al., 2018). Third, high-level remote sensing land products such as leaf area index (LAI), fraction of absorbed photosynthetically active radiation (FPAR), clumping index (CI), land surface temperature (LST) and soil moisture (SM) are used by some models. These variables are not directly observed but retrieved by complicated algorithms, and their accuracy still needs significant improvement to meet requirements of earth system models (GCOS, 2011).

Alternative approaches which heavily rely on reliable satellite observations with low dependence on uncertain model structure/parameterization and model inputs are highly required. Solar-induced fluorescence (SIF) emerged in recent years may provide a new opportunity for GPP estimation (Guanter et al., 2014). Linear relationships have been found between SIF and GPP at various ecosystems (Liu et al., 2017; Magney et al., 2019; Yang et al., 2015). However, satellite SIF data generally have coarse resolution, large spatial gaps, short temporal coverage, and limited quality (Bacour et al., 2019; Zhang et al., 2018), and therefore not suitable for many applications.

70

Near-infrared reflectance of vegetation ($NIR_{V,Ref}$), defined as the product of normalized difference vegetation index (NDVI) and observed NIR reflectance (NIR_{Ref}) (Eq. [1]), has recently been presented as a proxy of GPP (Badgley et al., 2017). A global monthly 0.5° GPP dataset has been produced from satellite data using the linear relationship between $NIR_{V,Ref}$ and GPP (Badgley et al., 2019), explaining 68% GPP variations observed by the FLUXNET network. Several field studies have recently found that taking incoming radiation into account further improves the $NIR_V \sim GPP$ relationship (Dechant et al., 2020; Wu et al., 2020). Because MODIS provides long-term and real-time (2000 – present) observations of red (Red_{Ref}) and NIR (NIR_{Ref}) reflectance and atmospheric conditions with high spatial (250 m for reflectance and 1 km for atmosphere) and temporal (daily) resolutions, now there is an unprecedented opportunity to generate an observation-based GPP product.

$$NIR_{V,Ref} = NDVI \times NIR_{Ref} = \frac{NIR_{Ref} - Red_{Ref}}{NIR_{Ref} + Red_{Ref}} \times NIR_{Ref} \quad (1)$$

80 Leveraging the concept of NIR_V , here we present a new GPP model and the resultant daily, 250m, and real-time GPP product (2000 – present) covering the Contiguous United States (CONUS) (Jiang and Guan, 2020). The product is named SatelLite Only Photosynthesis Estimation (SLOPE) because (1) the model only uses satellite data, and (2) the model only has two slope parameters. Detailed model design, multi-source satellite data processing, and comprehensive evaluation procedures are elucidated below.

85 **2 Production of the SLOPE product**

The method we used to estimate GPP using the novel vegetation index $NIR_{V,Ref}$ follows the concept of light use efficiency (LUE) (Monteith, 1972; Monteith and Moss, 1977):

$$GPP = PAR \times FPAR \times LUE \quad (2)$$

Since $NIR_{V,Ref}$ has been found strongly correlated to FPAR (Badgley et al., 2017), and moderately correlated to LUE (Dechant et al., 2019), it is possible to simplify Eq. (2) as:

$$GPP \approx PAR \times (a \times NIR_{V,Ref} + b) \quad (3)$$

90 where a and b are slope and intercept which can be fitted from ground GPP observations. Both PAR and $NIR_{V,Ref}$ can be easily derived from satellite observations with high spatial and temporal resolutions in real time, avoiding complicated but uncertain

algorithm/parameterization to quantify FPAR and LUE in Eq. (2). This linear relationship is likely to converge within C3 species (Badgley et al., 2019), but differs between C3 and C4 species (Wu et al., 2019). Accordingly, land cover data with considerably large time lags and relatively low accuracy may not be necessary for the model parameterization. Instead, an in-
 95 season C3/C4 species dataset is needed for the accurate calibration of the linear relationship.

Defining the ratio of GPP to PAR as the incident PAR use efficiency (iPUE) gives:

$$iPUE = GPP/PAR = FPAR \times LUE \approx a \times NIR_{V,Ref} + b \quad (4)$$

Here iPUE is a confounding factor of canopy structure and leaf physiology, representing the capacity of plants to use incoming radiation for photosynthesis. When vegetation is absent, iPUE is zero and $NIR_{V,Ref}$ is expected to be zero too. However, this is
 100 not true in reality as >99.9% soils have positive $NIR_{V,Ref}$ values according to a global soil spectral library (Jiang and Fang, 2019), and the correction of $NIR_{V,Ref}$ for soil is needed for better performance at low vegetation cover (Zeng et al., 2019). To address this issue, we will propose spatially-explicit correction for $NIR_{V,Ref}$ to derive a soil adjusted index $SANIR_V$ (see details in section 2.2). Since $SANIR_V = 0$ when $iPUE = 0$, Eq. (4) becomes:

$$iPUE \approx c \times SANIR_V \quad (5)$$

where c is the slope coefficient.

105

Considering the presence of mixed pixel of C3 and C4 species with the 250 m pixels, Eq. (5) can be rewritten as:

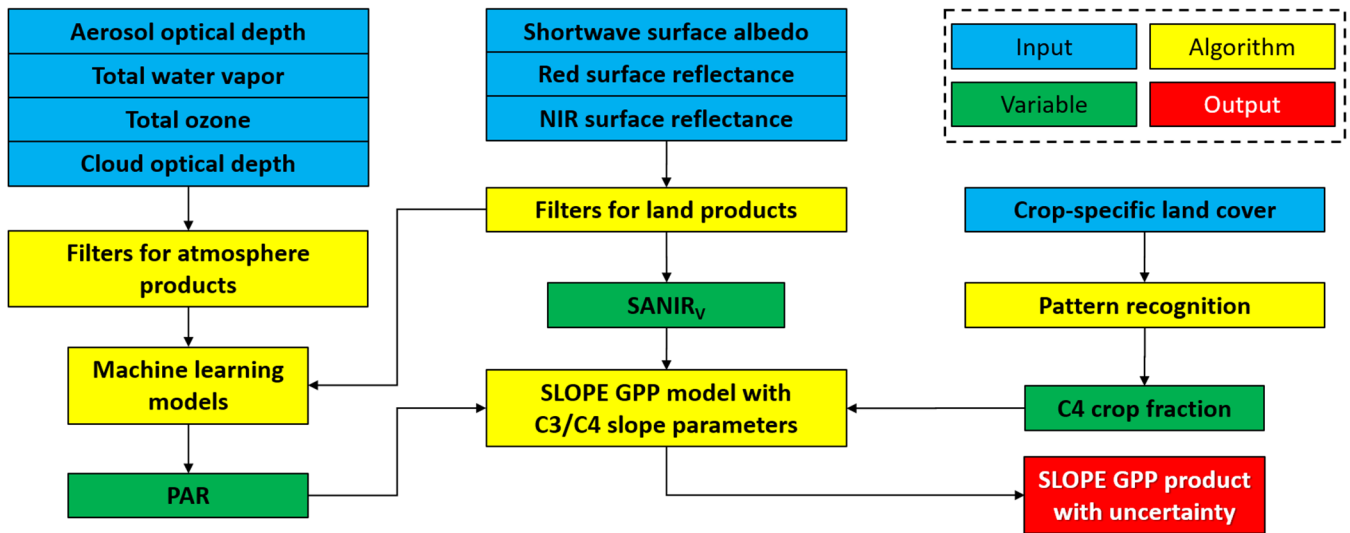

$$iPUE \approx [c_{C4} \times f_{C4} + c_{C3} \times (1 - f_{C4})] \times SANIR_V \quad (6)$$

where c_{C4} and c_{C3} are the coefficients for C4 and C3 species, respectively, and f_{C4} is the fraction of C4 species in vegetation. Therefore, the SLOPE GPP model is:

$$GPP \approx [c_{C4} \times f_{C4} + c_{C3} \times (1 - f_{C4})] \times PAR \times SANIR_V \quad (7)$$

110 In the SLOPE model (Eq. [7]), PAR, $SANIR_V$ and f_{C4} are remote sensing inputs, whereas c_{C4} and c_{C3} are model parameters to be calibrated using ground-truth GPP data (Fig. 1). In the following sections, we will elaborate on the derivation of PAR, $SANIR_V$, and f_{C4} , along with their quantitative uncertainties, and the model calibration for parameters c_{C4} and c_{C3} . With the uncertainty of each term (Δc_{C4} , Δc_{C3} , Δf_{C4} , ΔPAR and $\Delta SANIR_V$), the uncertainty of GPP can be estimated in a spatiotemporally-explicit manner by:

$$\begin{aligned} \Delta GPP &= (f_{C4} \times PAR \times SANIR_V) \times \Delta c_{C4} \\ &+ [(1 - f_{C4}) \times PAR \times SANIR_V] \Delta c_{C3} \\ &+ [(c_{C4} - c_{C3}) \times PAR \times SANIR_V] \Delta f_{C4} \\ &+ \{[c_{C4} \times f_{C4} + c_{C3} \times (1 - f_{C4})] \times SANIR_V\} \Delta PAR \\ &+ \{[c_{C4} \times f_{C4} + c_{C3} \times (1 - f_{C4})] \times PAR\} \Delta SANIR_V \end{aligned} \quad (8)$$

115 Figure 1. Framework to produce the SLOPE GPP product. The box with dash lines is the legend.

2.1 Derivation of PAR

120 SLOPE adopts several machine learning approaches to compute PAR using forcing data mainly from Terra & Aqua/MODIS Atmosphere and Land products (data solely from morning satellite Terra, afternoon satellite Aqua, and combined of the two satellites are called MOD, MYD and MCD, respectively hereinafter). The list of inputs include aerosol optical depth (AOD) at 3 km and 1 km resolutions from MOD/MYD04_3K and MCD19A2 products (Lyapustin et al., 2011; Remer et al., 2013), respectively, total column water vapour (TWV) at 1 km resolution from MOD/MYD05_L2 products (Chang et al., 2015), cloud optical thickness (COT) at 1 km resolution from MOD/MYD06_L2 products (Baum et al., 2012), total column ozone burden (TO3) at 5 km resolution from MOD/MYD07_L2 products (Borbas et al., 2015), white-sky land surface shortwave albedo (ALB) at 500 m resolution from MCD43A3 product (Román et al., 2009), and altitude (ALT) at 30 m resolution from Shuttle Radar Topography Mission Global 1 arc second (SRTMGL1) product (Kobrick and Crippen, 2017).

130 MODIS atmosphere products are swath data and swaths vary day by day. To maintain consistency and facilitate further usage, all data are reprojected using the nearest neighbor resampling approach to the Conus Albers projection on a NAD83 datum (EPSG: 6350) with a 1 km spatial resolution. For swath data, overlap area exists between two paths. In this case, data with smaller sensor view zenith angles provided by MOD/MYD03_L2 products are chosen. MODIS land products and SRTMGL1 are tile data with finer resolution than 1 km. They are reprojected to the EPSG 6350 spatial reference by aggregating all fine resolution pixels within each 1 km grid.

135 Data gaps exist in all MODIS products and gap-filling is required. For MODIS atmosphere products, gaps in MOD/MYD are first filled by data in MYD/MOD counterpart on the same day, followed by multi-year average on that day. Since the multi-

year average of COT is always non-zero, directly using it for gap-filling always implies a cloudy condition. Therefore, CLARA-2 cloud mask at 0.05° acquired from NOAA/AVHRR data is employed (Karlsson et al., 2017). Only MODIS data gaps for AVHRR cloudy pixels are filled by multi-year average of COT, whereas MODIS COT data gaps for AVHRR clear pixels are set to 0. For the MODIS land product, i.e., ALB, a temporally moving window with a 7-day radius is utilized for a specific day, and a Gaussian filter is applied to the time series data within the moving window on a per pixel basis. The filtered values are used to fill gaps on that specific day.

Machine learning approaches are used to upscale ground-truth to satellite. Ground-truth is from the Surface Radiation Budget (SURFRAD) Network (Augustine et al., 2000), including seven long-term continuous sites across the CONUS. Daily mean shortwave radiation (SWR) and PAR on the surface are calculated from site observations at 1 – 3 min intervals from 2000 through 2018. Daily mean SWR at the top of atmosphere (SWR_{TOA}) is calculated using latitude and day of year (DOY) information (Allen et al., 1998). Subsequently, atmospheric transmittance (t_{SWR}) and proportion of PAR in SW (p_{PAR}) are calculated as SWR/SWR_{TOA} and PAR/SWR .

Models are built to estimate t_{SWR} first, followed by p_{PAR} . MOD data representing atmospheric conditions in the morning and MYD for the afternoon are used separately for the estimation, and the two estimates are averaged to account for discrepancies between morning and afternoon. Clear and cloudy conditions are also treated separately in modeling considering the absence/presence of non-zero COT data. For the estimation of t_{SWR} , ALB, ALT and SWR_{TOA} are used in addition to atmosphere data, whereas for p_{PAR} , ALB, ALT and the estimated t_{SWR} are used. A summary of model inputs is listed in Table 1.

Four different machine learning approaches are employed to estimate t_{SWR} and p_{PAR} . They are least absolute shrinkage and selection operator (LASSO) (Tibshirani, 1996), multivariate adaptive regression splines (MARS) (Friedman, 1991), k-nearest neighbors regression (KNN) (Goldberger et al., 2005), and random forest regression (RF) (Liaw and Wiener, 2002). We used Scikit-learn, a free software machine learning library for the Python programming language, to build the models. All the four algorithms were automatically optimized by tuning their hyperparameters using five-fold-cross-validation on their training dataset. All inputs and outputs are the same for the four approaches. Four different PAR estimations are then obtained by Eq. (9), and their ensemble mean and standard deviation are considered as the final estimation and uncertainty, respectively.

$$PAR = SWR_{TOA} \times t_{SWR} \times p_{PAR} \quad (9)$$

Table 1. Summary of machine learning model inputs for the estimation of t_{SWR} and p_{PAR} . Daily estimations from MOD and MYD atmosphere data are averaged.

| Inputs | For daily t_{SWR} estimation | | | | For daily p_{PAR} estimation | | | |
|--------|--------------------------------|--------|-------|--------|--------------------------------|--------|-------|--------|
| | MOD | | MYD | | MOD | | MYD | |
| | Clear | Cloudy | Clear | Cloudy | Clear | Cloudy | Clear | Cloudy |

| | | | | | | | | |
|--------------------|---|---|---|---|---|---|---|---|
| log(COT) | | √ | | √ | | √ | | √ |
| log(AOD) | √ | √ | √ | √ | √ | √ | √ | √ |
| TWV | √ | √ | √ | √ | √ | √ | √ | √ |
| TO3 | √ | √ | √ | √ | √ | √ | √ | √ |
| ALB | √ | √ | √ | √ | √ | √ | √ | √ |
| ALT | √ | √ | √ | √ | √ | √ | √ | √ |
| SWR _{TOA} | √ | √ | √ | √ | | | | |
| t_{SWR} | | | | | √ | √ | √ | √ |

2.2 Derivation of SANIR_v

170 SLOPE derives $NIR_{V,Ref}$ (Eq. [1]) from MODIS band 1 (red) and band 2 (NIR) surface reflectance (SR) at 250 m resolution from MOD/MYD09GQ products (Vermote et al., 2002). Only pixels with quality control (QC) information of ‘corrected product produced at ideal quality all bands’ were used. Since cloud and cloud shadows substantially reduce $NIR_{V,Ref}$ values, SLOPE adopts three strategies to mitigate the cloud contamination.

175 First, the cloud mask is applied. MOD/MYD COT data processed in Section 2.1 are resampled to the same spatial reference with MOD/MYD SR data and used to mask out cloudy pixels. At this point, a morphological dilation operation is used to enlarge the cloud mask to account for cloud edges. However, since COT data have a coarser resolution (1 km) than SR data (250 m), there are still partial clouds and cloud shadows left after this step.

180 Second, MOD and MYD data are combined. Ideally, on a specific day, MOD and MYD $NIR_{V,Ref}$ should be identical if they are obtained under the same conditions. However, the remaining cloud contamination and sun-target-sensor geometry could cause differences between morning and afternoon observations. Considering vegetation index is more sensitive to cloud contamination than sensor view zenith angle, a simple criterion is applied to combine MOD and MYD observations. If the difference between MOD and MYD $NIR_{V,Ref}$ is greater than or equal to a predefined threshold (0.1 in this study), then the smaller one is likely cloud contaminated and the larger one is used. Otherwise, the average value of the two is used. However, 185 in many cases, both MOD and MYD data are contaminated, and sensor view zenith angle may cause unexpected day-to-day variations.

190 Third, a temporal filter is applied. The filter is based on the assumption that $NIR_{V,Ref}$ should change smoothly within a short time period. Accordingly, a temporally moving window with a 7-day radius is utilized for a specific day. Mean and standard deviation are calculated from the $NIR_{V,Ref}$ time series on a per pixel basis. Values outside the range of mean \pm 1.5 standard deviations are considered as outliers and dropped. Subsequently, the mean of the first 3 days and that of the last 7 days are

calculated, respectively. If the $NIR_{V,Ref}$ value of the target day is 20% smaller or larger than both the first 3 days mean and the last 3 days mean, then that $NIR_{V,Ref}$ value is considered as an outlier and dropped.

195 After the removal of outliers, a large amount of data gaps exist and gap-filling is required. Similar to ALB in Section 2.1, a temporally moving window with a 7-day radius is utilized for a specific day, and a Gaussian filter is applied and used to fill gaps on that day. The rest of data gaps are filled with multi-year average of $NIR_{V,Ref}$. Considering extreme cases that no data is available on a specific day over all years, multi-year average of ± 3 days is used for the final gap-filling.

200 To minimize the effects of variations in soil brightness on $NIR_{V,Ref}$, soil background NIR_V ($NIR_{V,Soil}$) is identified from multi-year average $NIR_{V,Ref}$ time series. For a specific pixel, soil background NIR_V ($NIR_{V,Soil}$) is supposed to 1) smaller than seasonal mean $NIR_{V,Ref}$ which includes vegetated period, and 2) smaller than 0.2 indicated by a global soil spectral library (Jiang and Fang, 2019). Therefore, $NIR_{V,Soil}$ is supposed to within a range of $[0, \min(\text{mean}(NIR_{V,Ref}), 0.2)]$. The mode of daily $NIR_{V,Ref}$ averaged over 2000 – 2019 within this value range is considered as $NIR_{V,Soil}$. An example is given in Figure S5. Theoretically,
 205 $NIR_{V,Soil}$ for evergreen species cannot be obtained from time series $NIR_{V,Ref}$ because of the persistent vegetation cover. Pixels with $NIR_{V,Soil}$ value larger than 0.1 and seasonal coefficient of variation (CV) of $NIR_{V,Ref}$ smaller than 33% are empirically considered as evergreen species, and their $NIR_{V,Soil}$ values are set to 0.

Finally, $SANIR_V$ is defined as:

$$SANIR_V = \frac{NIR_{V,Ref} - NIR_{V,Soil}}{NIR_{V,Peak} - NIR_{V,Soil}} \times NIR_{V,Peak} \quad (10)$$

210 where $NIR_{V,Peak}$ is the maximum value of multi-year average $NIR_{V,Ref}$ time series on a per-pixel basis. $SANIR_V$ does not change $NIR_{V,Peak}$, but changes more for low $NIR_{V,Ref}$ values. $SANIR_{V,Ref}$ is set 0 when $NIR_{V,Ref} \leq NIR_{V,Soil}$. In general, $SANIR_V$ is supposed to be smooth within a short time period, therefore, the standard deviation within the ± 3 -day temporal window is calculated as uncertainty.

215 2.3 Derivation of C4 fraction

A National Land Cover Database (NLCD) along with a crop-specific land cover product Cropland Data Layer (CDL) are used to derive the fraction cover of C4 crop in vegetation (f_{C4}). NLCD is a comprehensive land cover database produced by the United States Geological Survey (USGS). It provides several main thematic classes such as urban, agriculture, and forest with high accuracy (Homer et al., 2004). The 30 m nationwide NLCD data are available in 2001, 2004, 2006, 2008, 2011, 2013 and
 220 2016. CDL is an agriculture-oriented product produced by the United States Department of Agriculture (USDA). It provides > 100 crop cover types and leverages other land cover types from NLCD (Boryan et al., 2011). Across the CONUS CDL data

are available at a 30m spatial resolution and in a yearly temporal frequency from 2008 through 2019, whereas in some areas annual data are available back to the 1990s.

225 The fraction of C4 crop in vegetated areas is first derived using existing CDL data. NLCD land cover types are categorized into vegetated areas and non-vegetated areas with 30 m resolution. Fraction of vegetated areas in total area is subsequently calculated for each 250 m pixel. Similarly, CDL crop types are categorized into C4-planted areas and non-C4 areas with 30 m resolution. Fraction of C4 crops in total area is subsequently calculated for each 250 m pixel. The ratio of fraction of C4 crops in total area to fraction of vegetated areas in total area is calculated to derive fraction of C4 crop in vegetated areas at 250 m
230 resolution. Since NLCD data is not available every year, an assumption is made that one year NLCD data can represent adjacent years. Specifically, NLCD 2001 is used for 2000 – 2002, NLCD 2004 is used for 2003 and 2004, NLCD 2006 is used for 2005 and 2006, NLCD 2008 is used for 2007 – 2009, NLCD 2011 is used for 2010 and 2011, NLCD 2013 is used for 2012 – 2014. NLCD 2016 is used for 2015 – 2019.

235 To predict the fraction of C4 crop in vegetation for region-years that no CDL data is available, crop rotation patterns are identified from historical data. Assuming that C4 crops are planted following three rotation strategies: C4/non-C4, C4/C4/non-C4, and non-C4/non-C4/C4, and assigning 1 to C4 and 0 to non-C4, a total of eight possible time series during the period of 2008 – 2019 when nationwide CDL data are available are listed in Table 2. On a per-pixel basis, the time series of the fraction of C4 crop in vegetation during 2008 – 2019 is compared with the eight predefined rotation patterns. PeaSLOPEn coefficient
240 r is calculated between actual time series and each of the eight patterns, and the pattern yielding the largest r is the identified rotation pattern. Once the pattern is identified, fraction of C4 crop in vegetated areas in any unknown year can be inferred. If one year is inferred as C4, then the multi-year average of C4 fraction over C4-dominated years is used. Otherwise, the multi-year average over C3-dominated years is used. If the largest r is smaller than 0.497, i.e., $p > 0.1$ for 12 years, then it is considered as no significant pattern and the multi-year average over all years is used. The RMSE between predicted and
245 reference CDL C4 fraction is calculated as uncertainty. To account for the land cover change, the predicted C4 crop fraction is set to 0 in years when NLCD data is not classified as cropland. It is worth mentioning that C4 grassland and shrubland are not considered in this study as no nationwide high-resolution distribution data is available.

Table 2. Predefined C4-planting patterns from 2008 through 2019. If C4 crop dominates in a specific year, 1 is assigned.

250 Otherwise, 0 is assigned.

| Year | Pattern 1 | Pattern 2 | Pattern 3 | Pattern 4 | Pattern 5 | Pattern 6 | Pattern 7 | Pattern 8 |
|-------------|------------------|------------------|------------------|------------------|------------------|------------------|------------------|------------------|
| 2008 | 1 | 0 | 1 | 1 | 0 | 0 | 0 | 1 |
| 2009 | 0 | 1 | 1 | 0 | 1 | 0 | 1 | 0 |
| 2010 | 1 | 0 | 0 | 1 | 1 | 1 | 0 | 0 |
| 2011 | 0 | 1 | 1 | 1 | 0 | 0 | 0 | 1 |

| | | | | | | | | |
|------|---|---|---|---|---|---|---|---|
| 2012 | 1 | 0 | 1 | 0 | 1 | 0 | 1 | 0 |
| 2013 | 0 | 1 | 0 | 1 | 1 | 1 | 0 | 0 |
| 2014 | 1 | 0 | 1 | 1 | 0 | 0 | 0 | 1 |
| 2015 | 0 | 1 | 1 | 0 | 1 | 0 | 1 | 0 |
| 2016 | 1 | 0 | 0 | 1 | 1 | 1 | 0 | 0 |
| 2017 | 0 | 1 | 1 | 1 | 0 | 0 | 0 | 1 |
| 2018 | 1 | 0 | 1 | 0 | 1 | 0 | 1 | 0 |
| 2019 | 0 | 1 | 0 | 1 | 1 | 1 | 0 | 0 |

2.4 Calibration for iPUE coefficients

SLOPE was calibrated using the GPP data derived from AmeriFlux site observations. The AmeriFlux network is a community of sites that use eddy-covariance technology to measure landscape-level carbon, water, and energy fluxes across the Americas (Baldocchi et al., 2001). A total of 48 sites (324 site years) were involved in this study (Table S3). All of the 43 sites in the FLUXNET2015 Tier 1 dataset (variable name: GPP_DT_VUT_MEAN; quality control: NEE_VUT_REF_QC) in the CONUS were used, because this dataset was produced by standardized data processing pipeline with strict data quality control protocols and is commonly considered as ground-truth. Additional 7 sites were from the AmeriFlux level 4 dataset (variable name: GPP_or_MDS; quality control: NEE_or_fMDSsqc). This dataset was generated more than ten years ago and only AmeriFlux Core Sites that are not covered by FLUXNET2015 were used for data quality consideration. For both datasets, only days with the best quality control flags were used in the SLOPE modelling and evaluation procedures.

We used Eq. (5) to conduct model calibration. Although SLOPE considers $iPUE \sim SANIR_V$ relationship for C3 and C4 species, we also tested other configurations for comparison purposes. Configuration 1 (“all”): all data were used together to fit a universal iPUE coefficient c . Configuration 2 (“C3/C4”): data were separated for C3 and C4 species to fit c_{C3} and c_{C4} , respectively. It is worth mentioning that only C4 crops (6 sites) were considered as C4 species, whereas C4 grass and shrubs (3 sites: US-SRG, US-SRM and US-Wkg) were still categorized into C3 species because of the lack of nationwide and high-resolution C4 grass/shrubs data. Configuration 3 (“PFTs”): data were separated for different PFTs: evergreen needleleaf forest (ENF; 14 sites), deciduous broadleaf forest and mixed forest (DBF & MF; 8 sites), shrubland and woody savannah (SHR & WSA, 5 sites), grassland (GRA; 8 sites), wetland (WET; 5 sites), C3 cropland (10 sites) and C4 cropland (6 sites), to fit PFT-specific iPUE coefficients. The RMSE between $SANIR_V$ -derived and AmeriFlux iPUE for C3 and C4 are calculated as uncertainties of c_{C3} and c_{C4} , respectively.

3 Evaluation of the SLOPE product

3.1 Performance of PAR

275

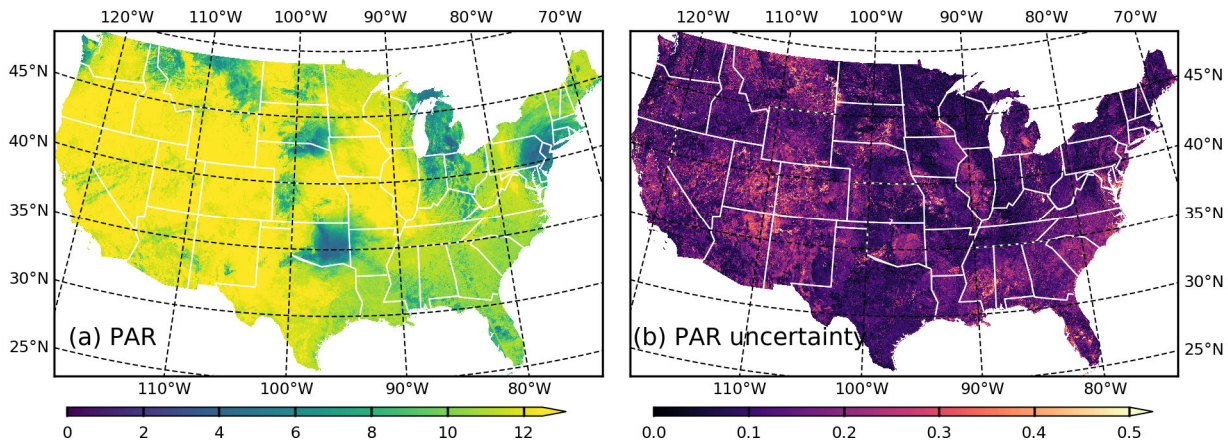

Figure 2. Spatial distribution of 1 km resolution (a) PAR ($\text{MJ m}^{-2} \text{d}^{-1}$) and (b) PAR uncertainty ($\text{MJ m}^{-2} \text{d}^{-1}$) on Jul 10, 2020.

SLOPE PAR demonstrates distinctive and detailed spatial variations in the CONUS because of the large spatial variations of atmospheric conditions (Fig. 2a). As an example, on Jul 10, 2020, large areas in New Jersey, Wisconsin, Oklahoma, South Dakota and Montana display significantly lower values than other areas, due to dominant impacts of cloud (Fig. S1). Aerosol optical depth (Fig. S2), total water vapor (Fig. S3) and total ozone burden (Fig. S4) also influences the amount of clear-sky PAR to some degree. For example, the southeastern part of the CONUS show more aerosol and thus lower PAR values than other cloud-free areas. In addition to the total amount of PAR, SLOPE PAR also reveals variations in the ratio of PAR to SWR (Fig. S5). Despite of a relatively small range (0.40–0.46), it is negatively correlates with cloud optical thickness and total ozone burden and positively correlates with total water vapor. PAR uncertainties caused by the difference of the four machine learning algorithms are generally small ($< 5\%$; Fig. 2b). Higher uncertainties are mainly distributed in cloudy and desert areas.

To evaluate the SLOPE PAR, we used two different site observation datasets which are independent of the PAR derivation procedure. The first dataset is SURFRAD (Table S1). While SURFRAD data from 2000 through 2018 were used for model training, we used data in 2019 for evaluation. The second dataset is FLUXNET2015 (Table S2). A total of 41 sites providing PAR data were used for the evaluation. For both datasets, only days with the best quality control flags were used.

Evaluation results show that SLOPE PAR is in a highly aligned agreement with ground truth independent from the training procedure (Fig. 3). Across the seven SURFRAD sites in 2019 and the 41 AmeriFlux sites from 2000 to 2014, SLOPE PAR achieves an overall coefficient of determination (R^2) of 0.91, and root-mean-square errors (RMSE) of 1.09 and 1.19 $\text{MJ m}^{-2} \text{d}^{-1}$

¹, respectively. In addition, the performance is reasonably stable under different sky conditions, indicated by similar R2 and RMSE values from low to high atmospheric transmittance (Figure S6).

300

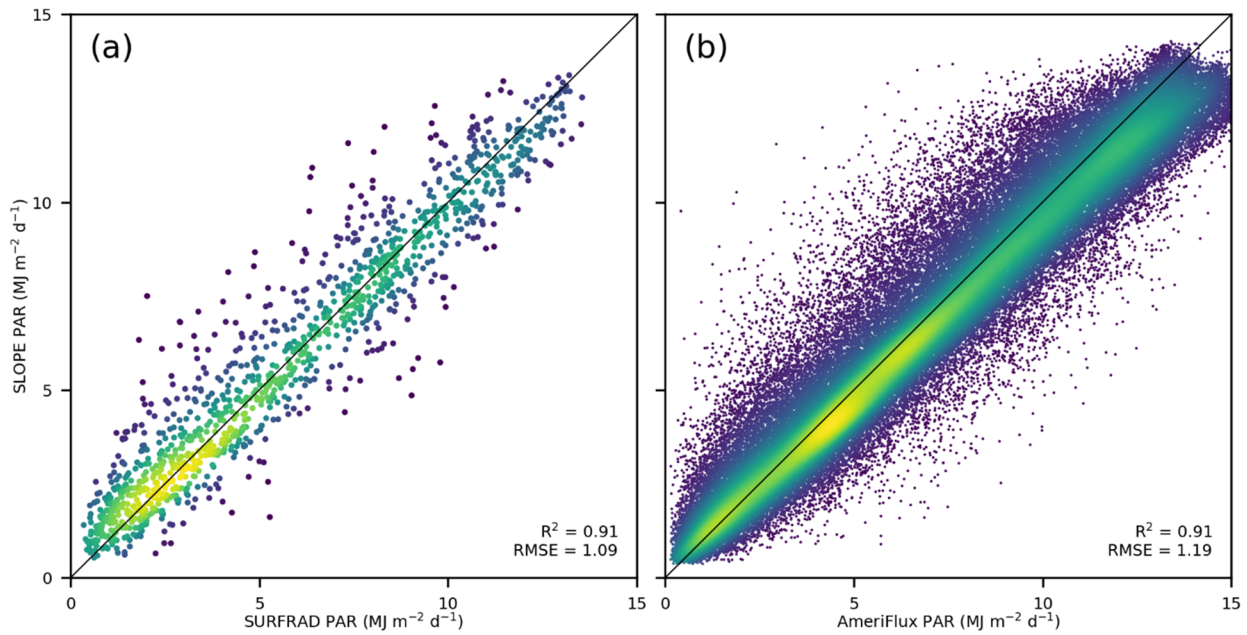

Figure 3. Comparison between site-observed PAR and SLOPE PAR. (a) Comparison across seven SURFRAD sites in 2019. (b) Comparison across 41 AmeriFlux sites from 2000 to 2014. All site data are independent of the training procedure.

305 3.2 Performance of SANIR_v

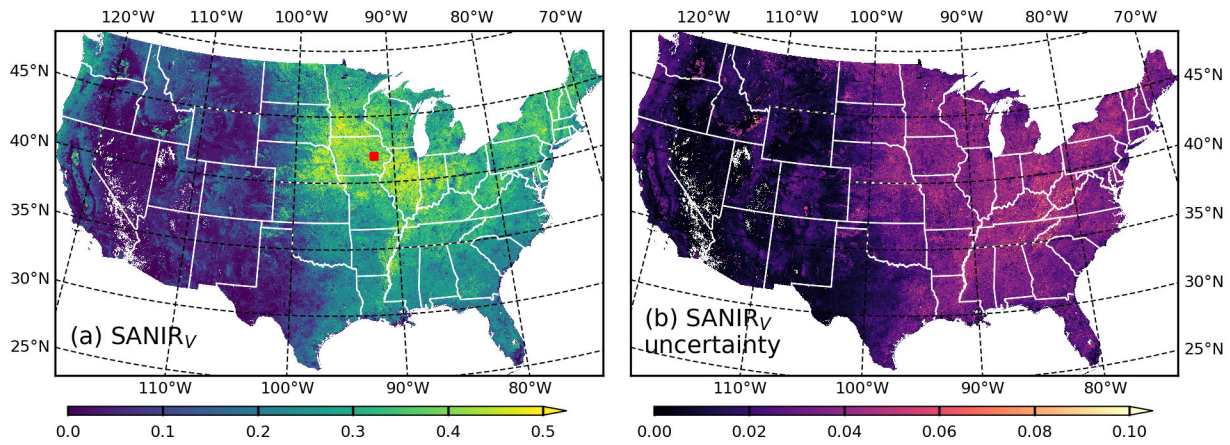

Figure 4. Spatial distribution of 250 m resolution (a) SANIR_V and (b) SANIR_V uncertainty across the CONUS on Jul 10, 2020.

310

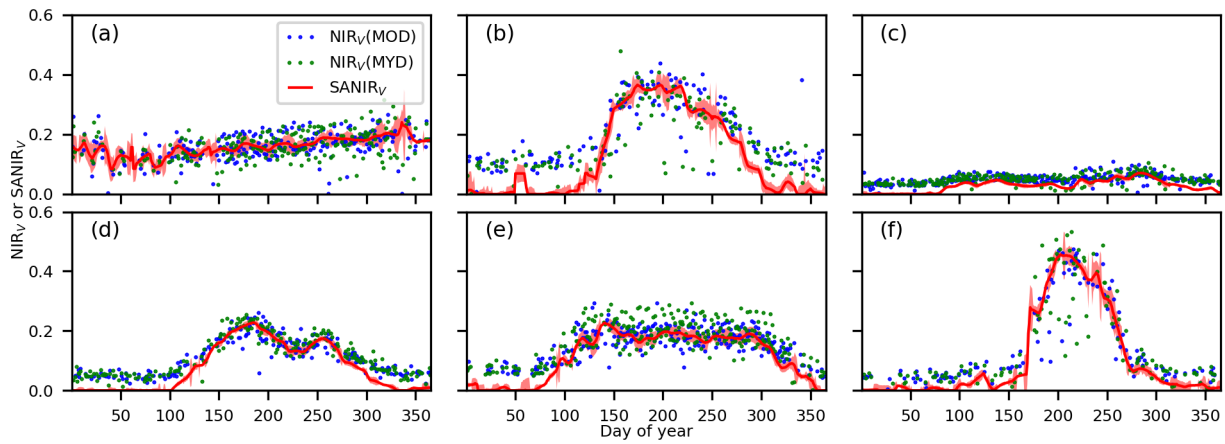

Figure 5. SANIR_V in a 50 × 75 km² area at Cedar Rapids, Iowa (red marker in Figure 4a) on (a) Aug 9, 2020 and (b) Aug 13, 2020. A severe derecho took place from August 10–11, 2020. The maps are shown with the sinusoidal projection.

315 SLOPE SANIR_V demonstrates detailed and distinctive spatial variations in the CONUS (Fig. 4a). In the peak growing season, remarkably high SANIR_V values (~ 0.5) from the Corn Belt in the Central US are observed. This area is one of the most productive areas on Earth, producing more than 30% of global corn and soybean (Green et al., 2018). Forested areas in the Eastern and Western US are characterized by relatively high values (0.3 – 0.4) and medium values (0.2 – 0.3), respectively. Low values (< 0.2) are mainly observed in grasslands and shrublands in the Western US. Uncertainty is associated with
320 SANIR_V data on the pixel basis (Fig. 4b). In general, areas with higher SANIR_V values also have higher uncertainties. However, this pattern is altered by atmospheric conditions, where areas with higher cloud optical thickness (Fig. S1), aerosol optical depth (Fig. S2), and water vapour (Fig. S3) values tend to have larger uncertainties.

Fig. 5 demonstrates that SLOPE SANIR_V is able to capture spatial and temporal variations at small scale (e.g., within a county).

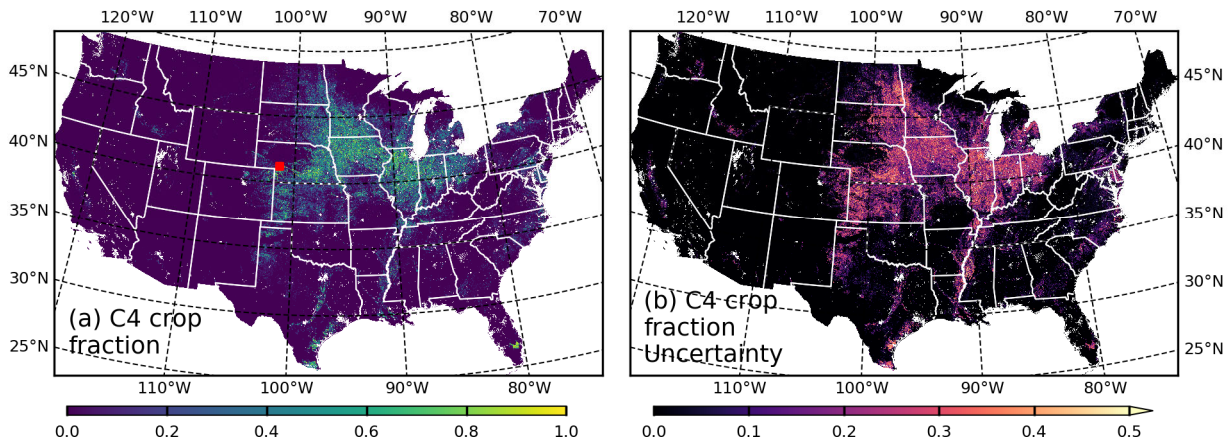

325 An overall drop in SANIR_V due to an extreme event damage can be observed within a short time period, thanks to the high temporal resolution (daily) of the SLOPE product. In addition, differences between plots possibly indicating different varieties, planting density and management, can also be observed, thanks to the high spatial resolution (250 m) of the SLOPE product.

330 Figure 6. Comparison between $SANIR_v$ and raw NIR_v derived from MOD09GQ and MYD09GQ products at six AmeriFlux sites (Table S3) in 2019. (a) US-Blo (evergreen needleleaf forest, ENF). (b) US-Ha1 (deciduous broadleaf forest, DBF). (c) US-Whs (open shrubland, OSH). (d) US-AR1 (grassland, GRA). (e) US-Myb (wetland, WET). (f) US-Bo1 (cropland, CRO). Shaded areas indicate uncertainties of $SANIR_v$.

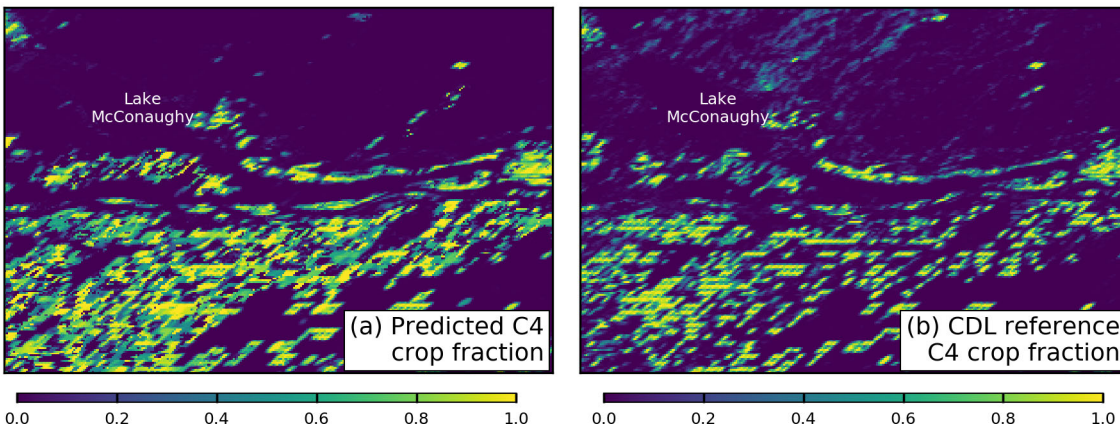

335 SLOPE $SANIR_v$ shows significantly different seasonality for different PFTs (Fig. 6). The evergreen needleleaf forest site US-Blo is characterized by a relatively stable $SANIR_v$ seasonal cycle in 2019 (Fig. 6a), indicated by a $CV = 14.9\%$ only. The deciduous broadleaf forest site US-Ha1 has a large seasonal variation with a $CV = 108.6\%$ (Fig. 6b). The $SANIR_v$ value suddenly rises from 0 to 0.3 in May, reaches 0.4 in June and July, and gradually decreases back to 0 in October. The hot desert open shrubland site US-Whs has an overall low $SANIR_v$ value (Fig. 6c), with a peak value observed in early October. The
 340 grassland site US-AR1 shows a distinct double-peak (in June and September) seasonal pattern (Fig. 6d), which is caused by the precipitation seasonality there. The wetland site US-Myb is characterized by a long growing season and a flat peak from April to November (Fig. 6e). The cropland site US-Bo1 has corn planted in 2019, and it shows the highest $SANIR_v$ peak up to 0.5 among all the shown six sites (Fig. 6f). It is worth mentioning that compared to the two raw satellite-observed NIR_v provided by MOD09GQ and MYD09GQ products, respectively, SLOPE $SANIR_v$ successfully removes the soil impact in the
 345 non-growing season as the values equal to or close to zero. In addition, SLOPE $SANIR_v$ is gap-free and much less contaminated by noises. Furthermore, spatiotemporally-explicit uncertainty is associated with each $SANIR_v$ value.

3.3 Performance of C4 fraction

350

Figure 7. Spatial distribution of 250 m resolution (a) predicted fraction of C4 crop in vegetation in 2000 and (b) C4 crop fraction uncertainty across the CONUS.

355 Figure 8. C4 crop fraction of (a) SLOPE predicted and (b) CDL reference data in a $50 \times 75 \text{ km}^2$ area in the Keith County, Nebraska (red marker in Figure 7a) in 2000. Only CDL data during 2008 – 2019 are used in the modelling procedure and therefore (b) is independent of (a). The maps are shown with the sinusoidal projection.

SLOPE predicts a reasonable fraction of C4 crop in vegetation in the CONUS (Fig. 7a). Most of the C4 crops are located in the Corn Belt, especially in Indiana, Illinois, Iowa and Nebraska. A direct comparison between predicted C4 crop fraction (Fig. 8a) and independent reference CDL data (Fig. 8b) indicates that the SLOPE prediction is able to reconstruct the spatial patterns of the fraction of C4 crop in vegetation at 250 m resolution. It is worth mentioning that the uncertainty metric RMSE is sensitive to extreme values, and it is different from misclassification rate (0.4 does not mean 40%). For a pure pixel of a corn/soybean rotation field, the $\text{RMSE} = 0.39$ if three out of 20 years is misclassified, i.e., misclassification rate = 0.15. A further

360

365 investigation with regard to interannual dynamics shows that the SLOPE predictions can even perform better than CDL
 reference data (Fig. 9), benchmarked with ground truth collected in the field. At this point, the CDL land cover could be prone
 to uncertainties in both satellite observation and classification algorithm, and classification is conducted year by year without
 an interannual consideration (Lark et al., 2017). SLOPE employs a rotation model to match decadal time series of CDL data,
 during which procedure noises in CDL data are suppressed. The features that SLOPE is able to reconstruct spatial and
 370 interannual patterns of CDL data enables producing GPP in years when CDL data is unavailable (e.g., 2020 and years before
 2008 for most regions). It is worth mentioning that uncertainty is also associated with each pixel (Fig. 7b).

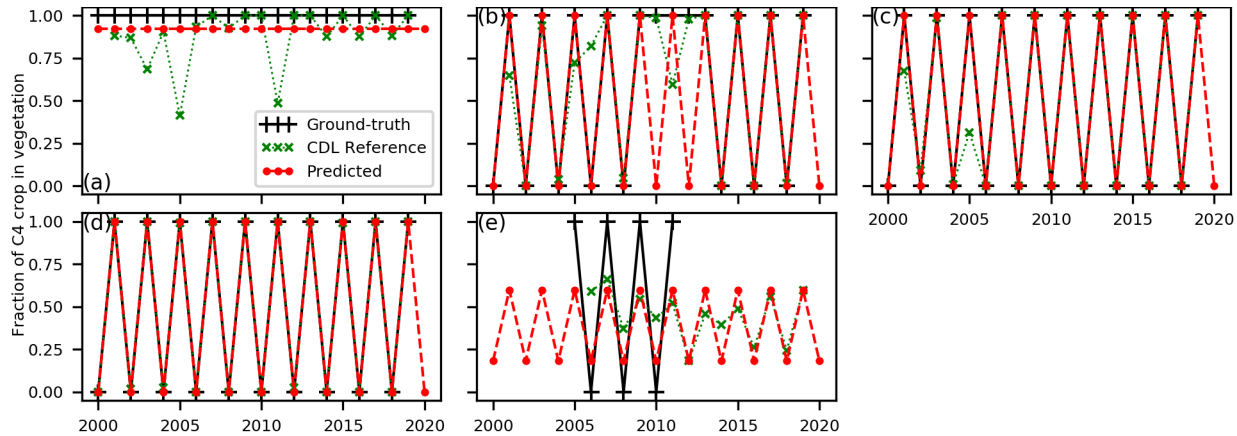

Figure 9. Comparison of fraction of C4 crop in vegetation between field collected ground truth, 250 m resolution CDL data and 250 m resolution SLOPE predictions at six AmeriFlux sites (Table S3) in the U.S. Corn Belt from 2000 to 2020. (a) US-Ne1 (uncertainty: 0.17). (b) US-Ne2 (uncertainty: 0.40). (c) US-Ne3 (uncertainty: 0.18). (d) US-Bo1 (uncertainty: 0). (e) US-Ro1 (uncertainty: 0.16). Uncertainty is the RMSE between the predicted and the CDL reference.

3.4 Performance of GPP

380

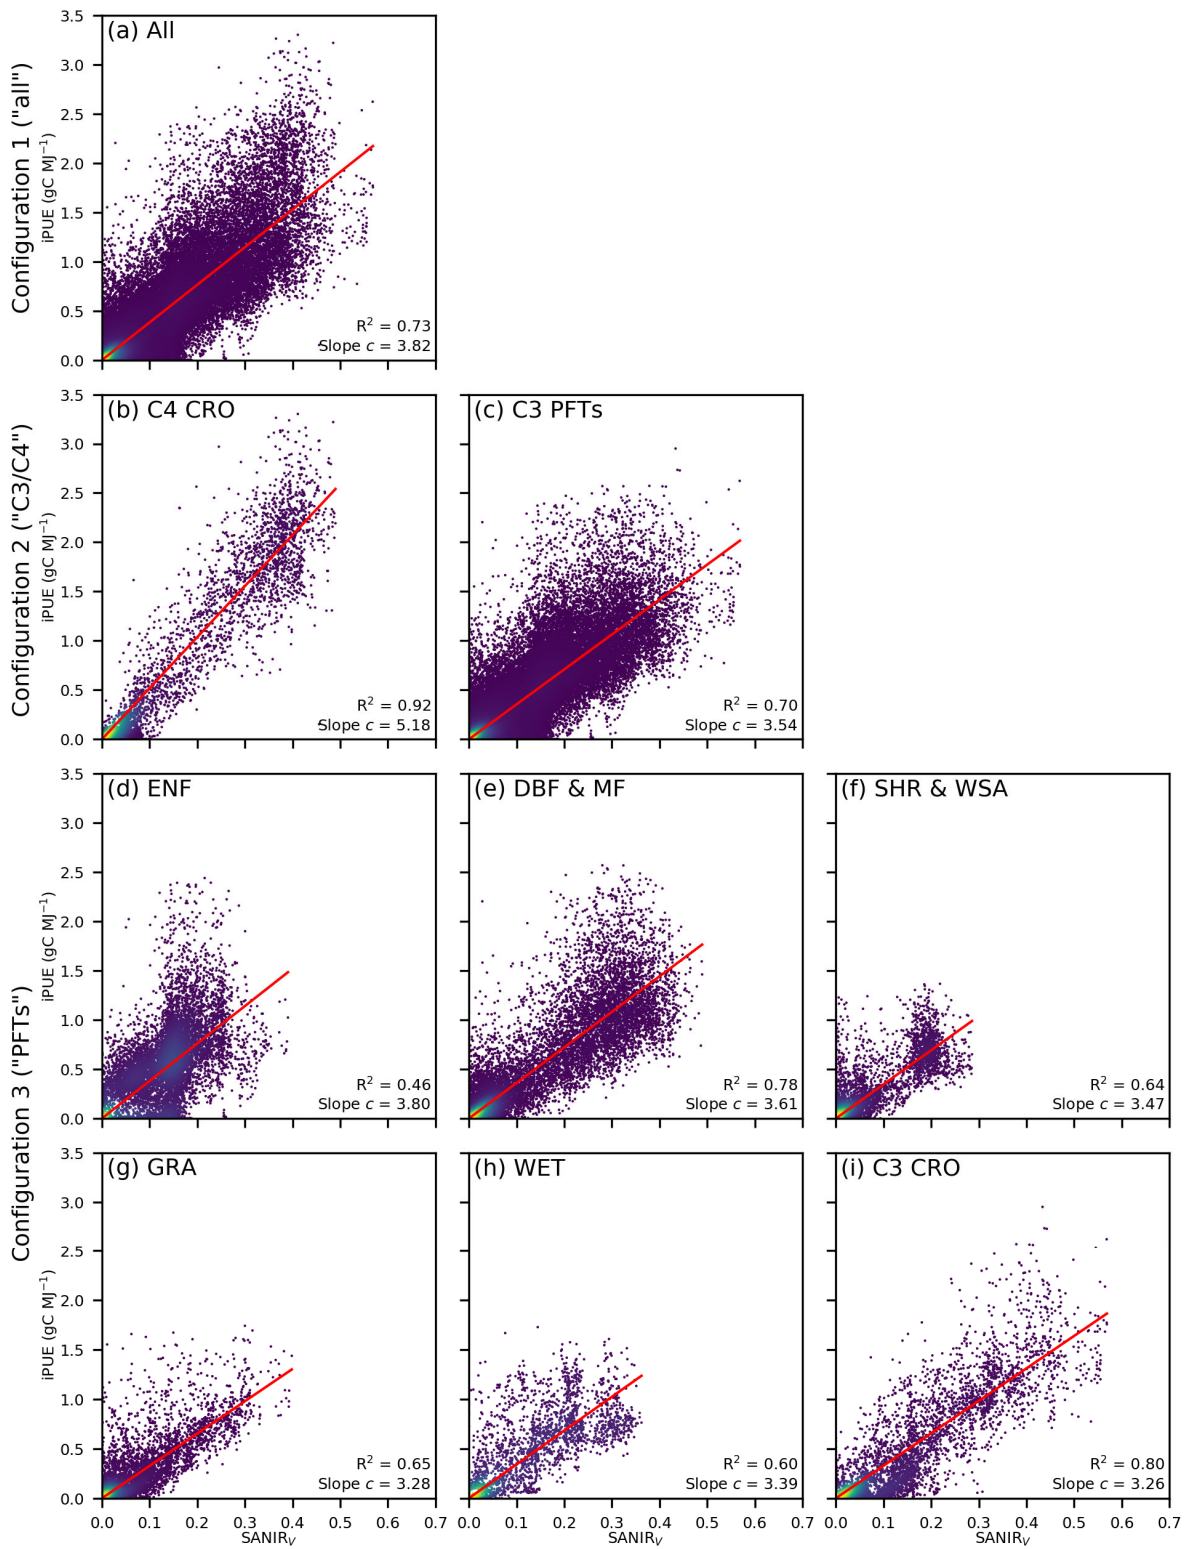

Figure 10. Comparison between SANIR_v and iPUE over different subsets. The slope value of the SANIR_v ~ iPUE relationship is the model parameter c (Eq. [5]). (a) is used by the model configuration 1 (“all”). (b) and (c) are used by the model configuration 2 (“C3/C4”) which is actually used by SLOPE. (b) and (d) – (i) are used by the model configuration 3 (“PFTs”).

385

SLOPE SANIR_v shows a strong linear correlation with iPUE (Fig. 10). When data from all 49 sites (324 site years) are used together, the SANIR_v ~ iPUE relationship has an overall R² value of 0.73 (Fig. 10a). This is composed of R² of 0.92 from C4 species (Fig. 10b) and 0.70 from C3 species (Fig. 10c). C3 species can be further decomposed into six PFTs (Fig. 10d – 10i), among which cropland has the highest R² value up to 0.80 (Fig. 10i), whereas evergreen needleleaf forest has the lowest value of 0.46 (Fig. 10d). This relatively weak iPUE ~ SANIR_v relationship is expected because evergreen needleleaf forest tends to allocate resources for leaf construction and maintenance at large time scales and does not have much flexibility to change canopy structure and leaf color as a response to varying environment at small time scales (Badgley et al., 2019; Chabot and Hicks, 1982). Previous studies found that changes in xanthophyll cycle instead of chlorophyll concentration or absorbed PAR explained the seasonal variation of photosynthetic capacity in evergreen needleleaf forest (Gamon et al., 2016; Magney et al., 2019). Therefore, SIF was suggested by some studies as a better proxy of photosynthetic capacity in this ecosystem (Smith et al., 2018; Turner et al., 2020), though satellite SIF has coarser spatial resolution, shorter temporal coverage, and larger temporal latency, and lower signal-to-noise ratio than SANIR_v. In addition, the relatively weak iPUE ~ SANIR_v relationship is also partly because of the small value ranges in both SANIR_v and iPUE.

400 The overall slope is 3.82 gC MJ⁻¹ for all data (Fig. 10a). Distinct difference is found between C4 (5.18; Fig. 10b) and C3 (3.54; Fig. 10c) species, suggesting the importance of separating C4 from C3 species in modelling. The slope values vary to a limited degree within C3 species (Fig. 10d – 10i), ranging from 3.26 gC MJ⁻¹ (cropland; Fig. 10i) to 3.80 gC MJ⁻¹ (evergreen needleleaf forest; Fig. 10d), indicating the insignificance of separating different PFTs. It is worth mentioning that the SANIR_v ~ iPUE relationship has a zero intercept because of the successful removal of the soil impact.

405

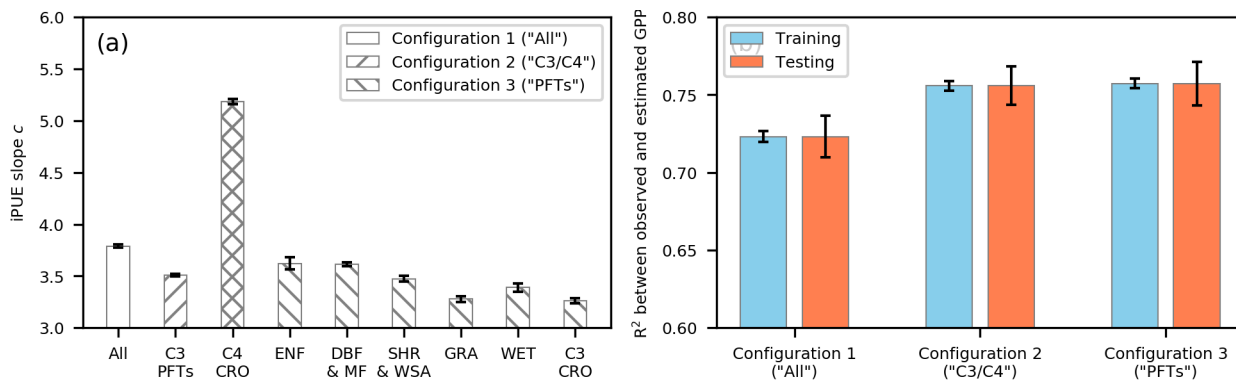

Figure 11. Statistics of the $\text{SANIR}_V \sim \text{iPUE}$ relationship from cross validation. (a) Slopes of the $\text{SANIR}_V \sim \text{iPUE}$ relationship over different subsets. (b) R^2 between AmeriFlux GPP and estimated GPP using different model configurations for the training and testing datasets, respectively. Error bars in both subplots indicate 95% confidential intervals over 500 experiments.

A 100-time repeated 5-fold cross-validation reveals the robustness of the $\text{SANIR}_V \sim \text{iPUE}$ relationships (Fig. 11). Here the repeated cross-validation means the whole GPP dataset from all 49 sites (324 site years) is randomly split into 5 folds, 4 folds for training and 1 fold for testing, and the process is repeated 100 times yielding 500 training-testing splits in total. In all subsets, the uncertainties of the iPUE coefficient c (the slope of the $\text{SANIR}_V \sim \text{iPUE}$ relationship) are less than 1% (Fig. 11a). When using the three different model configurations, the model performances in simulating the whole training/testing datasets also show little variation (Fig. 11b), in general $< 0.5\%$ and $< 1.5\%$ for the training and testing datasets, respectively. Moreover, the R^2 values between training and testing datasets, and between C3/C4 and PFT-based configurations are almost identical (~ 0.76). These results suggest using $c_{C4} = 5.18$ (Fig. 10b) and $c_{C3} = 3.54$ (Fig. 10c) in SLOPE is reasonable. The 95% confidential intervals of c for C4 and C3 species (Fig. 11a) are used as their uncertainties in SLOPE.

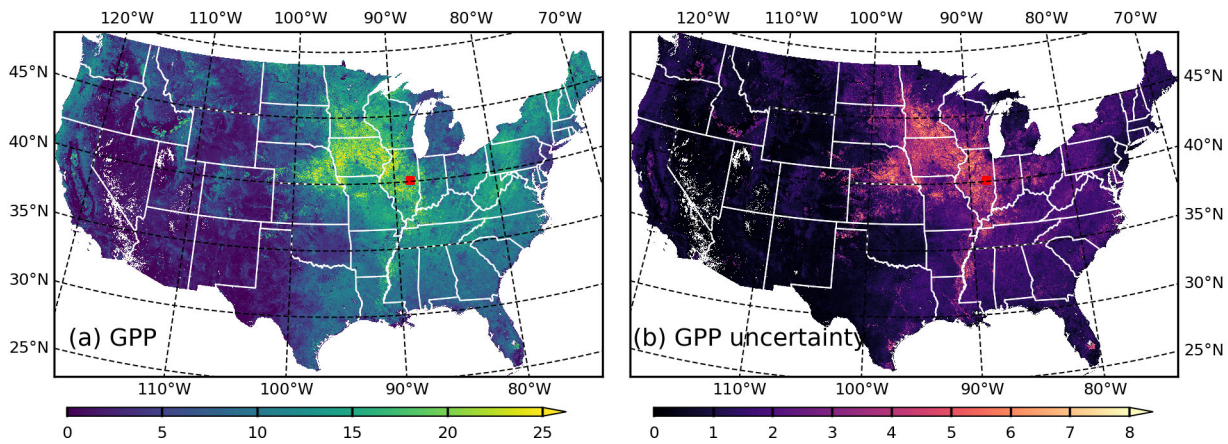

Figure 12. Spatial distribution of 250 m resolution (a) GPP ($\text{gC m}^{-2} \text{d}^{-1}$) and (b) GPP uncertainty ($\text{gC m}^{-2} \text{d}^{-1}$) across the CONUS on Jul 10, 2020.

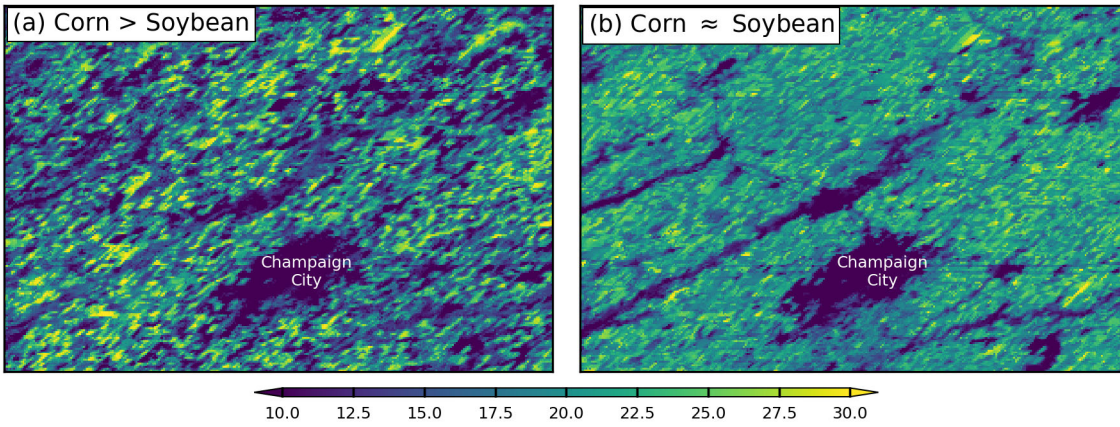

Figure 13. GPP ($\text{gC m}^{-2} \text{d}^{-1}$) in a $50 \times 75 \text{ km}^2$ area in Champaign County, Illinois (red marker in Figure 12a) on (a) Jul 10, 430 2020 and (b) Aug 20, 2020. The maps are shown with the sinusoidal projection.

SLOPE GPP demonstrates detailed and distinctive spatial variations in the CONUS (Fig. 12a). The Corn Belt is the most productive area, largely contributed by the C4 crop corn whose GPP could reach up to $30 \text{ gC m}^{-2} \text{d}^{-1}$ (Fig. 13a). Forested areas in the Eastern US show medium GPP values, followed by forests and croplands in the Western US. Grasslands and shrublands in the Central and Western US generally show low productivity. On this example day, the R^2 of spatial patterns between GPP and SANIR_V , GPP and C4 fraction, and GPP and PAR across the CONUS are 0.89, 0.34, and 0.01, respectively. SANIR_V , an integrated vegetation index containing information of both FPAR and LUE (Eq. [4]), explains the majority of GPP spatial variation. C4 fraction mainly contributes to the distribution and magnitude of the peak in GPP spatial variation. Although PAR does not influence the nationwide GPP spatial variation, it regulates GPP values at local scale. For example, Northeastern Nebraska shows smaller GPP values than Southeastern Nebraska in spite of similar SANIR_V (Fig. 4a) and C4 fraction (Fig. 7a) because of smaller PAR values (Fig. 2a). At small scale (e.g., within a county), the 250 m resolution ($\sim 0.06 \text{ km}^2$ per pixel) SLOPE GPP is close to revealing field-level heterogeneity, considering that the mean and median crop field sizes in the CONUS are 0.19 km^2 and 0.28 km^2 , respectively (Yan and Roy, 2016). For example, Fig. 13a shows large contrast in GPP but Fig. 13b is more homogeneous. This is because corn reaches peak growing season in early July when soybean canopy is still open and sparse. SLOPE GPP with its pixel size much smaller than field area is therefore able to show GPP difference between corn and soybean. In late August, corn turns yellow while soybean is still green and active, and therefore they have similar GPP values considering corn is C4 while soybean is C3. We suggest that the 250 m resolution makes a big difference from existing global GPP products whose spatial resolutions are at least 500 m ($\sim 0.25 \text{ km}^2$ per pixel). Quantitative uncertainty is provided for each SLOPE GPP estimate (Eq. [8]). The spatial pattern shows that the Corn Belt has the largest uncertainty (Fig. 450 12b; e.g., $5 \text{ gC m}^{-2} \text{d}^{-1}$) due to the considerable contribution from the uncertainty of C4 fraction (Fig. 7b).

Figure 14. Performance of the SLOPE GPP. (a) Comparison between AmeriFlux GPP and SLOPE GPP across all sites. (b) R^2 and RMSE of individual sites. Sites with a C3/C4 rotation are separated into C3 CRO and C4 CRO.

SLOPE GPP agrees fairly well with ground-truth from the AmeriFlux (Fig. 14). Across all of the 49 sites (328 site years; Fig. 14a), SLOPE GPP achieves an overall R^2 of 0.85, RMSE of 1.63 $\text{gC m}^{-2} \text{d}^{-1}$, and relative error of 37.8%. For individual sites (Fig. 14b), the median R^2 and RMSE are 0.80 and 1.69 $\text{gC m}^{-2} \text{d}^{-1}$, respectively. C4 cropland generally shows the highest median R^2 value (0.94), followed by deciduous broadleaf forest and mixed forest (0.88) and C3 cropland (0.87). The lowest median R^2 value (0.69) is observed for evergreen needleleaf forest. With regard to RMSE, smaller median values are found in grassland (1.09 $\text{gC m}^{-2} \text{d}^{-1}$), shrubland and woody savannah (1.48 $\text{gC m}^{-2} \text{d}^{-1}$), and deciduous broadleaf forest and mixed forest (1.48 $\text{gC m}^{-2} \text{d}^{-1}$), whereas C3 (2.15 $\text{gC m}^{-2} \text{d}^{-1}$) and C4 (2.01 $\text{gC m}^{-2} \text{d}^{-1}$) cropland tend to have larger RMSE values.

465

Figure 15. Comparison between AmeriFlux (black dots) and SLOPE (red curves) daily GPP at six AmeriFlux sites (Table S3) from 2000 to 2019. (a) US-Blo (evergreen needleleaf forest, ENF). (b) US-Ha1 (deciduous broadleaf forest, DBF). (c) US-Whs (open shrubland, OSH). (d) US-AR1 (grassland, GRA). (e) US-Myb (wetland, WET). (f) US-Bo1 (cropland, CRO). Shaded areas indicate uncertainties of SLOPE GPP.

470

SLOPE GPP generally captures seasonal and interannual variations of AmeriFlux GPP for different PFTs (Fig. 15). At the evergreen needleleaf forest site US-Blo (Fig. 15a), the GPP seasonal cycle is mainly driven by PAR as the iPUE indicated by SANIR_v is fairly stable (Fig. 6a). At the deciduous broadleaf forest site US-Ha1 (Fig. 15b), the start of season and the end of season agree well between AmeriFlux GPP and SLOPE GPP. At the open shrubland site US-Whs (Fig. 15c), the quick rise and drop of GPP in response to the start and end of the wet season are clearly observed in SLOPE GPP. Even the double-peak pattern in 2011 can be observed in SLOPE GPP. At the grassland site US-AR1 (Fig. 15d), the impact of a severe drought in the Southern Great Plains in 2011 is distinct in SLOPE GPP, as the GPP values in 2011 are only about half of those in 2010 and 2012. At the cropland site US-Bo1 (Fig. 15f), the rotation-caused year-to-year variation is distinct, indicated by higher values in odd number years with C4 crop corn planted and lower values in even years with C3 crop soybean planted (Fig. 9d). It is also observed the lowest GPP peak in 2012 when a severe drought attacked the Central US.

4 Data availability and data format

The archived daily 250 m resolution SLOPE GPP data product from 2000 to 2019 is distributed under a Creative Commons Attribution 4.0 License. It is publicly available at the NASA's Oak Ridge National Laboratory Distributed Active Archive Center (ORNL DAAC) with a DOI <https://doi.org/10.3334/ORNLDAAC/1786> (Download page: https://daac.ornl.gov/daacdata/cms/SLOPE_GPP_CONUS/data/) (Jiang and Guan, 2020). Data from 2020 are available from the authors upon request. All data are projected in the standard MODIS Land Integerized Sinusoidal tile map projection and are stored in GeoTIFF format files with a data type of signed 16-bit integer. Each processing tile is in size of 4800 pixels by 4800 pixels, representing approximately 1200 km by 1200 km land region. In addition to the GPP product, SLOPE PAR, SANIR_v, and C4 fraction, along with their uncertainties, are also released. These datasets are also stored in the same spatial projection and file format with the GPP dataset. PAR (resampled from 1 km to 250 m to be consistent with GPP) and SANIR_v are provided on a daily basis, whereas C4 fraction is provided on an annual basis. A README file is provided along with the SLOPE product, which instructs the usage of the data.

5 Conclusions

This study produces a long-term and real-time (2000 – present) GPP product with daily and 250 m spatial and temporal resolutions. The product is based on remote sensing only (SLOPE) model, which uses accurate PAR, soil-adjusted NIR_v, and dynamic C4 fraction as inputs. Evaluation against AmeriFlux ground-truth GPP shows that the SLOPE GPP product has a reasonable accuracy, with an overall R² of 0.85 and RMSE of 1.63 gC m⁻² d⁻¹. To demonstrate the real-time capacity of the SLOPE GPP product, the latest GPP data on Nov 2, 2020, two days prior to the revision of this manuscript, is shown in Fig. S7. The spatiotemporal resolution and instantaneity of the SLOPE GPP product are higher than existing global GPP products, such as MOD17, VPM, GLASS, FLUXCOM and BESS. We expect this novel GPP product can significantly contribute to

various researchers and stakeholders in fields related to the regional carbon cycle, land surface processes, ecosystem monitoring and management, and agriculture. The approaches used in this study, in particular, the derivation of SANIR_v, can also be applied to any other satellite platforms with the two most classical bands: red and NIR. For example, SaTallite dAta IntegRation (STAIR) Landsat-MODIS fusion data which has daily, 30 m spatiotemporal resolution and can be applied at large scale (Jiang et al., 2019; Luo et al., 2018), commercial Planet Labs data with a daily interval and spatial resolution up to 3m (Houborg and McCabe, 2016; Kimm et al., 2020), and the Advanced Very High Resolution Radiometer (AVHRR) with a temporal coverage as far back as 1982 (Franch et al., 2017; Jiang et al., 2017). However, caution should be used in the interpretation of GPP seasonal trajectory in evergreen needleleaf forests because of relatively poor relationship between SANIR_v and iPUE, and GPP magnitude in southwestern US grasslands because of the ignorance of fraction of C4 grasslands. Finally, although the SLOPE product has been generated from 2000 to present, caution should also be used in the interpretation of long-term trend because the SLOPE model, as many other LUE models, does not explicitly consider the CO₂ fertilization effects on vegetation productivity.
