**Abstract:** Station-based serially complete datasets (SCDs) of precipitation and temperature observations are important for hydrometeorological studies. Motivated by the lack of serially-complete station observations for North America, this study seeks to develop a SCD from 1979 to 2018 from station data. The new SCD for North America (SCDNA) includes daily precipitation, minimum temperature ( $T_{\min}$ ), and maximum temperature ( $T_{\max}$ ) data for 27276 stations. Raw meteorological station data were obtained from the Global Historical Climate Network Daily (GHCN-D), the Global Surface Summary of the Day (GSOD), Environment and Climate Change Canada (ECCC), and a compiled station database in Mexico. Stations with at least 8-year records were selected, which underwent location correction and were subjected to strict quality control. Outputs from three reanalysis products (ERA5, JRA-55, and MERRA-2) provided auxiliary information to estimate station records. Infilling during the observation period and reconstruction beyond the observation period were accomplished by combining estimates from 16 strategies (variants of quantile mapping, spatial interpolation, and machine learning). A sensitivity experiment was conducted by assuming 30% observations of stations were missing – this enabled independent validation and provided a reference for reconstruction. Quantile mapping and mean-value corrections were applied to the final estimates. The median Kling-Gupta efficiency (KGE') values of the final SCDNA for all stations are 0.90, 0.98, and 0.99 for precipitation,  $T_{\min}$  and  $T_{\max}$ , respectively. The SCDNA is closer to station observations than the four benchmark gridded products, and can be used in applications that require either quality-controlled meteorological station observations or reconstructed long-term estimates for analysis and modelling. The dataset is available at <https://doi.org/10.5281/zenodo.3735533> (Tang et al., 2020).

**Key words:** serially complete dataset; precipitation; temperature; North America

## 32 **1 Introduction**

33 Station-based serially complete datasets (SCDs, see Table A1 for all acronyms) are important for meteorological,  
34 climatological and hydrological studies (Kanda et al., 2018; Ramos - Calzado et al., 2008), such as producing  
35 retrospective gridded products (Di Luzio et al., 2008; Kenawy et al., 2013; Newman et al., 2019; Serrano-Notivoli et  
36 al., 2019), trend analyses (Knowles et al., 2006; Anderson et al., 2009; Papalexiou and Montanari, 2019), and  
37 climatologic index calculation (Alexander et al., 2006; Papalexiou et al., 2018). These SCDs are useful because  
38 station-based observational datasets often contain missing values due to factors such as observer absence, instrument  
39 failures, and interrupted communication (Hasanpour Kashani and Dinpashoh, 2012). Moreover, station observations  
40 failing quality control tests such as outlier and homogeneity checks may not be reliable (Menne et al., 2012), and many  
41 stations are only maintained over a relatively short period of time or portions of the year, resulting in data gaps that  
42 could affect the analysis of climate variability or long-term trends (Rubin, 1976; Stooksbury et al., 1999). Serial  
43 completeness is also a critical requirement for real-time station-based applications, which regularly contend with  
44 missing data values due to latencies in station reporting, quality control and processing (Tang et al., 2009).

45 Many methods have been developed to estimate missing observations and reconstruct time series of meteorological  
46 stations that provide point-scale regular observations of atmospheric conditions (Longman et al., 2020). They can be  
47 classified as self-contained infilling, spatial interpolation, quantile mapping, and machine learning methods.

48 1. Self-contained infilling only uses records from the target station to estimate its own missing values. Typical methods  
49 include interpolation based on data from previous and subsequent days or replacing missing values by long-term  
50 mean (Kemp et al., 1983; Pappas et al., 2014). Self-contained infilling, however, only performs well for variables  
51 with high temporal autocorrelation such as temperature and is problematic for daily precipitation (Simolo et al.,  
52 2010; Teegavarapu and Chandramouli, 2005), and in covering lengthy data gaps.

53 2. Spatial interpolation uses neighboring stations (identified on spatial distance or statistical similarity) to estimate data  
54 at the target station. Spatial interpolation methods can be divided into two types: the first uses information only from  
55 neighboring stations; and common methods include linear interpolation and inverse distance weighting (IDW;  
56 Shepard, 1968). The second method needs information from both neighboring and target stations. Typical examples  
57 include the revised normal ratio (NR; Young, 1992) and the single best estimator (Eischeid et al., 1995, 2000), both  
58 of which use correlation coefficients (CCs) between target and neighboring stations to estimate merging weights.  
59 This second type of spatial interpolation also includes more sophisticated methods (e.g., multiple linear regression,  
60 optimal interpolation, and kriging) that build a functional relationship between neighboring and target stations  
61 (Simolo et al., 2010). Previous studies have shown that multiple linear regression based on the least absolute  
62 deviation criteria (MLAD) performs better than many interpolation methods such as IDW, NR, and optimal  
63 interpolation in infilling/reconstruction (Eischeid et al., 2000; Kanda et al., 2018).

64 3. Quantile mapping (QM) is widely used to correct biases in meteorological data (Maraun, 2013; Cannon et al., 2015)  
65 and performs well in estimating missing station data (Simolo et al., 2010; Newman et al., 2015, 2019; Devi et al.,

66 2019). In QM-based estimation, the cumulative distribution functions (CDFs) of observations from neighboring and  
67 target stations are derived, and the record at the target station is estimated as the inverse of its CDF using concurrent  
68 CDF probability information from neighboring stations. QM can avoid the problem of overestimating wet days in  
69 precipitation series and preserve the frequency distribution of time series, which is useful for estimating extreme  
70 events (Cannon et al., 2015).

71 4. Machine learning techniques have been successfully applied to infill station record gaps (Dastorani et al., 2010;  
72 Wambua et al., 2016). For example, Coulibaly and Evora (2007) estimated missing daily precipitation and  
73 temperature in northeastern Canada using six types of artificial neural networks (ANNs). Ustaoglu et al. (2008)  
74 estimated daily temperature using three ANN methods in the Geyve and Sakarya basin, Turkey. Gene expression  
75 programming was applied in the estimation of missing monthly rainfall data in Malaysia (Che Ghani et al., 2014).  
76 Sattari et al. (2017) recommended that a decision-tree algorithm can be used to estimate monthly precipitation due  
77 to its simplicity and high accuracy. Serrano-Notivoli et al. (2019) applied the  $k$ -nearest neighbours regression to  
78 reconstruct minimum temperature ( $T_{\min}$ ) and maximum temperature ( $T_{\max}$ ) observations in Spain to form a gridded  
79 dataset.

80 Previous SCDs have been developed using multiple infilling and reconstruction methods. For instance, Eischeid et al.  
81 (2000) produced a daily SCD from 1951 to 1991 for the western United States (U.S.), including 2962 precipitation  
82 stations and 2034 temperature stations; Vicente-Serrano et al. (2003) produced a daily SCD from 1901 to 2002 for  
83 northeast Spain using 3106 precipitation stations; Di Piazza et al. (2011) built a monthly SCD from 1921 to 2004 for  
84 Sicily, Italy using 247 precipitation stations; and Woldesenbet et al. (2017) produced a daily SCD of precipitation and  
85 temperature from 1980 to 2013 for the Upper Blue Nile Basin using six stations. There is currently no SCD for North  
86 America; this means that researchers often must collect station data from different databases, which is time-consuming  
87 and may cause inconsistencies between studies based on different methods.

88 Responding to this need, we develop a retrospective 40-year daily SCD for North America (SCDNA) of precipitation,  
89  $T_{\min}$  and  $T_{\max}$  from 1979 to 2018. Central America and Caribbean are also covered by SCDNA. The three variables  
90 are selected because (1) most stations measure precipitation and temperature, while other variables, such as humidity  
91 and wind speed are measured at fewer stations, and (2) precipitation and temperature data are fundamental inputs for  
92 hydrological modeling. Station observations are collected from four global and regional databases and undergo strict  
93 quality control to eliminate dubious records. Since the performance of infilling and reconstruction methods differs in  
94 space and time, the results from 16 strategies are merged to produce a single deterministic estimate. Finally, the  
95 SCDNA is compared to four gridded products to demonstrate its performance and areas for improvement. The SCDNA  
96 is expected to have a wide variety of applications in North America, and the methodology can be used to produce  
97 SCDs in other regions of the world.

## 98 2 Datasets

### 99 2.1 Meteorological station data

100 This study uses precipitation,  $T_{\min}$ , and  $T_{\max}$  station data from four databases, the Global Historical Climate Network  
101 Daily (GHCN-D; <https://www.ncdc.noaa.gov/ghcnd-data-access>; Menne et al., 2012), the Global Surface Summary  
102 of the Day (GSOD; <https://catalog.data.gov/dataset/global-surface-summary-of-the-day-gsod>), Environment and  
103 Climate Change Canada (ECCC; [https://climate.weather.gc.ca/historical\\_data/search\\_historic\\_data\\_e.html](https://climate.weather.gc.ca/historical_data/search_historic_data_e.html)), and the  
104 Mexico database from Servicio Meteorológico Nacional, under the Comisión Nacional del Agua (Livneh et al., 2015).  
105 This study uses daily precipitation totals from each dataset. Only stations with at least 8-year precipitation or  $T_{\min}$  and  
106  $T_{\max}$  records between 1979 to 2018 are utilized. The requirement for minimum recording length is different among  
107 studies (e.g., Eischeid et al., 2000; Newman et al., 2015). We adopted a relatively short time limitation because (1) 8-  
108 year records are sufficient to provide basic support for missing value estimation (Fig. S1), and (2) the open-access  
109 dataset and codes enable users to design customized data selection criteria according to their research requirements.

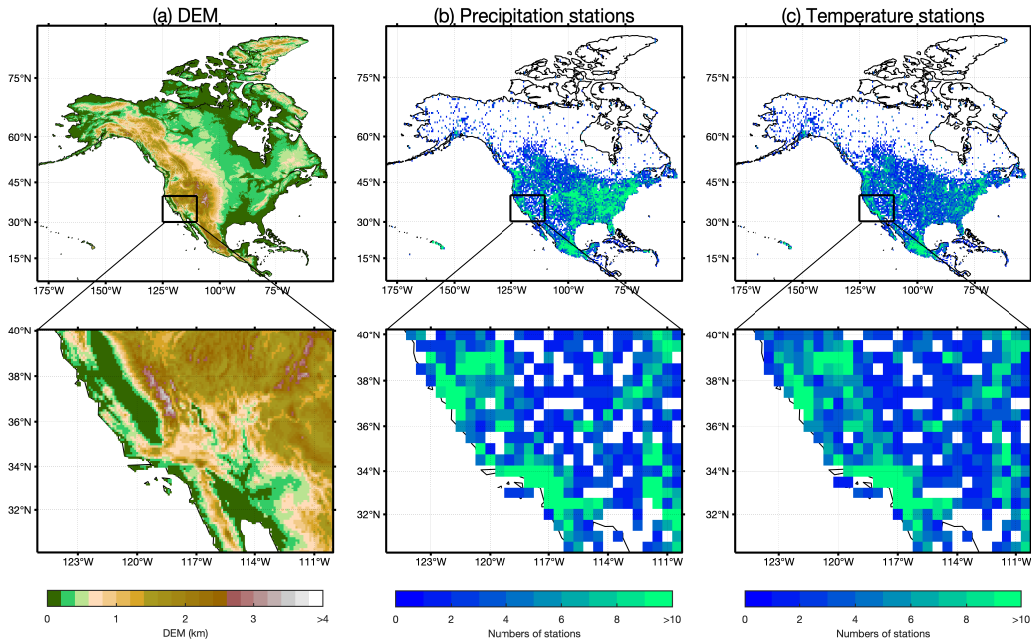

110 The numbers of stations with at least 8-year records are 33026, 4619, 3634, and 4049 for GHCN-D, GSOD, ECCC,  
111 and the Mexico database, respectively (Table 1). Their spatial distributions are shown in Fig. S2. GHCN-D has  
112 compiled a large amount of data from many sources including the Mexico database and ECCC. For identical stations  
113 from different sources, we keep the one with longer observation history, resulting in the exclusion of ~95% of stations  
114 from the Mexico database and adoption of ~91% of stations from ECCC. Stations with more than 30% missing values  
115 in the observation period are excluded because they could be seasonal stations or suffer serious instrumentation  
116 problems. Stations overlapping in space (same latitude and longitude) and without sufficient metadata for  
117 discrimination are merged (see Sect. 3.2). The above screening reduces the available stations from 45328 to 31772  
118 (Table 1), yet more stations are discarded due to quality control procedures (Sect. 3.1). The final SCDNA includes  
119 24615 precipitation, 19604  $T_{\min}$ , and 19611  $T_{\max}$  stations; note that the numbers of  $T_{\min}$  and  $T_{\max}$  stations differ as  
120 quality controls can result in excluding the one and reserving the other in some stations.

121 Most stations are located in the Contiguous United States (CONUS), southern Canada, and Mexico, while few stations  
122 are located in high-latitude regions such as the Arctic Archipelago (Fig. 1b and c). The spatial distributions of  
123 precipitation and temperature stations are similar, except in eastern CONUS where precipitation stations have a higher  
124 density.

125 Table 1. Numbers of stations with at least 8-year records from 1979 to 2018

Station numbers	GHCN-D	GSOD	ECCC	Mexico	Merge	Total
Original numbers	33026	4619	3634	4049	0	45328
SCDNA input	24765	4331	3100	187	207	31772
SCDNA output: precipitation	19255	2551	2440	170	199	24615
SCDNA output: $T_{\min}$	13394	3631	2219	166	194	19604

126 Notification: “Merge” is derived from stations with overlapped locations from all the other data sources (Sect. 3.1.1).

127

128 Figure 1. (a) Digital elevation model (DEM; Sect. 2.3) of North America. (b) and (c) are the densities of stations at  
 129 the  $0.5^\circ \times 0.5^\circ$  resolution for precipitation and temperature, respectively.  $T_{\min}$  and  $T_{\max}$  stations are highly consistent,  
 130 and thus  $T_{\min}$  is used to represent temperature in (c). The nested black boxes show examples of DEM and station  
 131 densities.

132 In North America, more station observations occur in the U.S. than in Canada and Mexico (Fig. 2). The number of  
 133 samples in the U.S. increases from 1979 to 2018, and there are more precipitation samples than temperature samples.  
 134 For Canada, the numbers of precipitation and temperature samples are similar and show a decrease from 1988 to 2018;  
 135 the sample number in 2018 is only 61.76% of that in 1988. Mexico has more meteorological samples than Canada,  
 136 yet this number decreases after 1983. The decreasing trend is especially sharp after 2012 which may be due to the  
 137 delay in data collection or termination of some stations.

138 Figure 3 shows the fractions of missing values for all stations during the observation period (referred as ratio-1) and  
 139 during the entire period from 1979 to 2018 (referred as ratio-2). For temperature,  $\sim 20\%$  of the stations have more than  
 140 20% missing values in the observation period (ratio-1), and  $\sim 20\%$  of the stations have more than 70% missing values  
 141 in the entire period (ratio-2). For precipitation, the fraction of missing values is larger. The fractions show strong  
 142 spatial variations (Fig. S3). Ratio-2 is smaller for precipitation stations in western U.S. and temperature stations in  
 143 central U.S., but larger in Canada and Alaska. Most stations in Mexico have higher ratio-1 than other regions in North  
 144 America, indicating that those stations have notable fractions of missing values during the observation period.

145 In summary, the curves of ratio-1 indicate that a small number of missing values need infilling during the observation  
 146 period, while the curves of ratio-2 indicate that extensive reconstruction is needed over the entire period.

147

148 Figure 2. Sample numbers of stations for each year from 1979 to 2018. CA represents Canada, US represents United  
 149 States, and MX represents Mexico.  $T_{max}$  stations are highly consistent with  $T_{min}$  stations, and thus  $T_{min}$  is used to  
 150 represent temperature. The numbers of samples could be a better indicator than the numbers of stations because many  
 151 stations have notable missing values.

152

153 Figure 3. The fraction of missing values for stations with at least 8-year records. Ratio-1 is the degree of missingness  
 154 during the observation period, and ratio-2 is the degree of missingness during the entire period of interest (1979 to  
 155 2018).  $T_{\min}$  is used to represent temperature because  $T_{\max}$  show almost overlapped curves with  $T_{\min}$ .

156 Many types of precipitation and temperature measurement instruments are used at stations from different sources. For  
 157 example, the Type-B rain gauge is used by Environment Canada since 1970s for most weather stations (Devine and  
 158 Mekis, 2008; Wang et al., 2017), while tipping bucket and weighing rain gauges are also used in some stations  
 159 (Metcalfé et al., 1997). Nipher-shielded snow gauges have been used by some synoptic stations, while ruler  
 160 measurements are still used by more stations (Mekis and Brown, 2010). Station data in the U.S. are from many  
 161 organizations or programs with different instrument configurations. For instance, the standard rain gauge is used by  
 162 the Cooperative Observer Program while Snow Telemetry uses storage-type gauges or tipping buckets. A better  
 163 understanding of instrument specifications and historical changes is important for climate studies (Pielke Sr et al.,  
 164 2007; Whitfield, 2014; Ma et al., 2019). A detailed summary of station instruments is provided in the documentation  
 165 of the dataset (<https://doi.org/10.5281/zenodo.3735533>).

166 **2.2 Reanalysis products**

167 We use reanalysis precipitation,  $T_{\min}$  and  $T_{\max}$  from the fifth generation of European Centre for Medium-Range  
 168 Weather Forecasts (ECMWF) atmospheric reanalyses of the global climate (ERA5; Copernicus Climate Change  
 169 Service (C3S), 2017), the Japanese 55-year Reanalysis (JRA-55; Kobayashi et al., 2015), and the Modern-Era  
 170 Retrospective analysis for Research and Applications, Version 2 (MERRA-2; Gelaro et al., 2017) (see Table 2). The  
 171 three products are chosen because they are representative products from different international organizations and they  
 172 or their predecessor (ERA-Interim, JRA-25, and MERRA) have been widely used by researchers. The ERA5 and  
 173 JRA-55 do not provide daily outputs, thus, daily precipitation is accumulated from sub-daily estimates while daily  
 174  $T_{\min}$  and  $T_{\max}$  are estimated by the sub-daily minimum and maximum temperature values. Gridded reanalysis  
 175 precipitation is linearly interpolated to match point-scale station data, and  $T_{\min}$  and  $T_{\max}$  are downscaled using  
 176 temperature lapse rate (TLR; see Sect. 3.1).

177 Table 2. Information on the three reanalysis products.

<b>Products</b>	<b>Spatial resolution</b>	<b>Temporal resolution</b>	<b>Period</b>	<b>Agency</b>
ERA5	0.25°×0.25°	1 h	1979-present	European Centre for Medium-Range Weather Forecasts
JRA-55	~55 km	3 h	1958-present	Japan Meteorological Agency
MERRA-2*	0.5°×0.625°	daily	1980-present	NASA’s Global Modeling and Assimilation Office

178 \* MERRA-2 provides outputs in temporal resolutions from 1 h to 1 month; here we use daily values.

179 **2.3 Auxiliary data**

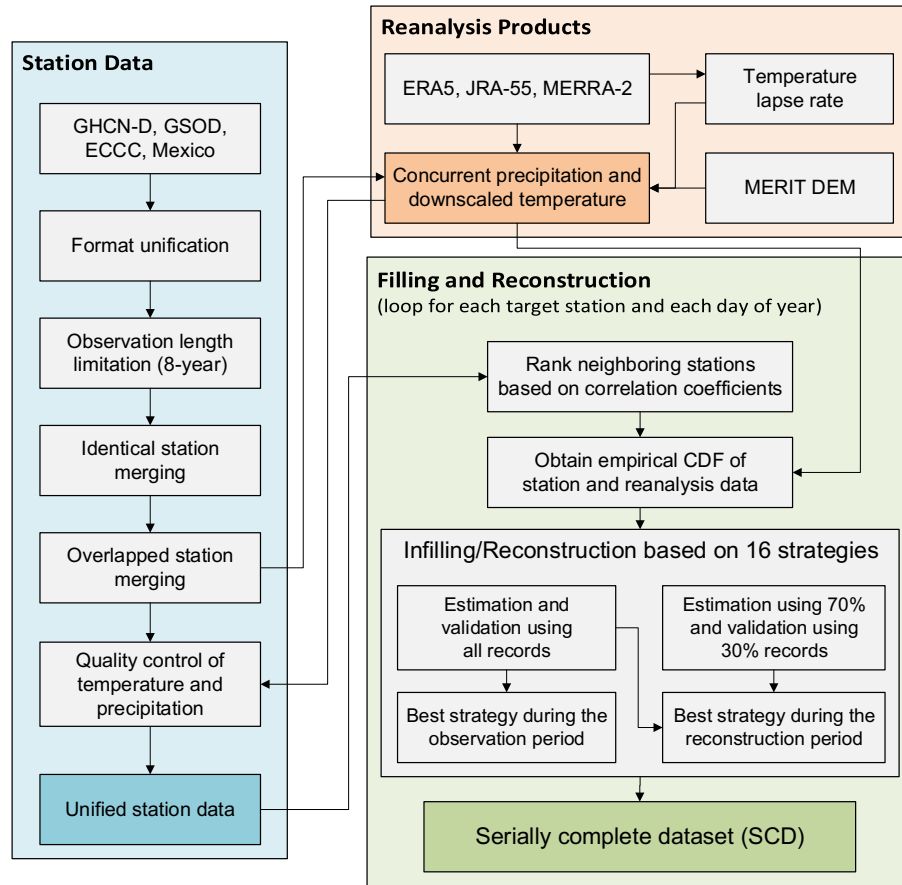

180 The Multi-Error-Removed Improved-Terrain digital elevation model (MERIT DEM) at a 3 sec (~90 m at the equator)  
181 resolution (Yamazaki et al., 2017) is used in this study. To enable temperature downscaling, the high-resolution DEM  
182 is spatially averaged to the original resolutions of ERA5, MERRA-2, and JRA-55 (Table 2). The MERIT DEM may  
183 be slightly different than the DEM data used in the three reanalysis products, and this will have a limited impact on  
184 missing data estimation (Sect. 3.3.2).

185 The Multi-Source Weighted-Ensemble Precipitation (MSWEP) V2.2 dataset (Beck et al., 2017, 2019) is utilized for  
186 the comparison with the SCDNA developed by this study. MSWEP merges data from ground observations, satellite  
187 products, and reanalysis models, and performs better than all products used for merging (Beck et al., 2019). The  
188 comparison can show whether the SCDNA is a better choice than MSWEP to fill gaps in station precipitation  
189 observations.

190 **3 Methodology**

191 The methodology to produce the SCDNA includes three primary steps (Fig. 4): (1) preparing a unified precipitation  
192 and temperature database from multiple sources (Sect. 2.1 and 3.1); (2) downscaling reanalysis estimates (Sect. 2.2  
193 and 3.2) that are used in QM- and machine learning-based data estimation (Sect. 3.3) and comparison with the SCDNA  
194 (Sect. 4.5); and (3) producing the SCDNA from 1979 to 2018 based on 16 strategies (Sect. 3.3). The following sub-  
195 sections summarize the work in each step of the methodology (Sect. 3.1, 3.2, and 3.3) as well as the approach used to  
196 evaluate the performance of the method (Sect. 3.4).

197

198 Figure 4. Flowchart of the production of the SCDNA, including station data preparation, reanalysis product processing,  
 199 and missing data infilling and reconstruction.

200 In this study, infilling refers to the estimation of missing values during the observation period, while reconstruction  
 201 refers to estimating values outside of the observation period when no station record is available (Fig. 5). Station records  
 202 that fail quality control are treated as missing values.

### 203 3.1 Prepare a unified precipitation and temperature database

#### 204 3.1.1 Merging of stations based on location

205 Stations are merged if their latitude and longitude match other stations. The problem of overlapped locations is caused  
 206 by identification alteration of one station for different periods, recording/rounding bias of station location information,  
 207 inconsistent naming rules of different sources, and other factors. Although it is possible that multiple stations are  
 208 deployed in the same location for experimental aims, location merging is done to preserve internal consistencies as  
 209 inconsistent records at the same location are self-contradictory.

210 The method for location merging includes several steps. First, overlapping stations are extracted and grouped. Stations  
 211 within the same group that have non-overlapping recording periods are simply merged into one time series. Otherwise,

212 the Spearman’s rank CC (SCC) between precipitation series from all station pairs in the group is calculated. For SCC  
213  $< 0.7$ , the station group is discarded due to large discrepancies; for  $0.7 < SCC < 0.9$  the discrepancy is considered as  
214 tolerable and the station with the longest record is kept; for  $SCC > 0.9$  stations are considered as highly correlated and  
215 their data are merged into one time series, while for overlapping periods the station with the longest record is used.

216 Overall, 1240 stations are involved in location merging, stratified in 586 station groups. Around 10% of the groups  
217 contain more than two stations and the largest group contains five stations. After location merging, only 207 groups  
218 are kept and merged into unified times series (Table 1). Despite the steps taken above, the merged series could contain  
219 inhomogeneities due to the combination of records from multiple stations.

### 220 3.1.2 Quality control

221 To ensure station observations undergo strict and comprehensive quality control, we adopted the methods used to  
222 produce previous station-based datasets. For  $T_{\min}$  and  $T_{\max}$ , we followed the method designed by Durre et al. (2010)  
223 which is adopted by GHCN-D (Menne et al., 2012). The procedures include five types of checks: integrity checks,  
224 outlier checks, internal and temporal consistency checks, spatial consistency checks, and extreme megaconsistency  
225 checks. A few of the procedures in Durre et al. (2010) require other variables such as snowfall, and thus are not  
226 adopted in this study. In addition, the quality flags in this study are partly different with those of GHCN-D because of  
227 the different sources, numbers and temporal periods of stations.

228 For precipitation, quality control procedures consist of three parts. The first part is similar with that for temperature.  
229 The second part (four types of checks) follows procedures designed by Hamada et al. (2011) which are adopted by  
230 the Asian Precipitation-Highly-Resolved Observational Data Integration Towards Evaluation (APHRODITE; Yatagai  
231 et al., 2012). The third part (two types of checks) adopts strategies by Beck et al. (2019) used in the production of  
232 MSWEP. Note that although Durre et al. (2010) and Hamada et al. (2011) share some common traits for precipitation,  
233 both of them are adopted to ensure quality control reliability.

234 The details of quality checks are in Appendix B.

### 235 3.2 Downscale reanalysis data

236 The reanalysis temperature estimates are downscaled to match point-scale station observations using temperature lapse  
237 rate (TLR) according to

$$T_s = T_R + \text{TLR} \times \Delta h \quad (1)$$

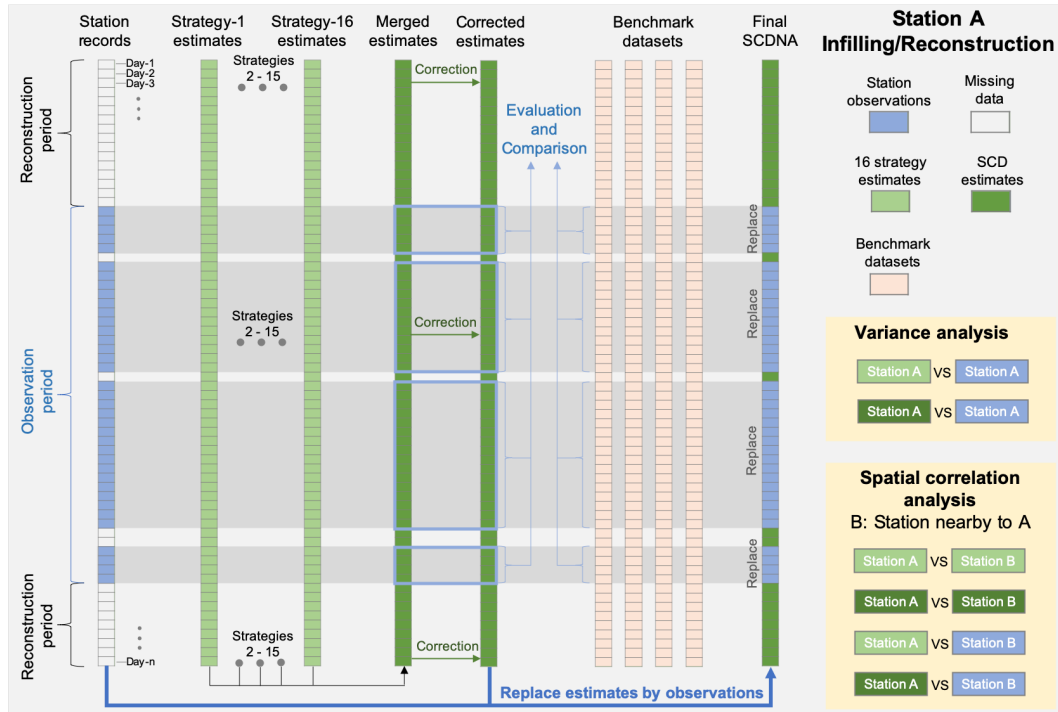

238 where  $T_R$  is 2-m reanalysis air temperature,  $T_s$  is downscaled temperature,  $\Delta h$  is the height difference between station  
239 elevation and reanalysis grid elevation. TLR shows notable spatiotemporal variations (Minder et al., 2010) and  
240 estimating TLR based on ground observations over a large domain is difficult due to the sparsity of stations. Yet recent  
241 studies show that reanalysis outputs offer an alternative in estimating gridded TLR (e.g., Gao et al., 2012). The gradient  
242 of air temperature at different pressure levels above the ground can be used to approximate near-surface TLR (Gao et

243 al., 2012, 2018; Gruber, 2012). Tang et al. (2018) compared eight temperature downscaling methods in CONUS and  
244 found that methods based on reanalysis-derived TLR can achieve higher accuracy compared to fixed TLR (e.g., -  
245 6.5°C/km) or statistical interpolation downscaling methods. Hence, this study uses the linear regression slope between  
246 MERRA-2 air temperature and geopotential heights from 300 hPa to 1000 hPa pressure levels to represent TLR for  
247 each month at the resolution of 0.5°×0.625° (Table 2). MERRA-2 is used because it directly provides monthly data  
248 and masks temperature data if the pressure level is below land surface. The choice of pressure levels needs further  
249 investigation because relationships between vertical and near-surface temperature vary with regions. Complicated  
250 TLR phenomena such as inverse lapse rate are not considered for simplicity. The climatological mean of TLR (Fig.  
251 S4) decreases from -4.8°C/km in the northeast continent (i.e., Canadian Arctic Archipelago) to -7.2°C/km in the  
252 southwest continent (i.e., Rocky Mountains in CONUS). The smaller TLR magnitude in high latitudes is consistent  
253 with previous studies (e.g., Gardner et al., 2009; Marshall et al., 2007).

### 254 **3.3 Produce the serially complete dataset**

255 To produce the high-quality SCDNA for North America, we use 16 strategies: four based on quantile mapping with  
256 neighboring stations (QMN; e.g., Longman et al., 2019; Newman et al., 2015, 2019), four on quantile mapping with  
257 concurrent reanalysis estimates (QMR), four using spatial interpolation methods (INT; e.g., Eischeid et al., 2000;  
258 Kanda et al., 2018; Woldesenbet et al., 2017), two using machine learning methods (MAL; e.g., Dastorani et al., 2010;  
259 Wambua et al., 2016), and two multi-strategy merging methods (MRG). Merging multiple infilling/reconstruction  
260 methods can provide better estimation than individual methods, as shown by previous data merging and gap infilling  
261 studies (e.g., Eischeid et al., 2000; Beck et al., 2017, 2019; Ma et al., 2018).

262 We generate estimates for every station and every day from 1979 to 2018 (Fig. 5). The estimates from these 16  
263 strategies and the SCDNA are evaluated using station observations, and the performance of the SCDNA is compared  
264 to four benchmark gridded products. Then, the estimates of the SCDNA are corrected for further accuracy  
265 improvement. Finally, estimates are replaced by station observations when observations exist and pass quality control  
266 checks. The variance and spatial correlation analyses are performed to compare the statistical properties of station  
267 observations and estimates (see Sect. 4).

268

269 Figure 5. Diagram of the infilling and reconstruction for a specific station (referred to as A). The entire period from  
 270 1979 to 2018 is divided into the observation period and the reconstruction period. The data flows of variance and  
 271 spatial correlation analyses are shown in the nested yellow boxes. Station B is a nearby station of A.

272 Only stations with at least 3000 valid values are included in the infilling and reconstruction effort. The nine steps  
 273 (termed Step-1 to Step-9) of SCDNA production are described as below. Unless otherwise stated, the steps are  
 274 implemented for each target station ( $s$ ), each variable (precipitation,  $T_{min}$ , and  $T_{max}$ ), and each day of the year (DOY,  
 275 i.e., 1-366).

### 276 3.3.1 Data extraction

277 **Step-1:** Spatiotemporally concurrent reanalysis estimates (ERA5, JRA-55, and MERRA-2) are extracted, including  
 278 precipitation,  $T_{min}$ ,  $T_{max}$ , and TLR. Precipitation is linearly interpolated from gridded reanalysis estimates, and  
 279 temperature is downscaled (i.e., corrected for the elevation difference between the reanalysis grid cell and the station  
 280 elevation) based on TLR (Sect. 3.1).

281 **Step-2:** Neighboring stations (at least one and at most 30) with at least 8-year overlapped period with station  $s$  are  
 282 found within the searching radius of 200 km. These stations are ranked from closest to farthest according to their CC  
 283 with the target station. SCC is used for precipitation, and Pearson CC (PCC) is used for  $T_{min}$  and  $T_{max}$ . CC is calculated  
 284 using data within a 31-day window centered around the current DOY from all years.

285 **Step-3:** The empirical CDFs of  $s$ , neighboring stations, and reanalysis estimates are obtained using data within the  
 286 same 31-day window.

287 3.3.2 Infilling and reconstruction

288 **Step-4:** For each day ( $d$ ) corresponding to the DOY, the estimated data are acquired based on 16 strategies which are  
 289 divided into five groups.

290 **Group 1: Quantile Mapping with Neighboring stations (QMN)**

- 291 • **QMN-1:** For all neighboring stations with valid records, the station with the highest CC in Step-2 is selected.  
 292 The estimated data for  $s$  and  $d$  is obtained using Eq. (2).

$$X_s = F_s^{-1}(F_i(X_i)) \quad (2)$$

293 where  $X_i$  is precipitation or temperature for  $d$  from the selected neighboring station  $i$ ,  $F_i$  is the empirical CDF of  
 294  $i$  corresponding to the DOY,  $F_s^{-1}$  is the inverse CDF of  $s$  corresponding to the DOY, and  $X_s$  is the estimated data.

- 295 • **QMN-2:** For all neighboring stations with observations, estimated values are obtained using Eq. (2) which are  
 296 merged based on Eq. (3).

$$X_s = \frac{\sum_i^n W_i F_s^{-1}(F_i(X_i))}{\sum_i^n W_i} \quad (3)$$

$$W_i = CC_i^2 \quad (4)$$

297 where  $n$  is the number of neighboring stations,  $F_s^{-1}(F_i(X_i))$  is the QM-based estimate from  $i$ , and  $W_i$  is the weight  
 298 calculated using Eq. (4).  $CC_i$  is CC (SCC or PCC) between data from  $s$  and  $i$  corresponding to the DOY.  $W_i$  is  
 299 assigned zero if  $CC_i$  is negative.

- 300 • **QMN-3:** Similar to QMN-2, but the weight is calculated according to the distance ( $D_i$ ) between  $s$  and  $i$  based on  
 301 Eq. (5). Although the exponent of distance ( $k$ ) varies in different studies, -2 is the most common choice  
 302 (Teegavarapu and Chandramouli, 2005).

$$W_i = D_i^k \quad (5)$$

- 303 • **QMN-4:** The median of QMN-1 to QMN-3 is used as the estimated data. The strategy of using median values is  
 304 the same with Eischeid et al (2000), which could be closer to actual observations than QMN-1 to 3.

305 **Group 2: Quantile Mapping with Reanalysis products (QMR)**

306 Reanalysis products provide useful information for SCDNA production as (1) remote regions may not have enough  
 307 neighboring stations, and (2) neighboring stations also have missing values which could result in gaps of estimates at  
 308 the target station.

309 • **QMR-1 to QMR-3:** Similar to QMN-1, but the neighboring station is replaced by concurrent ERA5, JRA-55,  
310 and MERRA-2 estimates, respectively.

311 • **QMR-4:** The median of QMR-1 to 3 is used as the estimated data.

### 312 **Group 3: Interpolation (INT)**

313 The three interpolation methods used in this study are MLAD (referred as INT-1), NR (referred as INT-2), and inverse  
314 distance weighting (IDW, referred as INT-3). They are described below. Following Eischeid et al. (2000), neighboring  
315 stations with CC lower than 0.35 are excluded. The remaining stations are ranked from high CC to low CC. A  
316 maximum of four neighboring stations are used in the interpolation. For  $T_{\min}$  and  $T_{\max}$ , direct interpolation from  
317 neighboring stations to  $s$  could be biased due to the elevation differences between stations. Temperature data from  
318 neighboring stations are downscaled to the elevation of  $s$  based on Eq. (1).

319 • **INT-1:** MLAD minimizes the sum of absolute errors. It is more robust than regression based on least squares  
320 because while least square estimation is effective when the errors are normally distributed and independent,  
321 environmental variables, especially precipitation, often violate the assumption of normality (Eischeid et al.,  
322 2000). MLAD has been well documented with better performance in gap infilling than other interpolation  
323 methods (Eischeid et al., 1995, 2000; Kanda et al., 2018; Young, 1992). The formula is shown in Eq. (6).

$$X_s = c_0 + \sum_i^n c_i X_i \quad (6)$$

324 where  $c_i$  ( $i = 0, 1, \dots, n$ ) is regression coefficients estimated using data within a 31-day window for each DOY.  
325 Different  $d$  corresponding to the same DOY could have different combinations of neighboring stations due to the  
326 limitation of observation availability. MLAD is performed for each combination to ensure that effective estimates  
327 are available for all days.

328 • **INT-2:** NR is an interpolation method proposed by Paulhus and Kohler (1952) and modified by Young (1992).  
329 The modified version is adopted in this study, which combines information from neighboring stations by  
330 replacing  $F_s^{-1}(F_i(X_i))$  with  $X_i$  in Eq. (3). The weight is calculated using Eq. (7).

$$W_i = CC_i^2 \frac{N_i - 2}{1 - CC_i^2} \quad (7)$$

331 where  $N_i$  is the number of samples used to calculate  $CC_i$  between  $s$  and  $i$ . SCC is used for precipitation and PCC  
332 is used for temperature.

333 • **INT-3:** IDW is one of the most common interpolation methods. It is implemented similar to NR, where the  
334 inverse squared distance, as shown in Eq. (5), is used as the weight.

- 335 • **INT-4:** The median of INT1, INT2 and INT3 is used as the estimated data.

336 **Group 4: Machine Learning (MAL)**

337 The two MAL methods used in this study are ANN (referred as MAL-1) and random forest (RF, referred as MAL-2;  
338 Breiman, 2001). Unlike QMN, QMR and INT that are carried out for each DOY, MAL uses complete observation  
339 records of  $s$  to ensure that ANN and RF are trained with enough values. MAL models are trained using the first 70%  
340 observations and tested using the remaining 30% observations. The MAL models' validation based on the 30%  
341 observations can indicate their performance in the reconstruction period.

342 The input data are from neighboring stations and concurrent reanalysis estimates. For each  $s$ , neighboring stations are  
343 determined in a way similar with Step-2, but CC is calculated using data in the entire observation period. Neighboring  
344 stations with CC lower than all reanalysis products (ERA5, JRA-55, and MERRA-2) are excluded. The remaining  
345 neighboring stations and three reanalysis products form a complete repository of input features. Then, for each day  
346 that  $s$  has no observation, the input features are extracted from the repository in three steps: (1) neighboring stations  
347 without observations for the day are excluded, (2) the remaining neighboring stations and reanalysis products are  
348 ranked according to their CC with  $s$ , and (3) at most five stations/reanalysis products with the highest CC are selected.  
349 In this way,  $s$  will have multiple combinations of input features to ensure that all days with missing values have  
350 estimates. All combinations are used to train and test the ANN and RF models, resulting in multiple estimated series  
351 for  $s$ . The final estimates of  $s$  are generated in three steps: (1) the Kling-Gupta Efficiency (KGE'; Kling et al., 2012)  
352 of all estimated series is calculated using all observations of  $s$ , and ranked from high to low KGE' (see Sect. 3.4 for  
353 definition of KGE'); (2) the series with higher KGE' is used to constitute the estimates of  $s$  in sequence; and (3) the  
354 second step is repeated until there are no missing values for  $s$ . This approach ensures that "best" and complete estimates  
355 are provided for  $s$ .

- 356 • **MAL-1:** A four-layer ANN is used. The input layer has a maximum of five nodes (depending on the number of  
357 input features), the two hidden layers both have 20 nodes, and the output layer has one node for generating  
358 precipitation or temperature estimates. The transfer functions are hyperbolic tangent sigmoid for hidden layers  
359 and linear for the output layer. The training function is resilient backpropagation. The model is trained using the  
360 first 50% data, validated using the subsequent 20% data, and tested using the final 30% data.

- 361 • **MAL-2:** A RF model with 50 trees is built with 70% training data and 30% testing data. The minimum number  
362 of samples per tree leaf is 5. The input nodes depend on the number of input features like MAL-1.

363 **Group 5: Multi-Strategy Merging (MRG)**

- 364 • **MRG-1:** KGE' is used to rank the performance of the 11 strategies (QMN-1 to 3, QMR-1 to 3, INT-1 to 3,  
365 and MAL-1 to 2) as CC cannot reflect the magnitude difference (e.g., bias) between target and reference

366 series. The first three cases of the 11 strategies are merged using squared KGE' as the weight. The individual  
367 weight is assigned zero if KGE' is negative.

- 368 • **MRG-2:** The median of the three selected strategies in MRG-1 is used as the estimated data.

### 369 3.3.3 Generating serially complete records

370 **Step-5:** In this step, Step-3 and -4 are repeated based on 70% data of  $s$  in the observation period. Then, the KGE' of  
371 estimates from all strategies are calculated using the remaining 30% observations. MAL-1 and 2 are not repeated  
372 because they are trained on 70% observations. Although the evaluation samples are different among stations, the  
373 results are reliable and stable as shown in the results section. This step is implemented because QMN-1 to 4, QMR-1  
374 to 4, and INT-1 in Step-4 use all data of  $s$  in the observation period to select stations, estimate empirical CDFs and  
375 carry out regression. This potential overfitting problem could lead to better performance of these strategies in the  
376 observation period but worse performance in the reconstruction period. KGE' calculated in Step-4 can represent the  
377 accuracy of estimates in the observation period, while KGE' calculated in Step-5 can represent the accuracy of  
378 estimates in the reconstruction period.

379 **Step-6:** In the observation period, the strategy with the highest KGE' in Step-4 is selected to contribute the  
380 extension/reconstruction to the SCDNA. In the reconstruction period, first, the strategy with the highest KGE' in Step-  
381 5 is determined; then, the estimates from the corresponding strategy in Step-4 are used to constitute the SCDNA  
382 because the empirical CDF and regression based on all observations in Step-4 could be more representative than the  
383 70% observations in Step-5.

384 **Step-7:** Estimates in Step-6 are corrected for certain climatological biases using station data in the observation period.  
385 Precipitation estimates are often subjected to wet-day bias. Two methods are implemented to address this problem.  
386 First, QM is performed based on the CDF of  $s$  in Step-3. However, QM may reduce the accuracy of estimated  
387 precipitation in some cases, for which the method used in Beck et al. (2019) is adopted. This method subtracts a tiny  
388 value (0.01 mm) from the original precipitation series and rescales the series to restore the original mean value. This  
389 operation is repeated until the estimated series show an equal number of wet days ( $>0.5$  mm d<sup>-1</sup>) with observations of  
390  $s$ . In addition to wet-day bias correction, mean-value correction is implemented. The ratio between the mean values  
391 of precipitation estimates and observations is calculated in the observation period, which is used to rescale estimated  
392 series in both observation and reconstruction periods. For  $T_{\min}$  and  $T_{\max}$ , QM correction and mean-value correction are  
393 also implemented.

394 **Step-8:** The accuracy of the SCDNA is evaluated and compared to benchmark datasets based on actual observations  
395 (Fig. 5). Then, the estimates are replaced by observations whenever possible to generate the final SCDNA. Very  
396 occasionally, estimated  $T_{\min}$  could be larger than estimated  $T_{\max}$ , for which  $T_{\max}$  is replaced by the maximum  $T_{\max}$ , and  
397  $T_{\min}$  is replaced by the minimum  $T_{\min}$  of the estimates from the 16 strategies.

398 **Step-9:** The serially complete data of SCDNA is quality controlled again using methods introduced Sect. 3.1.2 to  
 399 exclude stations with unreliable estimates.

### 400 **3.4 Evaluate the precipitation and temperature estimates**

401 KGE', which is proposed by Gupta et al. (2009) and modified by Kling et al. (2012), is used to support the merging  
 402 of different strategies (Sect. 3.3) and the evaluation of the estimated precipitation and temperature.

$$\begin{cases} KGE' = 1 - \sqrt{(r - 1)^2 + (\beta - 1)^2 + (\gamma - 1)^2} \\ \beta = \frac{\mu_s}{\mu_o} \\ \gamma = \frac{CV_s}{CV_o} = \frac{\sigma_s/\mu_s}{\sigma_o/\mu_o} \end{cases} \quad (8)$$

403 where  $r$  is the PCC,  $\beta$  is the bias ratio, and  $\gamma$  is the variability ratio;  $\mu$  is the mean value, and  $\sigma$  is the standard  
 404 deviation. The subscripts  $s$  and  $o$  represent estimated and reference time series, respectively. KGE' ranges from  
 405 negative infinity to one. If two series exactly match, the KGE' is one. A  $\beta$  or  $\gamma$  value smaller/larger than one indicates  
 406 that the mean value or variability of observations is underestimated/overestimated.

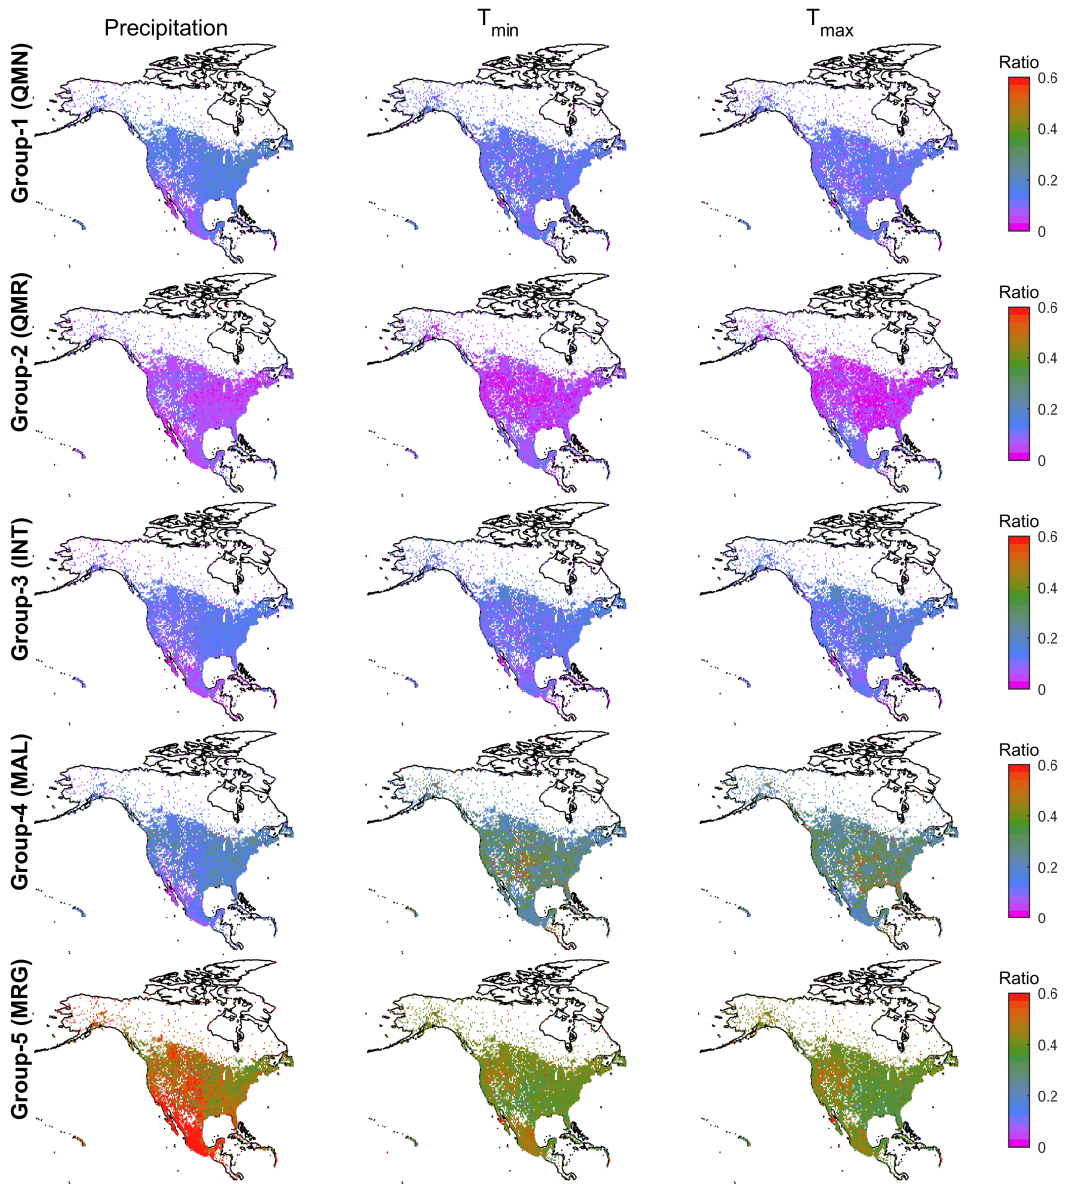

407 In Sect. 4, the evaluation during the observation period is based on the complete station observations (i.e., Step-4 in  
 408 Sect. 3.3.2), while the evaluation during the reconstruction period is realized using 30% independent station  
 409 observations (i.e., Step-5 in Sect. 3.3.3). Unless otherwise stated, SCDNA estimates in Sect. 4 are after correction  
 410 (Step-7 in Sect. 3.3.3). In Sect. 4.5, SCDNA estimates are compared with gridded products (ERA5, JRA-55, MERRA-  
 411 2, and MSWEP). In addition to the three SCDNA variables (precipitation,  $T_{\min}$ , and  $T_{\max}$ ), mean temperature ( $T_{\text{mean}}$ ,  
 412 the mean of  $T_{\min}$  and  $T_{\max}$ ) and daily temperature range ( $T_{\text{range}}$ , the difference between  $T_{\max}$  and  $T_{\min}$ ) are also included.  
 413 The involvement of  $T_{\text{range}}$  can contribute to more objective comparison between SCDNA and reanalysis products  
 414 because the TLR-based downscaling of reanalysis temperature contains uncertainties, which could affect the  
 415 evaluation of  $T_{\min}$ ,  $T_{\max}$ , and  $T_{\text{mean}}$ . Although there exist differences between TLR of  $T_{\min}$  and  $T_{\max}$ ,  $T_{\text{range}}$  can reduce  
 416 the effect of scale-mismatch between gridded reanalysis temperature and point station temperature on evaluation  
 417 results.

## 418 **4 Results**

### 419 **4.1 Comparison of infilling and reconstruction strategies**

420 The value of a given infilling/reconstruction strategy can be quantified by the extent that a strategy is selected for use  
 421 in the final SCDNA dataset. In this sense, the contribution ratios define the proportion of estimates that come from a  
 422 specific strategy. Fig. 6 shows that the contribution ratios of QMN, QMR, and INT to missing value estimation are  
 423 generally smaller than 20% in North America. Please note that QMN refers to all strategies within this group unless  
 424 the strategy number is specified right after QMN. This also applies to other groups. QMR shows the smallest  
 425 contribution ratios for almost all stations among the five groups. Compared with other regions in North America,

426 contribution ratios of QMR are higher for precipitation stations in western U.S. and temperature stations in Mexico.  
 427 INT shows lower contribution ratios in the Rocky Mountains compared with the western U.S., indicating statistical  
 428 interpolation without considering topographic effect is subjected to substantial uncertainties in complex terrain. MAL  
 429 shows notably higher contribution ratios than QMN, QMR, and INT, particularly for  $T_{\min}$  and  $T_{\max}$ . The ratios of MAL  
 430 are higher than 20% for ~30% precipitation stations, ~65%  $T_{\min}$  stations, and ~68%  $T_{\max}$  stations. MRG has the highest  
 431 contribution ratios throughout North America. The average contribution ratios of MRG are 59.88%, 41.59%, and  
 432 40.56% for precipitation,  $T_{\min}$ , and  $T_{\max}$ , respectively. For precipitation, MRG is particularly effective in high-latitude  
 433 regions (northern Canada and Alaska), western U.S. and Mexico.

434

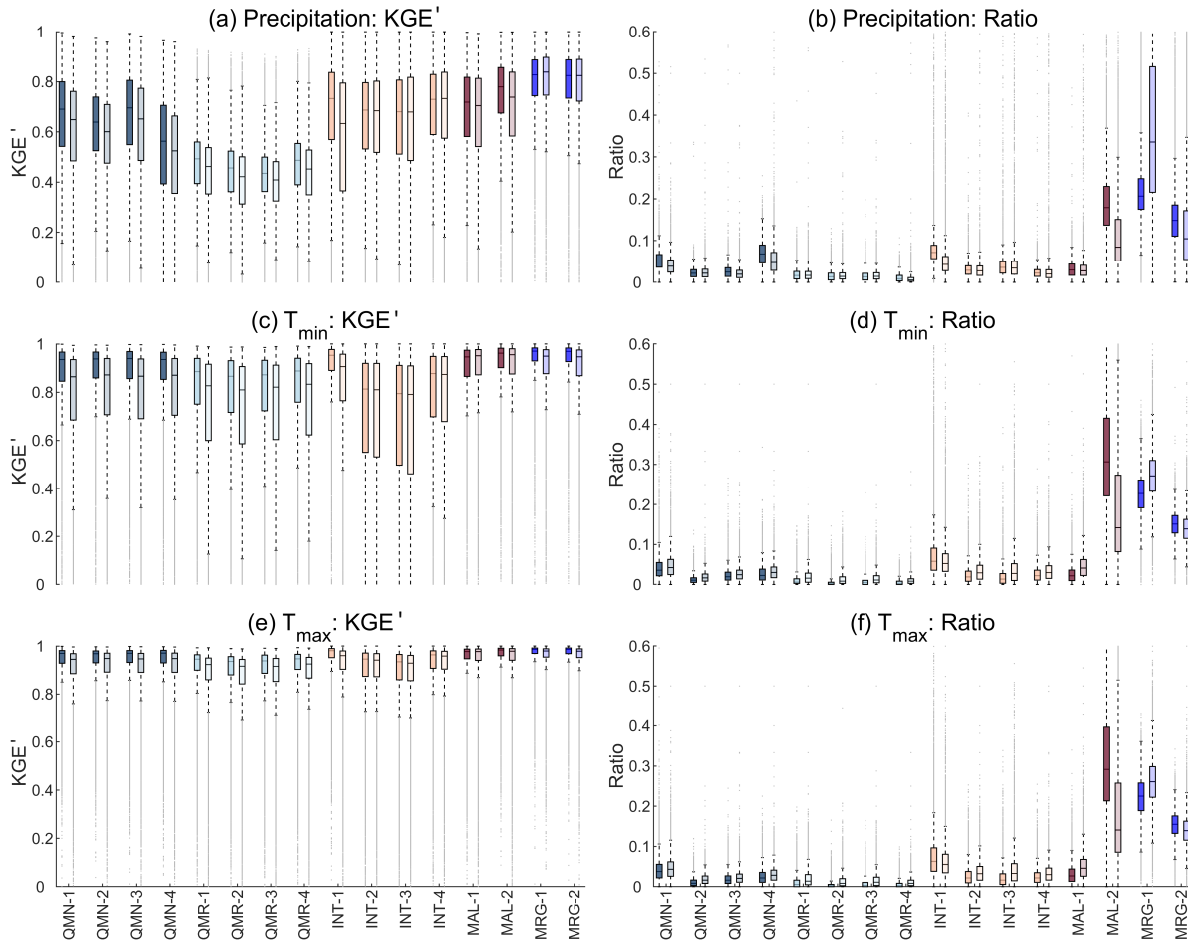

435 Figure 6. The contribution ratios of estimates from five infilling/reconstruction groups to the missing values of all  
436 stations from 1979 to 2018. The three columns from left to right represent precipitation,  $T_{\min}$ , and  $T_{\max}$ , respectively.  
437 The five rows from top to bottom represent Group-1 (QMN), Group-2 (QMR), Group-3 (INT), Group-4 (MAL), and  
438 Group-5 (MRG), respectively. The maps are at the resolution of  $0.5^\circ$ . The ratio for each grid cell is the mean value of  
439 all stations within this grid cell.

440 Figure 7 shows the KGE' and contribution ratios of 16 strategies. The KGE' of estimated precipitation is lower than  
441 that of estimated  $T_{\min}$  and  $T_{\max}$  due to the stronger spatial and temporal homogeneity of temperature (Fig. 7). The  
442 median KGE' values of  $T_{\min}$  and  $T_{\max}$  are generally above 0.9, and the accuracy of estimated  $T_{\max}$  is higher than that  
443 of  $T_{\min}$ . The KGE' during the reconstruction period is smaller than that during the observation period, which is  
444 particularly obvious for QMN, QMR, and INT-1 compared with other strategies, because QMN and QMR transfer  
445 CDF during the observation period to other periods, and INT-1 transfers regression relationship during the observation  
446 period to other periods. MAL suffers a slight degradation in the reconstruction period, and the better performance of  
447 MAL-2 than MAL-1 shows that RF could be a better choice than ANN in estimating missing data. For MRG, the  
448 differences of KGE' between the two periods are relatively small. For example, the median KGE' values of MRG-1  
449 for  $T_{\max}$  are 0.99 and 0.98 for observation and reconstruction periods, respectively. MRG also shows higher KGE' and  
450 a narrower quantile ranges than other strategies, particularly for precipitation, benefiting from merging estimates from  
451 multiple strategies

452 Regarding contribution ratios (Fig. 7), strategies with higher KGE' often have larger contributions to the estimated  
453 series. However, this is not always true because the selection of strategies is performed for each DOY. Note that the  
454 contribution ratios of MAL-2 are even higher than MRG-1 during the observation period for  $T_{\min}$  and  $T_{\max}$ , although  
455 MRG-1 achieves higher KGE' than MAL-2 for most stations. This is because MAL-2 could be the best choice for  
456 more DOY than MRG-1 even though MRG-1 may achieve the best overall performance. An example using  $T_{\min}$  data  
457 from one station is shown in Fig. S5.

458 In the reconstruction period when observations are absent, the contribution ratios of MAL-2 decrease drastically  
459 compared with the observation period, contributing to the increased ratios of other strategies (particularly MRG-1).  
460 Although QMR shows the lowest contribution ratios, reanalysis products have implicit contributions to other strategies  
461 (e.g., MAL and MRG). Overall, MRG-1 shows much higher contribution ratios than all the other strategies (including  
462 MRG-2) during the reconstruction periods, indicating that it is the most important strategy in missing value estimation.  
463 Hence, combining information from multiple strategies is more reliable, and KGE'-based merging is more effective  
464 than the median-value-based estimation.

465

466

467 Figure 7. Boxplots of (a, c, and e) the  $KGE'$  and (b, d, and f) the contribution ratio of 16 strategies for all stations.  
 468 Each strategy corresponds to two boxes in each sub-figure; the left one with darker color represents the observation  
 469 period, and the right one with lighter color represents the reconstruction period. The line within the box is the median.  
 470 The upper and lower edges of the box represent the 25th and 75th percentiles, respectively. Values more than 1.5  
 471 times the interquartile range away from the upper or lower edges are outliers (dots).

472 **4.2 Impact of reconstruction on spatial correlation and series variance**

473 All infilling/reconstruction strategies except QMR rely on information from neighboring stations; this could affect the  
 474 spatial correlation structure and the variance of SCDNA series. Space-time correlations and other properties (e.g.,  
 475 intermittency of precipitation) are important considerations because they can influence the performance of follow-on  
 476 applications that use the SCDNA as input. Theoretically, QMN strategies could significantly inflate spatial correlation  
 477 but retain variance of station observations. The spatial correlation inflation in INT strategies could be lower but the  
 478 variance would be underestimated due to smoothing. QMR-1 is used as an example to demonstrate the effect of QM  
 479 on spatial correlation and series variance (Fig. S6), because QMN uses different station combinations for every DOY  
 480 which would mask the effect of QM on final estimates. If the ERA5 used by QMR-1 is replaced by station observations,  
 481 the results should be generally consistent. According to Fig. S6, the spatial correlation is substantially inflated by

482 QMR-1, particularly for  $T_{\min}$  and  $T_{\max}$ , while the standard deviation of QMR-1 estimates is very close to that of  
483 observations. This supports the design of estimating missing data using neighboring stations for each DOY as  
484 otherwise, the inflation of CC could be very substantial for the entire period.

485 The spatial correlation based on station observations (Fig. 8a, d, and g) shows obvious seasonal variations, with CC  
486 lower in the warm season and higher in the cold season. The seasonality of CC for  $T_{\max}$  is weaker compared with that  
487 for precipitation and  $T_{\min}$ . The SCDNA estimates capture the seasonal patterns but underestimates the variation (Fig.  
488 8b, e, and h) because the inflation of spatial CC is larger in the warm season than cold season (Fig. 8c, f, and i).  
489 Moreover, the inflation is larger for neighboring stations with lower correlation with the target station. We tested  
490 selecting neighboring stations according to their distance from the target station, and similar results were acquired.  
491 For precipitation, the median CC differences of all stations are close to 0.1 in the cold season and range between 0.1  
492 and 0.15 in the warm season. For  $T_{\min}$ , the median CC differences are generally between 0.05 and 0.15. The CC  
493 differences of  $T_{\max}$  are relatively homogeneous for different seasons and generally fluctuate between 0.05 and 0.1. The  
494 inflation of CC is because (1) the estimates from the 10 neighboring stations and the target station are generally derived  
495 using highly overlapped information (Sect. 3.3.1), and (2) estimation is realized for each DOY for all strategies except  
496 MAL, meaning that calculating CC for each DOY show the inflation to the largest extent.

497 The final SCDNA replaces estimates by observations, which can largely relieve the inflation of spatial correlation  
498 (Fig. S7), depending on the degree to which observations are present in the record. For  $T_{\min}$  and  $T_{\max}$ , CC is very close  
499 to that based on observations; for precipitation, correlation in wintertime is even lower than that based on observations.

500

501 Figure 8. CC between target and neighboring stations for all DOY using station observations (the first column),  
 502 SCDNA estimates (second column), and differences between SCDNA- and observation-based CC (the third column).  
 503 CC is calculated in the observation period. For each target station, 10 neighboring stations are selected according to  
 504 the correlation between time series from target and neighboring stations. Smaller numbers represent higher correlation.  
 505 For example, station 1 represents the neighbor with the highest CC with the target station. Each curve represents the  
 506 median CC of all stations.

507 Figures 9 and 10 show CC between estimates at the target station and observations at the neighboring station. For  
 508 precipitation, most strategies exhibit similar spatial correlation structure with observations for most stations. QMR  
 509 largely underestimates CC compared with observations, which should be attributed to the differences between  
 510 precipitation of reanalysis products and stations. There are notable differences in different strategies within one group.  
 511 For example, QMN-1 shows larger inflation when observation-based CC is higher, which is not seen in QMN-2 to 4.  
 512 This is probably because QMN-1 only uses information from the one neighboring station with the highest correlation  
 513 with the target station for each DOY. Higher observation-based CC in Fig. 9 means this neighboring station could be  
 514 more frequently used by QMN-1 to estimate data for the target station, resulting in the larger inflation of CC. Another  
 515 example is that INT-1 underestimates the CC for 68.75% stations, whereas INT-2 to 4 overestimates the CC for almost  
 516 all stations. For SCD-1, inflation of CC is observed for 76.60% stations, whereas the magnitude of overestimation is

517 smaller than that in Fig. 8. The mean values of observation-based and estimate-based CC are 0.71 and 0.77,  
518 respectively. SCD-2 replaces estimates by observations and is the final dataset of this study. It reduces the mean  
519 estimate-based CC to 0.70. The overall spatial correlation structure of observations is generally preserved by SCD-2.  
520 However, SCD-2 calculates CC for the entire period which is different from the period of observation-based CC,  
521 resulting in uncertainties such as the underestimation for some stations when observation-based CC is larger than 0.7.

522 The spatial correlation of  $T_{\min}$  is much stronger than that of precipitation (Fig. 10). Most strategies overestimate the  
523 CC for most stations, whereas the magnitude is quite small. For example, SCD-1 inflates the CC for 96.96% stations,  
524 while the mean CC values for observations (0.95) and SCD-1 (0.96) are very close to each other. QMR still  
525 underestimates CC similar to Fig. 9 for precipitation. CC based on SCD-2 is generally consistent with that based on  
526 observations, while slight underestimation exists for some stations when observation-based CC is higher than 0.9.  $T_{\max}$   
527 shows similar spatial correlation patterns with  $T_{\min}$  (Fig. S8).

528 In summary, inflation of CC is inevitable particularly when estimates are obtained using information from a sole data  
529 source such as one neighboring station or one reanalysis product. The inflation is larger if each DOY is treated  
530 separately (Fig. 8 and S7), but smaller if CC is calculated for all years (Fig. 9, 10 and S8). Combining information  
531 from multiple sources (stations and reanalysis) and combining multiple strategies for each DOY are beneficial in  
532 estimating the overall spatial correlation structure. The spatial correlation structures vary for different strategies, and  
533 further studies are needed to clearly demonstrate how and why the estimate-based CC differs from observation-based  
534 CC.

535

536 Figure 9. Scatter density plots of CC between precipitation from the target station and neighboring stations. For each  
 537 target station, the neighboring station with the highest correlation with the target station is selected. X-axis represents  
 538 the CC between observed precipitation from target and neighboring stations. Y-axis represents the CC between  
 539 estimated precipitation from the target station and the observed precipitation from the neighboring station. Each sub-  
 540 figure corresponds to one strategy in Sect. 3.3.2. SCD-1 represents SCD estimates after correction, while SCD-2  
 541 replaces estimates by observations. CC is calculated during the overlapped observation period between target and  
 542 neighboring stations, and the only exception is SCD-2 which calculates CC using precipitation from target and  
 543 neighboring stations during the entire period.

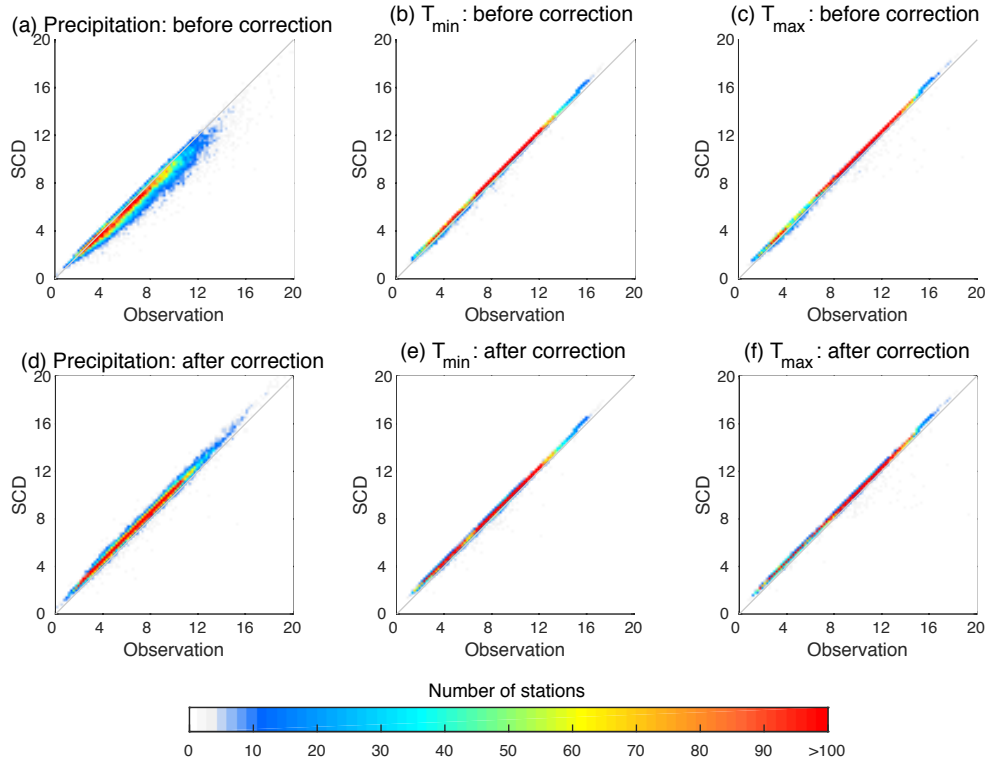

544

545 Figure 10. Similar with Fig. 9, but for  $T_{\min}$ .

546 The variability of observations and of the corrected and uncorrected SCDNA estimates (Step-7 in Sect. 3.3.3) are  
 547 compared using the standard deviation of the observation period (Fig. 11). The standard deviation of uncorrected  
 548 SCDNA precipitation is lower than that of observations, while after correction, the standard deviation agrees very well  
 549 with observations. The mean values of standard deviation are 7.36, 6.30, and 7.36 for observations, uncorrected  
 550 SCDNA, and corrected SCDNA, respectively. For  $T_{\min}$  and  $T_{\max}$ , corrected and uncorrected SCDNA estimates both  
 551 show consistent variability with observations.

552

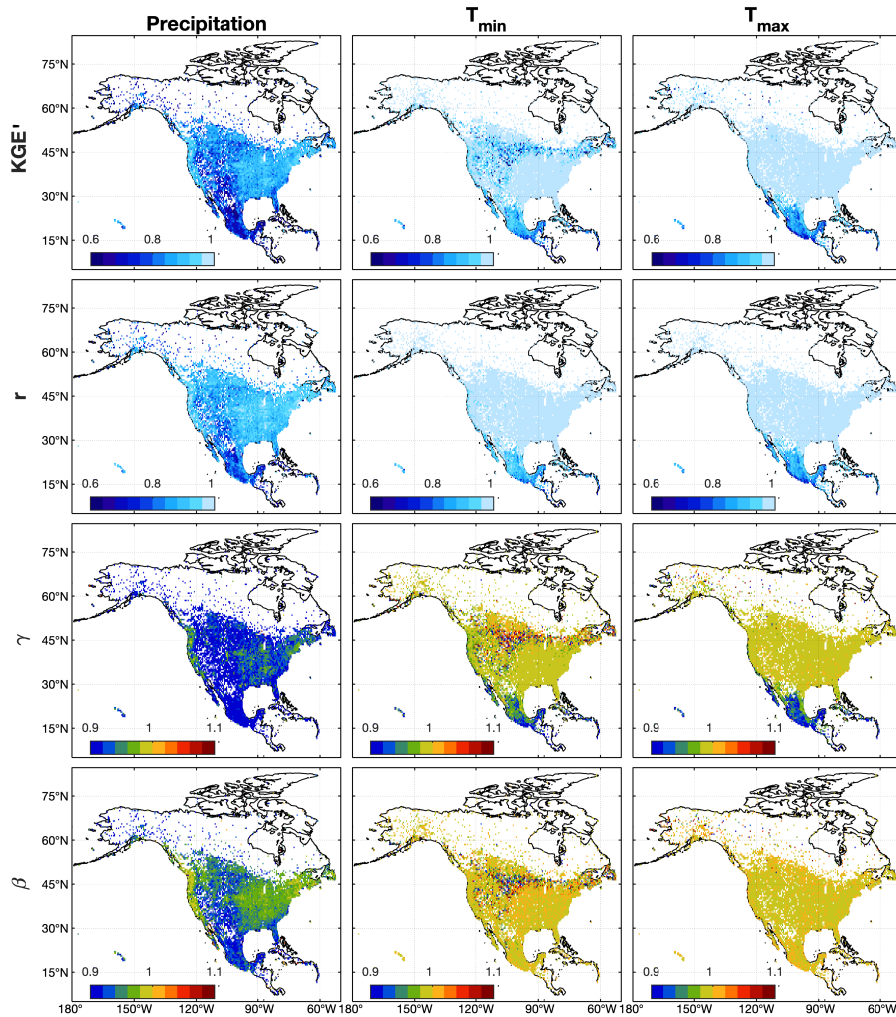

553 Figure 11. The standard deviation of observations and SCDNA estimates before and after correction. Data in the  
 554 observation period are used.

### 555 4.3 The performance of the serially complete dataset

556 Uncorrected SCDNA estimates show high accuracy in North America (Fig. 12). For precipitation, the median KGE'  
 557 of all stations is 0.87, and the median values of  $r$ ,  $\beta$ , and  $\gamma$  are 0.91, 0.92, and 0.96, respectively. The KGE' for Mexico  
 558 stations generally ranges between 0.6 and 0.8, which is smaller than that in U.S. and southern Canada. Some stations  
 559 in Rocky Mountains, Caribbean, Alaska and northern Canada (regions with complex topography or climate), also  
 560 show lower KGE' for precipitation estimates. The spatial distribution of  $r$  is similar with that of KGE', while the  
 561 magnitude is higher. According to  $\gamma$ , most stations underestimate precipitation variability which is consistent with Fig.  
 562 11;  $\beta$  is generally lower than one in most regions of North America, particularly in the Rocky Mountains and Mexico  
 563 where SCDNA underestimates precipitation.

564 Estimated temperature shows much higher KGE' compared with precipitation. The median KGE' and  $r$  of  $T_{\min}$  are  
 565 0.97 and 0.99, respectively. For  $T_{\max}$ , the median of KGE' and  $r$  are 0.99 and 0.99, respectively. The median  $\gamma$  and  $\beta$   
 566 are both between 0.99 and 1 for  $T_{\min}$  and  $T_{\max}$  with small variations, particularly for  $T_{\max}$  (Fig. 12); the KGE' of  $T_{\min}$   
 567 and  $T_{\max}$  is lower in Caribbean and Mexico. For  $T_{\min}$ , the KGE' for some stations around 45°N and the Rocky  
 568 Mountains is lower than surrounding regions although  $\gamma$  is spatially homogeneous for the same region. This is because  
 569 the mean  $T_{\min}$  is close to zero for some stations in this region, resulting in the large magnitude of  $\beta$  and  $\gamma$ . In contrast,  
 570  $T_{\max}$  exhibits homogeneous performance in the same region for all metrics.

571 Corrected SCDNA estimates (see Step-7; Fig. S9) have higher accuracy than uncorrected estimates (Fig. 12). For  
 572 example, the median KGE' for precipitation is improved from 0.87 to 0.90 after correction. The KGE' for  $T_{\min}$  and  
 573  $T_{\max}$  is also improved but not as significant as precipitation.  $\beta$  equals to one for all stations due to the mean-value  
 574 correction.  $\gamma$  for precipitation changes from negative to positive for all stations, whereas the magnitude of bias  
 575 (deviation from one) is smaller after correction. As a result, the spatial distribution of metrics for  $T_{\min}$  is also more  
 576 homogeneous.

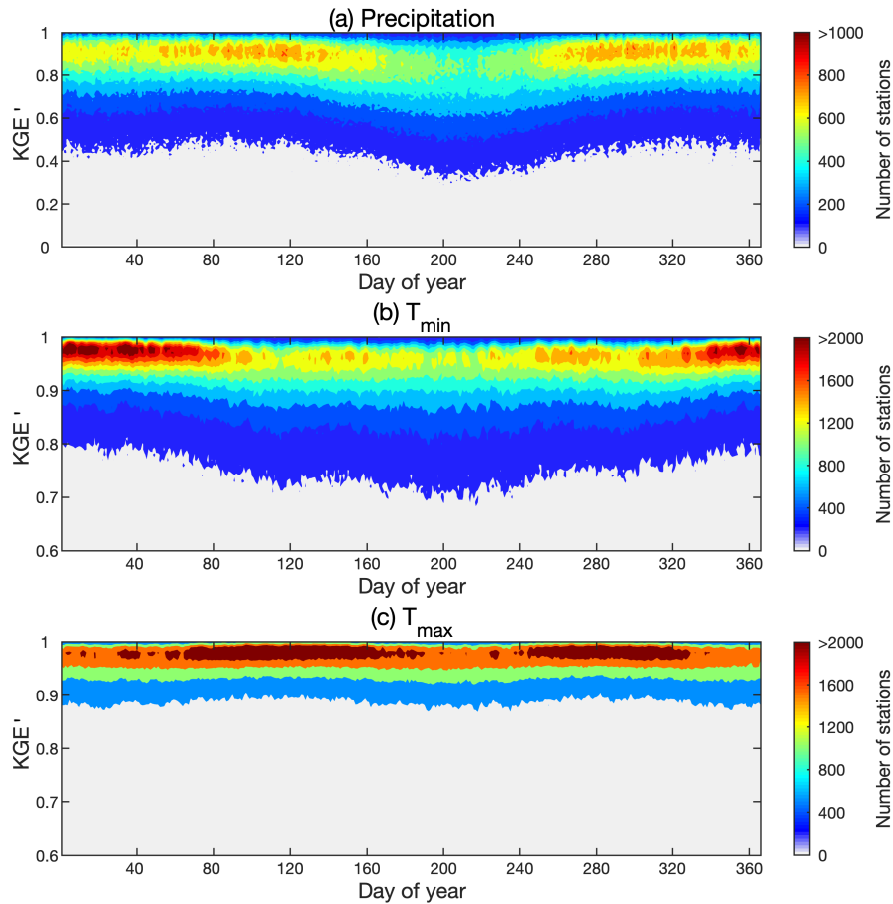

577

578 Figure 12. The spatial distributions of KGE' and its three components ( $r$  is CC,  $\beta$  is the bias ratio, and  $\gamma$  is the  
 579 variability ratio) for uncorrected SCDNA estimates over North America during the observation period. The maps are  
 580 at the resolution of  $0.5^\circ$ . The value for each grid cell is the median value of all stations within this grid cell.

581 The distributions of KGE' vary during the year (Fig. 13). For precipitation, more stations show lower KGE' during  
 582 summer (DOY 150 to 250) than at other times of the year, which may be due to the variability of summertime  
 583 convective precipitation. For  $T_{\min}$ , some stations show lower KGE' from DOY 100 to 250. The seasonal variation of

584 KGE' for  $T_{\max}$  is relatively weak, although KGE' is slightly more concentrated at a higher level during spring and  
 585 autumn than winter and summer. The overall performance of  $T_{\max}$  is better than  $T_{\min}$  and precipitation.

586

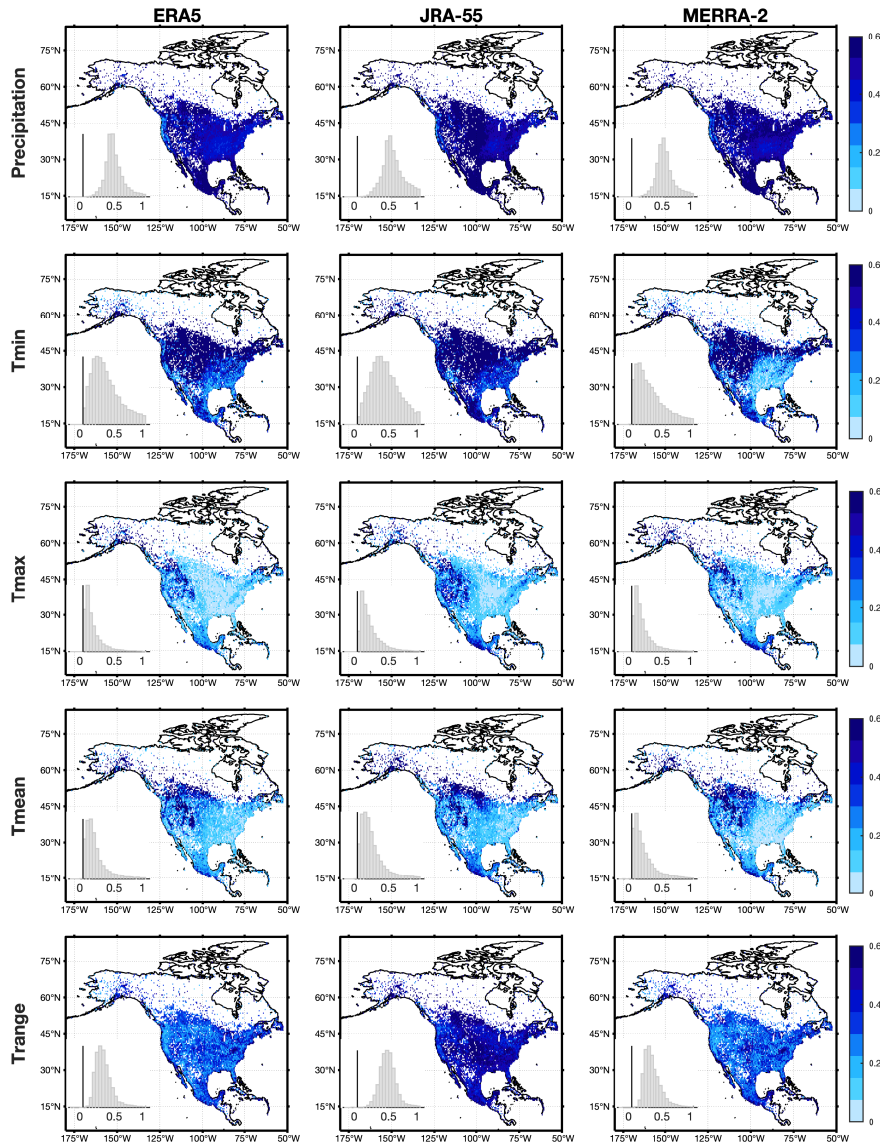

587 Figure 13. The distribution of KGE' for each day of year for (a) precipitation, (b)  $T_{\min}$ , and (c)  $T_{\max}$ . Corrected SCDNA  
 588 estimates are used.

589 **4.4 Comparison between the serially complete dataset and gridded products**

590 SCDNA precipitation and temperature are compared with benchmark gridded products to demonstrate whether the  
 591 SCDNA is a good choice when station data are unavailable. Actual station observations are used as reference.  
 592 Although assessing gridded products using point-scale station data contains uncertainties (Tang et al., 2018a), the  
 593 objective of this section is to illustrate their agreement with station observations in lieu of providing an exhaustive  
 594 quantitative assessment of their real-world accuracy.

595 Overall, the SCDNA achieves much higher KGE' than reanalysis products for all variables (Fig. 14). For precipitation,  
 596 the median KGE' differences between the SCDNA and ERA5, JRA-55 and MERRA-2 are 0.48, 0.57, and 0.54,  
 597 respectively. The corresponding KGE' differences for  $T_{\min}$  are 0.46, 0.61, and 0.36, respectively. The improvement  
 598 for  $T_{\max}$  is smaller, particularly in the eastern U.S. where the topography is relatively flatter compared with western

599 U.S. The KGE' differences of  $T_{\text{mean}}$  are lower than  $T_{\text{min}}$  but higher than  $T_{\text{max}}$  due to the offset effect.  $T_{\text{range}}$  suffers little  
 600 from the elevation differences between stations and reanalysis grids, and is suitable to demonstrate the differences  
 601 between SCDNA and reanalysis products. The median KGE' differences for  $T_{\text{range}}$  between the SCDNA and ERA5,  
 602 JRA-55 and MERRA-2 are 0.31, 0.48, and 0.31, respectively.

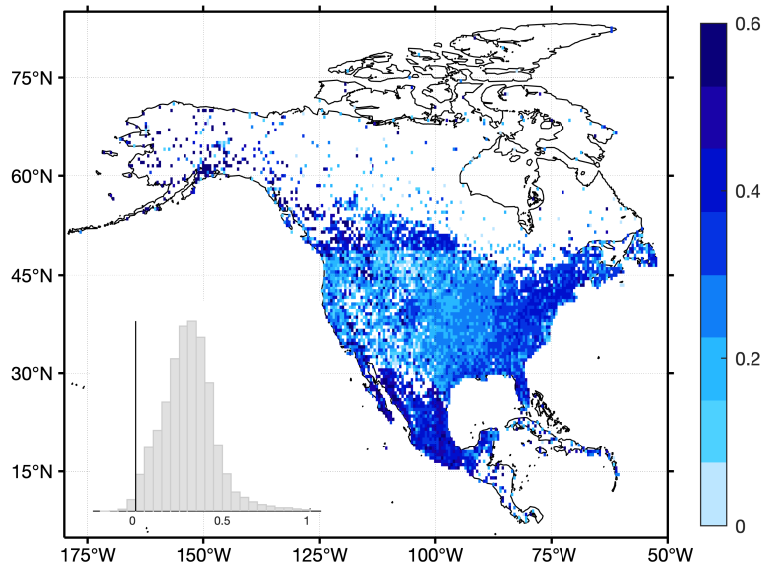

603

604 Figure 14. Spatial distributions of KGE' differences between SCDNA estimates and three reanalysis products (ERA5,  
 605 JRA-55, and MERRA-2). The nested histograms show KGE' differences between the SCDNA and reanalysis products.  
 606 Corrected SCDNA estimates are used.

607 SCDNA and MSWEP precipitation is compared (Fig. 15). Since MSWEP merges data from numerous stations, the  
 608 evaluation of MSWEP based on station data is not independent, which could result in the overestimation of its KGE'.  
 609 Even so, SCDNA precipitation shows higher KGE' than MSWEP for 98.97% stations with a median KGE' difference

610 of 0.31. Fig. 15 shows notable differences between MSWEP and SCDNA at the Canada-USA border and the USA-  
611 Mexico border. This is because MSWEP infers gauge reporting time by searching for the highest correlation between  
612 gauge data and the temporally shifted reanalysis/satellite estimates (Beck et al., 2019). The estimated temporal shift  
613 could vary with countries, which results in distinct differences of station-based evaluation results along national  
614 boundaries. The accumulation periods of station and MSWEP precipitation are inconsistent in some cases, which  
615 could affect the evaluation of MSWEP (see Sect. 5.1).

616 Note that the evaluation does not indicate that the SCDNA has higher accuracy than the gridded products; rather, the  
617 results show that SCDNA is a better substitute than gridded products when station observations are unavailable.

618  
619 Figure 15. Spatial distributions of KGE' differences between SCDNA and MSWEP precipitation. Corrected SCDNA  
620 estimates are used.

## 621 5. Discussion

### 622 5.1 Observation time of stations

623 Meteorological stations in different countries usually have different local observation time, and stations in the same  
624 country may also experience change of observation time (Vincent et al., 2012). Most station databases including those  
625 used in this study do not account for reporting-time inconsistencies due to lack of hourly observations and well-  
626 documented station metadata. Vincent et al. (2009) examined several methods to adjust the time of daily precipitation  
627 observations, which, however, often altered observed precipitation intensity. Beck et al. (2019) inferred the reporting  
628 time of daily precipitation observations by calculating SCC between the series of stations and gridded products, which  
629 is useful to correct the bias of gridded products. A simple experiment is carried out using the method of Beck et al.  
630 (2019) to infer the lag day of station series. For precipitation, 6418 stations show nonnegligible time shift from the

631 reporting date (Fig. S10). However, this method may be unsuitable for temperature because the estimated lag day is  
632 mostly zero, and the inferred reporting time cannot be directly applied to adjust station observations.

633 The inconsistent reporting time has different impact on precipitation,  $T_{\min}$ , and  $T_{\max}$ . For example, if a station records  
634 data from 8:00 a.m. on January 1st to 8:00 a.m. on January 2nd, the station will probably use January 2nd as the  
635 reporting time. However, two thirds of the 24-h time are within January 1st, indicating that the accumulated  
636 precipitation could mostly occur on January 1st.  $T_{\max}$  could also occur during the daytime on January 1st, but it is hard  
637 to determine on which day  $T_{\min}$  occurs, which makes it challenging to adjust precipitation,  $T_{\min}$  and  $T_{\max}$  at the same  
638 time. The difference between universal and local time makes this problem more complicated. Thus, the reporting time  
639 of stations is not corrected here due to aforementioned difficulties.

## 640 **5.2 Homogenization**

641 Inhomogeneities in station observations are defined as variations that are not caused by weather and climate factors.  
642 Long-term station records are often subjected to inhomogeneities due to factors like station re-location, observation  
643 time change, instrument change, and surrounding environment change (Venema et al., 2012). Many methods have  
644 been developed to identify breakpoints and homogenize station series in annual, monthly or even daily scales (e.g.,  
645 Ma et al., 2008; Vincent et al., 2002, 2012). Different methods could generate different estimates of inhomogeneities  
646 as shown by many comparison studies (e.g., Beaulieu et al., 2008; Reeves et al., 2007; Venema et al., 2012). The four  
647 station databases (Sect. 2.1) used in this study provide original station records without homogenization. The SCDNA  
648 would inherit the potential inhomogeneities contained in these databases, and the infilling/reconstruction may also  
649 lead to discontinuities. The homogenization of the SCDNA is challenging considering that (1) the dataset covers a  
650 broad range of climate, topography, and countries, (2) the number of stations is large and differences between station  
651 periods (ranging from 8 to 40 years) are substantial, and (3) whether existing methods are suitable for homogenization  
652 of infilling/reconstruction estimates needs exploration. Therefore, homogenization is not carried out in this study,  
653 which, however, is an important direction for future studies.

## 654 **5.3 Limitations of the KGE' statistic**

655 We use KGE' because it incorporates information about correlation, bias, and variability, and hence provides more  
656 information on methodological performance than an individual metric. For example, the PCC between temperature  
657 estimates and observations is usually close to one and cannot reflect the bias term, while the mean square error is  
658 prone to the effect of extreme values (or outliers). However, KGE' also has limitations. For example, the values of  
659 KGE' depend on the units of measurement (e.g., Santos et al., 2018) – in our case, the  $\beta$  values for temperature are  
660 clearly always close to one if the units of measurement for temperature are in Kelvin. Since these statistics incorrectly  
661 indicate very small temperature biases, we used °C for all KGE' calculations in this study, ensuring that  $\beta$  has more  
662 leverage in the KGE' statistic. Moreover, and critical for our analysis, the normalization used in the KGE' formula ( $\beta$   
663 and  $\gamma$ ) means that the KGE' values are low when the denominators of  $\beta$  and  $\gamma$  are close to zero (e.g., Santos et al.,  
664 2018). This problem is especially acute for temperature – for instance, we found that KGE' values were very small for

665 cases where  $\mu_o$  is close to zero. Nevertheless, the number of cases where  $\mu_o$  is close to zero is rather small, where  
666  $\sim 0.5\%$  of all cases (based on all stations and all DOY) show absolute values of mean  $T_{\min}$  smaller than  $0.1^\circ\text{C}$ . For cases  
667 with  $\mu_o$  close to zero, the ranking based on KGE' is similar to the ranking based on mean absolute error, which  
668 means that KGE' can still function as a ranking indicator when its value is low. Further work is needed to both  
669 comprehensively evaluate the alternative infilling strategies presented in this paper and evaluate more advanced multi-  
670 method merging strategies.

#### 671 **5.4 Potential improvement directions**

672 Several steps could be taken to improve the SCDNA. First, the optimal strategy could be different for each station as  
673 shown by the results in this study. Therefore, the quality of SCDNA may be further improved by using more  
674 infilling/reconstruction methods, which would yield diminishing returns at some point. For example, the long short-  
675 term memory (LSTM) could be suitable to impute missing station observations. Optimizing the configuration of  
676 various strategies will be necessary to balance computation efficiency and estimation accuracy, particularly when the  
677 number of stations is large. Second, some stations suffer from undercatch, which depends on gauge type, precipitation  
678 phase, environmental conditions, etc. The bias caused by undercatch can be substantial for stations located in high  
679 latitudes and the mountains (Yang et al., 2005; Scaff et al., 2015). Third, the SCDNA does not distinguish between  
680 rainfall and snowfall. Considering that a large part of North America has frequent snowfall in winter, precipitation  
681 phase classification will be useful for hydrometeorological studies. Auxiliary data from reanalysis and satellite  
682 products could be used to partition precipitation into rain and snow. Finally, although the SCDNA agrees well with  
683 station observations, long-term trends are difficult to reconstruct when actual observations are unavailable, meaning  
684 the SCDNA may not be suitable for climate trend analysis in the reconstruction period. Some gridded datasets use  
685 only stations with long-term records (e.g., (Wood, 2008; Werner et al., 2019) to achieve temporally consistent  
686 estimates, whereas such stations are very few. Reasonable trend estimation is challenging but meaningful for SCD.

687 Furthermore, other variables such as wind and humidity observed by stations also suffer from the same problems faced  
688 by precipitation and temperature. Future studies should explore whether the current methodology is applicable to other  
689 variables. A SCD covering more variables would be useful for research in various fields.

#### 690 **6 Data availability**

691 The SCDNA dataset is available at <https://doi.org/10.5281/zenodo.3735533> (Tang et al., 2020) in netCDF format. The  
692 basic variables are station identification, latitude, longitude, elevation, date, and TLR derived in Sect. 3.2. Stations  
693 that undergo location merging (Sect. 3.1.1) are identified and all relevant stations are included in the data file. For  
694 precipitation,  $T_{\min}$ , and  $T_{\max}$ , the variables in the netCDF4 file include original station observations, quality flags  
695 provided by original station databases, quality flags provided by this study, estimates from 16 strategies, uncorrected  
696 SCDNA estimates, corrected SCDNA estimates, the final SCDNA with estimates replaced by observations, data  
697 source flags indicating the source of each record in SCDNA (observations or 16 strategies), and accuracy metrics  
698 (KGE' and its three components) for all estimates (16 strategies and SCDNA).

699 Scripts used to produce the SCDNA are available at <https://github.com/tgq14/GapFill>. The dataset will be regularly  
700 updated to cover the latest periods.

## 701 **7 Conclusions**

702 This study developed a daily SCD of precipitation,  $T_{\min}$ , and  $T_{\max}$  for 27276 stations from 1979 to 2018 over North  
703 America (SCDNA). The original station data are compiled from multiple sources and undergo strict quality control.  
704 Many stations have nonnegligible fractions of missing values in observation and reconstruction periods. For each  
705 station, the infilling and reconstruction are implemented using 16 strategies (quantile mapping, statistical interpolation,  
706 and machine learning) based on information from neighboring stations and concurrent reanalysis estimates (ERA5,  
707 JRA-55, and MERRA-2). The final SCDNA combines estimates from the 16 strategies and is corrected using station  
708 observations. The spatial correlation is preserved and might be slightly inflated. The SCDNA estimates reproduce the  
709 variance of original station observations very well, particularly for temperature. The median KGE' of the final  
710 precipitation,  $T_{\min}$ , and  $T_{\max}$  for all stations is 0.90, 0.98, and 0.99, respectively. The comparison with four benchmark  
711 gridded products shows that the SCDNA has much better agreement with station observations. The SCDNA will be  
712 useful for a variety of hydrometeorological studies in North America.

713

714 **Author contributions:** GT and MC designed the study. GT performed the analyses and wrote the paper. All authors  
715 contributed to data analysis, discussions about the methods and results, and paper improvement.

716 **Competing interests:** The authors declare that they have no conflict of interest.

717 **Acknowledgements:** The study is funded by the Global Water Futures (GWF) program in Canada. The authors  
718 appreciate the extensive efforts from the developers of the ground and reanalysis datasets to make their products  
719 available. The authors also thank Zenodo (<https://zenodo.org/>) for publishing our dataset as open access to users.

## 720 **Appendix A**

721 Table A1. Acronyms used in this paper

Acronym	Full name
ANN	Artificial neural network
APHRODITE	Asian Precipitation-Highly-Resolved Observational Data Integration Towards Evaluation
CC	Correlation coefficient
CDF	Cumulative distribution function
CONUS	Contiguous United States
DEM	Digital elevation model

DOY	Day of year
ECCC	Environment and Climate Change Canada
ERA5	the fifth generation of ECMWF atmospheric reanalyses of the global climate
fD	Fraction of days without precipitation
GHCN-D	Global Historical Climate Network Daily
GSOD	Global Surface Summary of the Day
IDW	Inverse distance weighting
INT	Interpolation
JRA-55	Japanese 55-year Reanalysis
KGE'	Kling-Gupta Efficiency
LSTM	Long short-term memory
MAL	Machine learning
MLAD	Multiple regression based on the least absolute deviation criteria
MERIT DEM	Multi-Error-Removed Improved-Terrain digital elevation model
MERRA-2	Modern-Era Retrospective analysis for Research and Applications, Version 2
MRG	Multi-strategy merging
MSWEP	Multi-Source Weighted-Ensemble Precipitation
NR	Revised normal ratio
PCC	Pearson CC
QM	Quantile mapping
QMN	QM using neighboring stations
QMR	Quantile mapping with concurrent reanalysis estimates
RF	Random forest
SCC	Spearman CC
SCDs	Serially complete datasets
TLR	Temperature lapse rate
$T_{\max}$	Maximum temperature
$T_{\text{mean}}$	Mean temperature
$T_{\min}$	Minimum temperature
$T_{\text{range}}$	Daily temperature range
U.S.	United States
UTC	Universal Time Coordinated

722

723 **Appendix B**

724 Five types of checks (Durre et al., 2010) are adopted for the quality control of temperature.

- 725 1. Integrity checks. The first type of integrity check is a *duplication check* to identify duplicated records for time  
726 series in different time periods. The second type of integrity check includes *the streak check* to identify  
727 consecutive identical values and *the frequent-value check* to identify close but not necessarily consecutive  
728 identical values. The *world record exceedance check* sets lower (-89.4°C) and upper (57.7°C) bounds of  
729 temperature.
- 730 2. Outlier checks, including *the gap check* that examines the frequency distributions for all calendar months, and  
731 the *climatological outlier check* that is based on the traditional z-score (e.g., Hubbard and You, 2005).
- 732 3. Internal and temporal consistency checks, including *the iterative temperature consistency check*, to ensure some  
733 inherent relationships are abided (e.g.,  $T_{\min}$  cannot be larger than  $T_{\max}$ ); *the spike/dip check*, identifies  
734 temperatures which deviate from previous and following days by at least 25°C; and *the lagged temperature range*  
735 *check*, which identifies abnormally large differences between  $T_{\min}$  and  $T_{\max}$  during a 3-day time window.
- 736 4. Spatial consistency checks, including *the regression check* and *the spatial corroboration check*. *The regression*  
737 *check* builds regression relationships between temperature at the target location and selected nearby stations to  
738 determine whether temperature at the target station should be flagged according to regression residuals and  
739 standardized residuals. *The spatial corroboration check* flags temperature at the target station if the value  
740 deviates far from the temperature at neighboring stations.
- 741 5. Extreme megaconsistency checks to ensure that certain relationships hold for the entire records of stations. For  
742 example,  $T_{\max}$  cannot be higher than the lowest  $T_{\min}$  for the calendar month, and vice versa.

743 For precipitation, quality control strategies are from three studies. The first part is similar with temperature, but does  
744 not include the third type of checks (internal and temporal consistency checks). The second part is from Hamada et al.  
745 (2011).

- 746 1. Repetition checks. The non-zero check identifies constant daily values ( $> 10 \text{ mm d}^{-1}$ ) that occur for more than  
747 four days. The zero check compares the annual zero-precipitation frequency with its climatological value to spot  
748 unusual frequencies of zero.
- 749 2. Duplicated monthly or sub-monthly record check. The temporal CC and the number of days with equal  
750 precipitation are used to identify whether two different months have the same records caused by human errors.
- 751 3. Z-score-based outlier check. Daily precipitation is flagged if its difference with the mean value from precipitation  
752 within a 15-day window of all years is larger than nine standard deviations. This step is repeated until no outlier  
753 is identified.

754 4. Spatiotemporally isolated value check. Extremely large precipitation is identified in both space and time based  
755 on the percentiles of precipitation differences between the target station and neighboring stations within a radius  
756 of 400 km.

757 The third part is from Beck et al. (2019).

758 1. Empirical criterion based on the fraction of days without precipitation ( $f_D$ ). This was designed to identify the long  
759 series of erroneous zero precipitation contained in GSOD station records. However, we found that this criterion  
760 misidentifies some acceptable records in GHCN-D. Therefore, the  $f_D$ -based check is only implemented for GSOD.

761 2. Discarding stations with fewer than 15 unique values or more than 99.5% dry records ( $<0.5 \text{ mm d}^{-1}$ ).
