**Abstract** Dating recent sediment archives (<150 years) constitutes a prerequisite for environmental and climatic reconstructions. Radiocaesium ( $^{137}\text{Cs}$ ) emitted during thermonuclear bomb testing (~1950–1980) and nuclear accidents, as well as the decrease of excess lead-210 ( $^{210}\text{Pb}_{\text{xs}}$ ) with depth are often combined to establish sediment core chronology. Although these methods have been widely used during the last several decades, there is a lack of structured and comprehensive worldwide synthesis of fallout radionuclide analyses used for dating sediment cores in environmental and Earth sciences. The current literature overview was based on the compilation of 573 articles published between 1977 and 2020, reporting the collection of 1351 individual dating sediment cores (the dataset can be accessed at <https://doi.pangaea.de/10.1594/PANGAEA.931493>). This review was conducted in order to map the locations where  $^{137}\text{Cs}$  fallout events were detected. These included the thermonuclear bomb testing peak in 1963, the Chernobyl accident in 1986, the Fukushima accident in 2011, and 24 additional events identified in 112 sites that led to local or regional radioactive releases (e.g. Sellafield accidents, Chinese nuclear tests). When  $^{210}\text{Pb}_{\text{xs}}$  records were used along with  $^{137}\text{Cs}$  data, detailed information on the  $^{210}\text{Pb}_{\text{xs}}$  age depth models were also synthesized.

With the current growing number of studies analyzing sediment cores and the increasing interest in the deployment of sediment fingerprinting techniques including radionuclides as potential discriminant properties, this spatialized synthesis provides a unique worldwide compilation for characterizing fallout radionuclide sources and levels at the global scale. This synthesis provides in particular a referential of  $^{137}\text{Cs}$  peak attribution for improving the sediment core dating and it outlines the main questions that deserve attention in future research as well as the regions where additional  $^{137}\text{Cs}$  fallout investigations should be conducted in priority.

## 1. Introduction

Sedimentary sequences have received a growing interest as a support for conducting climatic and environmental reconstructions covering the 20<sup>th</sup> century period, which has been highly impacted by socio-environmental changes  
40 (Syvitski *et al.*, 2020). These natural archives provide a powerful and unique tool for reconstructing the trajectory, the magnitude and the resilience of terrestrial and aquatic ecosystems facing major environmental changes, climate forcing or contamination pressures (Dearing and Jones, 2003; Jaegler *et al.*, 2019; Sabatier *et al.*, 2014). These recent paleo-reconstructions were carried out in various environments such as lakes, alluvial plains, lagoons, estuaries or even the open ocean. Establishing an age depth model is the first prerequisite of any paleo-investigation  
45 based on these sediment archives. Fallout of short-lived radionuclides (caesium-137, lead-210) characterized by different half-lives ( $T_{1/2}$ ) are particularly useful to derive this crucial temporal information.

Among these radionuclides, two complementary radioisotopes are classically analyzed. Caesium-137 ( $^{137}\text{Cs}$ ) is used as a discrete time marker, which provides anchoring points after 1950. In contrast, the excess of lead-210 ( $^{210}\text{Pb}_{\text{xs}}$ ) is used as a continuous time marker to reconstruct sedimentation rates for the last 100 to 150 years (e.g.  
50 [Oldfield \*et al.\*, 1978](#); Sanchez-Cabeza *et al.*, 2000).

The  $^{137}\text{Cs}$  is an artificial radionuclide ( $T_{1/2} = 30.15$  years) produced by the global thermonuclear weapon tests that started in 1954 and whose fallout peaked in 1963 in the Northern Hemisphere. Furthermore, additional  $^{137}\text{Cs}$  releases occurred in certain regions of the world (i.e., mainly in Europe and in the Northern Hemisphere (Appleby,  
55 2001; Appleby *et al.*, 1991) following the Chernobyl (1986) and the Fukushima Dai-ichi (2011) nuclear accidents.

Other more local [or regional](#) sources of  $^{137}\text{Cs}$  releases have also been recorded. [Local sources are generally found along river systems \(and the radionuclides remain generally disseminated within a few dozens or hundreds of kilometers from the source\) whereas the regional sources can be detected in zones situated at several thousands of kilometers from the source due to atmospheric fallout. The radioactive releases from the Mayak weapon production plant \(Russia, 1949, 1957\) and the Sellafield accidents \(UK, 1957, 1974, 1981\) provide examples of these local and regional sources, respectively](#) (e.g. Madsen *et al.*, 2005). To identify unambiguously  $^{137}\text{Cs}$  sources, complementary analyses of plutonium isotope signatures (Meusburger *et al.*, 2020) or the detection of additional radionuclides including americium-241 ( $^{241}\text{Am}$ ) can be conducted (Appleby *et al.*, 1991). The use and limitations of  $^{137}\text{Cs}$  for dating sediment sequences have been widely described in previous publications (Delaval *et al.*, 2020;  
60 Klaminder *et al.*, 2012; Miller and Heit, 1986).

In contrast to  $^{137}\text{Cs}$ ,  $^{210}\text{Pb}$  is a natural radionuclide ( $T_{1/2} = 22.3$  years), which is a decay product of the  $^{238}\text{U}$  chain ( $T_{1/2} = 4.5 \cdot 10^9$  years).  $^{238}\text{U}$  decays through a series of nuclides (e.g.,  $^{226}\text{Ra}$ ,  $^{222}\text{Rn}$ ).  $^{222}\text{Rn}$  ( $T_{1/2} = 3.82$  days) is a gas that partly remains in situ, forming “supported”  $^{210}\text{Pb}$ , and that partly escapes to the atmosphere, forming “excess”  $^{210}\text{Pb}$  ( $^{210}\text{Pb}_{\text{xs}}$ ) when falling back on the soil surface as a result of wet and dry fallout. The evolution of  $^{210}\text{Pb}_{\text{xs}}$  activities with depth in sediment cores follows an exponential decrease from which it is possible to calculate the  
70 sedimentation rates for the last 100-150 years. Several dating models were established in the literature in order to infer sediment ages from  $^{210}\text{Pb}_{\text{xs}}$  (Appleby and Oldfield, 1978; Bruel and Sabatier, 2020; Goldberg, 1963; Sanchez-Cabeza and Ruiz-Fernández, 2012) and several limitations to this method were also described (e.g. Binford, 1990). Sediment core inventories are often reported for both radionuclides to compare the study location with a reference site. The “reference” core must be chosen not to be affected by post-depositional disturbance processes (e.g.  
75 erosion, accumulation) and must be located in the vicinity of the studied sediment core. Comparing the

radionuclide inventories calculated in the sediment cores of interest with that found at a nearby reference site may provide information on sediment dynamics (e.g. through the calculation of erosion or accumulation rates). Although both  $^{137}\text{Cs}$  and  $^{210}\text{Pb}_{\text{xs}}$  activities were largely used to assign ages (often in years) to the succession of layers in sedimentary sequences, there is a lack of structured and comprehensive worldwide synthesis of 80 radionuclide fallout. Accordingly, the current literature overview was based on a Web of Science search with the objectives to: (1) identify the worldwide distribution of studies using these radionuclides for sediment dating, (2) identify the presence of discrete peaks of  $^{137}\text{Cs}$  in these archives (attributed to global and regional fallout or to local sources) and the ages and activities associated with these peaks (3) characterize the  $^{210}\text{Pb}_{\text{xs}}$  models used for dating sediment archives when they were applied in combination with  $^{137}\text{Cs}$ .  
85 The overall goal of this synthesis was to build a worldwide referential and make it available to the scientific community sharing interests in sediment core dating or sediment source fingerprinting. It will also raise questions that should deserve attention in future research.

## 2. Literature overview

Journal articles using  $^{137}\text{Cs}$  for dating sediment cores published in English language were extracted from the 90 Thomson Reuters Web of Science database until 29 February 2020. The search words “ $^{137}\text{Cs}$ ” and “sediment core” were used in combination. A total of 910 publications were found by the automatic literature searching tool starting from 1977. Soil science studies focusing on the depth distribution of  $^{137}\text{Cs}$  in soils (Jagercikova et al., 2014), publications reporting  $^{137}\text{Cs}$  measurements conducted on surface soil layers or deploying sediment fingerprinting approaches using  $^{137}\text{Cs}$  as a diagnostic property (Evrard et al., 2020) were excluded from further analysis and 95 removed from the database.

Among the remaining references, 573 publications were selected to feed a database including a total of 1351 individual dated sediment cores (Fig. 1) – (the database is freely downloadable from <https://doi.pangaea.de/10.1594/PANGAEA.931493>).

100 The database includes the following categories of information:

- Publication metadata (site name, authors information, DOI or permanent link, journal title, publication year, main processes studied, GPS coordinates, country)
- Sampling information (sampling year, core length, coring environment –e.g. lacustrine, coastal, floodplain –, corer type, corer diameter, subsampling increment, sediment compaction measured during 105 the core collection)
- Catchment and lake characteristics (name, size, main land use in the drainage catchment, slope, elevation range)
- Description of the  $^{137}\text{Cs}$ -related properties (surface activity, activity and sediment depth of the Fukushima, Chernobyl and 1963 peak fallout, total  $^{137}\text{Cs}$  inventory in the core,  $^{137}\text{Cs}$  inventory at a 110 nearby reference site, sedimentation rate, detection of local releases)
- Description of the  $^{210}\text{Pb}_{\text{xs}}$ -related properties (sedimentation rate,  $^{210}\text{Pb}_{\text{xs}}$  analysis technique,  $^{210}\text{Pb}_{\text{xs}}$  age model used, total  $^{210}\text{Pb}_{\text{xs}}$  inventory in the core,  $^{210}\text{Pb}_{\text{xs}}$  inventory at a nearby reference site)

In this meta-analysis, both  $^{137}\text{Cs}$  and  $^{210}\text{Pb}_{\text{xs}}$  activities and inventories were systematically decay-corrected from the sampling date to 1 January 2020 to allow comparisons between cores.

115

## 2.1 Publication characteristics

120

Studies included in the database mainly provided dating of lacustrine sediment (47%) and coastal/bay/estuarine sequences (29%) and to a lesser extent, marine sediment (9%), floodplain/riverine sediment (8%), marsh/wetland/peatland sediment (4.5%) and lagoon sediment (2.5%). These studies where published in a large variety of journals (n=153) dealing mainly with geosciences, chemistry and environmental radioactivity. The most frequently encountered journals in the database are the Journal of Environmental Radioactivity (n=49), Science of the Total Environment (n=45), Estuarine, Coastal and Shelf Science (n=23), Environmental Science and Technology (n=22) and Marine Pollution Bulletin (n=16). The compiled articles were published between 1977 and 2020. The number of studies reporting the use of  $^{137}\text{Cs}$  for dating sediment cores has significantly increased from the 1970s to 2020 (Fig. 2).

125

130

135

140

Studies compiled in the database mainly focus on contaminant/pollution-related topics (in 31% of the publications) followed by investigations of sedimentation rates (26%), monitoring of radionuclide concentrations in the environment (21%), paleo-environmental reconstructions (9%) and core chronology methods and limitations (3.5%). They were conducted in 63 different countries around the world. The countries with the highest number of studies are the United States of America (21%), China (10%), the United Kingdom (10%), France (6%) and Canada (5%). Most studies were conducted in Europe during the entire 1977-2020 period (with 43% of publications) followed by America (32%, respectively 28.4% for North America and 3.6% for South America), Asia (20%), Africa (3.5%) and Oceania (1.5%) – (Fig. 1). However, the proportion of publications per continent has largely changed during the 1977-2020 period. Virtually all publications were conducted in study sites located in Europe and North America during the 1977-1990 period (with 50 and 48.3% of studies, respectively) with only some marginal contributions from studies carried out in Asia (1.4%). Then, between 1990 and 2005, although Europe's (46%) and North America's (34%) dominant positions remained, the share of studies conducted in Asia increased (13%). Finally, among the 313 studies published between 2005 and 2020, only 35% of studies were carried out in Europe, followed closely by Asia (30%) and America (including 21 and 5.5% for North and South America, respectively) - (Fig. 1). This data compilation underlines the emergence of Asian publications during the last two decades whereas North American and European publications remained stable. In the absence of a large number of studies conducted in the Southern Hemisphere, the current compilation is mainly representative of observations made in the Northern Hemisphere.

## 2.2 Research design

### Metadata and core collection:

145

As metadata is required to extend the data lifecycle and promote knowledge integration by the community, a minimum reporting guidelines has been recently suggested for short-lived radionuclides (Bruel and Sabatier, 2020; Courtney Mustaphi et al., 2019). Among them, the sampling year is one of the most important and it was reported in 92% of publications. On average, 5.5 years (standard deviation – SD: 3.5 years) occurred between the core collection in the field and the publication. Coring or site coordinates were provided in 45% of the publications.

150 Alternatively, the site location was indicated on a map or the name of the location of interest (city, river, lake, area) was given in the publication text (52%). Only 3% of the publications did not provide any information about the sampling location.

The type of coring device used for sample collection was usually mentioned (81% of publications). In total, 32 different corer types were reported to have been used. Gravity corer was the most commonly used device (39%) followed by hand coring (9.6%), piston corer (8.7%), box-corer (8.2%) and vibra-corer (7.3%). Piston and gravity corers were mostly used in lacustrine studies (in 64 and 76% of the studies, respectively), a box corer was used in 81% of the marine and the coastal/estuarine studies. In contrast, a vibra-corer was mainly used in floodplain/riverine environments (44% of the studies). When the corer type was provided, the corer brand was only reported in 18.8% of the publications (the most cited brands are Uwitec, Kajac and Eijkelkamp in respectively 160 40, 10 and 6% of the articles reporting this information). Technical characteristics of the corer, as corer diameter or size are detailed in 44% of the studies (their mean diameter amounts to 8.6 cm (SD: 3.2 cm)).

Information about the drainage catchment (e.g. surface area), land use and lake characteristics are only reported in 20, 10 and 17.5% of the studies that investigated continental environments. When they were mentioned, the average catchment and water body (lake, pond, dam reservoir) surface areas reached on average 8330 km<sup>2</sup> (SD: 165 55,400 km<sup>2</sup>, range: 0.045 to 525,000 km<sup>2</sup>) and 260 km<sup>2</sup> (SD: 1130 km<sup>2</sup>, range: 0.0005 to 10,000 km<sup>2</sup>). These average values were likely overestimated because few studies provided the catchment metadata. To improve the inter-comparison between study sites in the future, we highly recommend the authors to provide systematically detailed information on the study site description.

170 **Core subsampling and data availability:**

Information about the total core length was present in 68% of the publications. This information was given in figures, tables or directly in the text. On average, the core length reached 0.85 m (SD: 1.8 m). The subsampling mode was detailed in 72% of the publications, with an average increment thickness of 2.1 cm (SD: 1.5 cm).

In 73% of the publications, the analytical method used to analyze <sup>210</sup>Pb<sub>xs</sub> was provided. Alpha spectrometry was 175 used in 33% of the studies whereas gamma spectrometry was used in the rest of the publications. As shown in Fig. 3, a shift between both analytical techniques was observed around 2005, due to the analytical developments made during this period and the improvement of gamma spectrometry potential at low energies, including at 46 keV, i.e. the gamma emission peak of <sup>210</sup>Pb.

In 60.5% of the studies, radionuclide data was provided in figures only, while in 30.7% of the articles they were 180 reported in both figures and tables. Tables only were found in 1.3% of the publications. In 7.5% of the studies, radionuclide activities were not presented at all, only the dating results (i.e. estimated year of sediment deposition in the successive layers) were provided. The studies in which the detailed data was not reported could not be included to conduct study comparisons. We highly encourage futures studies to include at least the peak radionuclide activities in the text or, even better, the provide a table with the comprehensive radionuclide analysis 185 results in the sediment archives.

### **3. Global radionuclide fallout synthesis**

#### **3.1. <sup>137</sup>Cs detection**

The first appearance of  $^{137}\text{Cs}$  in the deepest sediment layers was discussed in 14% of studies. In most of them, this fallout was attributed to the 1954-1955 period corresponding to the initial ubiquitous fallout of this radionuclide around the world (Evrard et al., 2020). As the  $^{137}\text{Cs}$  fallout activities in 1954 remained relatively low and largely (~75%) decayed since then, the first  $^{137}\text{Cs}$  appearance found in depth in a sediment core likely corresponds to deposition that took place in 1955. It was detected at the average depth of 41 cm (SD: 45 cm, range: 2 to 360 cm). In some studies, conducted in both the northern (e.g. Canada) and Southern Hemispheres (e.g. South-Africa) the deepest fallout appearance in the core was nevertheless attributed to 1957 or 1958, without any further explanation

190  
195 in the text.

Fallout associated with the atmospheric nuclear tests (~1950 to ~1980, with a peak in 1963) was detected in 50.9% of the sediment cores (n=668) at a mean depth of 27.5 cm (SD: 36 cm, range: 1 to 286 cm) with an average activity of 69.8 Bq kg $^{-1}$  (SD: 91 Bq kg $^{-1}$ , range: 0.8 to 473 Bq kg $^{-1}$ ) in the Northern Hemisphere and 11.7 Bq kg $^{-1}$  (SD: 16 Bq kg $^{-1}$ , range: 0.4 to 85 Bq kg $^{-1}$ ) in the Southern Hemisphere. The year of maximal fallout was commonly attributed to 1963 in both the northern and Southern Hemispheres although studies conducted in the Southern Hemisphere attributed on several occasions the year 1964 (n=5) or 1965 (n=4) to this peak, to take into account the time needed for a full atmosphere homogenization.

200

The Chernobyl accident was identified by the publication authors in 20.5% of the sediment cores (n=278 sediment cores). This event was mainly recorded in Europe (77.7%), although it was also reported from cores collected in Asia (17.6%, mostly in the western part of the continent) as well as in Northern Africa (1.4%) – (Fig. 4). Surprisingly, a peak of radiocaesium was also attributed to this accident in cores from China (n=17), Eastern Asia, in North America (2.9%, Canada [n=4] and Mexico [n=3]) as well as in central Africa (Ghana [n=2]) or in Oceania (Australia [n=1]). The average activity associated with this accidental fallout was 670 Bq kg $^{-1}$  (SD: 5070 Bq kg $^{-1}$ , range: 2.3 to 48,000 Bq kg $^{-1}$ ). The highest activities associated with the Chernobyl accident were detected in the vicinity of the nuclear plant, especially in Ukraine, where the highest activities were recorded, as well as in Sweden, Germany, Poland, Romania and in the Alps. The lowest activities attributed to this accident were mostly located in western Europe (e.g. United Kingdom) and in southeastern Europe (Greece, Turkey). On average, this event was detected at a 30-cm depth (SD: 59 cm, range: 1 to 420 cm) in the sediment cores.

210  
215

The discrimination between fallout that occurred in 1963 and after Chernobyl can be achieved through the analysis of  $^{239+240}\text{Pu}$  and  $^{241}\text{Am}$ . Both radionuclides were respectively searched for in 12.7% and 11% of the sedimentary sequences compiled in this database. Accordingly,  $^{241}\text{Am}$  was found in 30% of studies where the 1963 fallout alone was identified.

Finally, fallout associated with the Fukushima accident was identified in 1.9% of the sediment cores (n=26). This level was mainly detected in mainland Japan or along the Japanese eastern coast (Fig. 4) although it was also surprisingly identified in Mexican and Ghanaian sediment sequences. The average activity associated with this fallout was 1920 Bq kg $^{-1}$  (SD: 7780 Bq kg $^{-1}$ , range: 6 to 35,700 Bq kg $^{-1}$ ). This level was identified at an average depth of 1.8 cm (SD: 3 cm, range: 0.25 and 11.5 cm) in the sediment sequences.

220

In addition to fallout attributed to the Fukushima and Chernobyl accidents and the atmospheric nuclear tests, 24 other local or regional events that have released radionuclides into the environment were identified by the authors and listed in the current database (Table 1). Among these events, emissions following the Sellafield Nuclear Plan accidents were observed in 40 sequences (3% of the sediment cores covered in the database), the fallout associated

225

with the Mayak Production Association (Russia) in 12 sediment cores (0.9%), the dumping of radioactive waste into the Kara Sea (Russia) in 8 sediment cores (0.6%), the Chinese Nuclear test fallout in 5 sediment archives (0.4%), the Mühlenberg Nuclear Power Plant (Switzerland) in 5 sediment cores, the Bugey and Crey-Malville nuclear facilities (France) in 5 cores and the Indian Point Nuclear Plant in 4 sequences (New York State, USA). Other events included releases from the Krasnoyarsk-26 site (Russia; n=4 cores), Rokkasho nuclear facilities (Japan; n=3), La Hague nuclear fuel reprocessing plant (France; n=3), and the underwater nuclear weapons tests conducted in Novaya Zemlya (Russia, n=3), (Fig.5 and Table 1).

235

As the calculation of radionuclide inventories required an estimation of the dry bulk density which was often lacking in publications,  $^{137}\text{Cs}$  inventories were only reported for 26% of the sediment cores. The average inventory in the Northern Hemisphere was  $30,890 \text{ Bq m}^{-2}$  (SD:  $359,000 \text{ Bq m}^{-2}$ , range: 10 to  $6,000,000 \text{ Bq m}^{-2}$ , the highest value was measured in Russia close to the Mayak site) compared to  $990 \text{ Bq m}^{-2}$  (SD:  $1030 \text{ Bq m}^{-2}$ , range: 205 to  $3180 \text{ Bq m}^{-2}$ ) in the Southern Hemisphere. The high standard deviation observed in the Northern Hemisphere is mainly due to the high inventories found in the vicinity of Chernobyl, Krasnoyarsk as well as the Mayak production site (Fig. 6).

240

Inventories of  $^{137}\text{Cs}$  at reference locations located nearby the sediment core collection site were provided in 7.7% of the publications. The average reference inventory was  $1610 \text{ Bq m}^{-2}$  (SD:  $2810 \text{ Bq m}^{-2}$ , range: 268 to  $24,000 \text{ Bq m}^{-2}$ ) in the Northern Hemisphere. Only one inventory was reported in the Southern Hemisphere ( $360 \text{ Bq m}^{-2}$ ).

245

Information about sedimentation rates based on  $^{137}\text{Cs}$  analyses was provided in 34.6% of the publications. The 1963 peak level was generally used for estimating this average sedimentation rate.

### **3.2. Latitudinal distribution of $^{137}\text{Cs}$ in sediment cores**

The maximal activities associated with the atmospheric nuclear tests (activities generally attributed to 1963) were recorded between the latitudinal bands comprised between  $40$  and  $60^\circ\text{N}$ , with an average activity of 90 and  $117 \text{ Bq kg}^{-1}$ , respectively. Values were not available for the bands located between  $0$ - $10^\circ\text{S}$ ,  $50$ - $60^\circ\text{S}$  and  $80$ - $90^\circ\text{S}$ . This is consistent with the United Nations Scientific Committee of the Effects of Atomic Radiation (UNSCEAR, 2000) compilations recording the highest inventories between  $40$  and  $60^\circ\text{N}$  for this event (inventories reached respectively 1186 and 1383  $\text{Bq m}^2$ ). Distribution of both databases were similar with a strong correlation coefficient between inventories and activities ( $r^2=0.87$ ,  $p$ -value  $<0.05$ ) – (Fig. 7).

255

Comparison between reference inventories of  $^{137}\text{Cs}$  compiled in the current research and those from UNSCEAR showed a lower correlation ( $r^2=0.4$ ,  $p$ -value  $<0.05$ ). This poorer correlation was mostly due to the absence of inventories reported between  $10^\circ\text{N}$  and  $30^\circ\text{S}$  and between  $30$  and  $90^\circ\text{S}$ . It can also be explained by the high inventories recorded between  $30^\circ$  and  $40^\circ\text{N}$ , which were impacted by the high values measured in the vicinity of the Mayak production site (Fig. 7).

### **3.3. $^{210}\text{Pb}_{\text{xs}}$ detection and use**

This natural radionuclide was often used in combination with  $^{137}\text{Cs}$  in this database (in 64% of the studies). In these publications, the core chronology based on  $^{210}\text{Pb}_{\text{xs}}$  was estimated with 7 different models (Constant Rate of Supply (CRS) (Appleby and Oldfield, 1978), Constant Initial Concentration (CIC) (Pennington *et al.*, 1976), Constant Flux Constant Sedimentation (CFCS) (Krishnaswamy *et al.*, 1971), Periodic Flux model (PF) (Sanchez-

Cabeza et al., 2000), Constant Initial Concentration and Constant Sedimentation rate (CICCS) (He and Walling, 1996), Constant Rate of Accumulation (CRA) and Constant Initial Activity (CIA) (Robbins and Herche, 1993). Among the most employed tools, the CRS model (also referred to as CRSMV model in some publications) was applied in 54% of the studies, the CIC model (also designed as CA model) in 23% of the articles and the CFCS 270 model (also called CF, CSM, CFS or RSSM model with some of them including limited adaptations) in 20% of the publications. Sedimentation rate was detailed in 56.7% of publications using the  $^{210}\text{Pb}_{\text{xs}}$  for establishing core chronology.

The  $^{210}\text{Pb}_{\text{xs}}$  inventories were given in 11.7% of the studies and the inventories of this natural radionuclide at references sites were presented in only 4.1% of the studies. The average inventory in the Northern Hemisphere 275 amounted to  $6510 \text{ Bq m}^{-2}$  (SD:  $10,640 \text{ Bq m}^{-2}$ , range: 20 to  $96,000 \text{ Bq m}^{-2}$ ). Only one value was available in the Southern Hemisphere ( $2560 \text{ Bq m}^{-2}$ ). The average inventory at reference sites in the Northern Hemisphere was  $1730 \text{ Bq.m}^{-2}$  (SD:  $760 \text{ Bq m}^{-2}$ ) with an average flux of  $90 \text{ Bq m}^{-2} \text{ yr}^{-1}$  (SD:  $100 \text{ Bq m}^{-2} \text{ yr}^{-1}$ ). Corresponding inventories at reference sites were not reported for the Southern Hemisphere and only one value of  $^{210}\text{Pb}_{\text{xs}}$  flux was provided ( $39 \text{ Bq m}^{-2} \text{ yr}^{-1}$ ).

#### 280           **3.4. Other radionuclides**

In addition to  $^{137}\text{Cs}$  and  $^{210}\text{Pb}_{\text{xs}}$ , other radionuclides were frequently detected in the sediment cores. Most of these additional radionuclides were analyzed in order to provide a discrimination between the different  $^{137}\text{Cs}$  sources including plutonium, americium, cobalt and strontium or to provide information on sediment dynamics over shorter periods (e.g.  $^7\text{Be}$ ,  $^{228}\text{Th}$ ). Among the 28 radionuclides frequently identified, the  $^{239+240}\text{Pu}$  ratio and  $^{241}\text{Am}$  285 activities were the most widely reported. The other reported radionuclides were beryllium isotopes ( $^7\text{Be}$  (1.7%),  $^8\text{Be}$  (0.07%),  $^9\text{Be}$  (0.07%),  $^{10}\text{Be}$  (0.22%),  $^{11}\text{Be}$  (0.07%)), bismuth ( $^{207}\text{Bi}$  (0.22%)  $^{214}\text{Bi}$  (0.59%)) caesium ( $^{134}\text{Cs}$  (4.9%)), cobalt ( $^{60}\text{Co}$  (1.4%)), neptunium ( $^{237}\text{Np}$  (0.15%)), plutonium ( $^{238}\text{Pu}$  (2.5%),  $^{241}\text{Pu}$  (0.3%),  $^{242}\text{Pu}$  (0.07%),  $^{243}\text{Pu}$  (0.07%)), potassium ( $^{40}\text{K}$  (1.5%)), radium ( $^{226}\text{Ra}$  (0.96%),  $^{228}\text{Ra}$  (0.14%)), strontium ( $^{90}\text{Sr}$  (2.8%)), 290 technetium ( $^{99}\text{Tc}$  (0.07%)), thorium ( $^{228}\text{Th}$  (0.3%),  $^{232}\text{Th}$  (0.3%),  $^{234}\text{Th}$ (0.37%)) and uranium ( $^{236}\text{U}$  (0.07%),  $^{238}\text{U}$  (0.3%)). The  $^{14}\text{C}$  was analyzed in 4.5% of the sediment cores. This isotope was exclusively analyzed by Accelerator Mass Spectrometry (AMS) in the articles included in the database for providing long term chronology.

### 4. Discussion

#### 4.1 General patterns of $^{137}\text{Cs}$ fallout

According to UNSCEAR (2000), 77% of the total worldwide fallout of  $^{137}\text{Cs}$  is estimated to have occurred in the 295 Northern Hemisphere. Previous studies have identified two main sources of  $^{137}\text{Cs}$  in Europe, including the fallout associated with the thermonuclear weapon tests and that emitted by the Chernobyl accident (Meusburger et al., 2020). In the current database,  $^{137}\text{Cs}$  deposition associated with above-ground nuclear tests was largely detected across the European continent with a peak systematically assigned to 1963 (Fig. 4). This peak was described in the literature as the most reliable time marker worldwide (He and Walling, 1997). In addition, no technical problem 300 was reported to detect the occurrence of fallout associated with the Chernobyl accident. This fallout was identified in sediment cores across Europe from North to South (from Norway to Spain) and from West to East (from Ireland

to Belarus). In certain areas as in western France, south-western England, Southern Spain, Portugal or in Iceland, this fallout was not detected (Fig. 4). This observation is in agreement with our previous knowledge on the spatial distribution of Chernobyl fallout across Europe (Evangelou et al., 2016). In some regions (e.g. Alps), the Chernobyl fallout appears to be highly heterogeneous and reflects the radioactive cloud pathway and the heterogeneous rainfall pattern after the catastrophe (Alric et al., 2013). In addition to the peaks associated with the Chernobyl accident and the global fallout, the current research has allowed to identify nine local or regional events in Europe that led to radionuclide releases and peaks in sediment sequences. The Sellafield/Windscale releases (1957, 1974, 1975, 1981, 1985) were the most often detected in European sequences (identified in the United Kingdom, along Greenland coasts and in the Baltic Sea) – (e.g. Perner *et al.*, 2010).

In North America, the 1963 peak was often detected in sediment cores (e.g. Van Metre *et al.*, 2004; Corcoran *et al.*, 2018) – (Fig. 4). Five local events were also identified in addition to this peak with a limited spatial extent as in the vicinity of the Savannah River Site (1964), (Lewis et al., 2000), the Indian Point Energy Center (1971-1975), (Bopp et al., 1982), the Oak Ridge National Laboratory (Sobocinski, 1990), the Peach Bottom Atomic Power Station (McLean and Summers, 1990) and the Hanford Plutonium Production Center (1944-1970), (Beasley and Jennings, 1984).

Asia and more specifically China proved to be the most complex region of the world for identifying the sources of the discrete peaks of  $^{137}\text{Cs}$ . The  $^{137}\text{Cs}$  peaks identified in parts of China (e.g. Xinjiang, Guangdong, Guizhou provinces - (Bai et al., 2002; Chen et al., 2014)) were associated with Chinese above-ground nuclear tests conducted during the 1960-1970s. In addition, several studies conducted in the northwest and the south of China (Xinjiang, Yunnan and adjacent areas) proposed that the uppermost  $^{137}\text{Cs}$  peak found in lacustrine sediment cores may be attributed to the Chernobyl fallout in 1986. In Chinese cores, fallout associated with the Chernobyl accident was even detected more frequently than the Chinese nuclear tests. It was detected in the Tibetan plateau (e.g. Lake Ngoring – Zhang *et al.*, 2014), in the headwaters of the Yellow river, as well as in cores collected in lower reaches of this river, in its delta (Wu et al., 2015) and along the Yellow Sea coastline (Sun et al., 2012). This event was also often identified in several lacustrine deposits of southwestern China (e.g. Yunnan Province) - (Zeng & Wu, 2009; Wang *et al.*, 2018). On the contrary, it was almost never detected in the central and northeastern parts of China (it was only reported in the Miyun reservoir, north of Beijing; Xia *et al.*, 2015). However, whether this/these peak(s) should be attributed to the Chinese nuclear tests, Russian tests or the Chernobyl accident remains debated in the scientific community. Nevertheless, the current literature review shows that a  $^{137}\text{Cs}$  peak in a lacustrine sediment core was never attributed to the Chernobyl accident in a vast region comprised between the eastern part of Turkey and China. Accordingly, it is very unlikely that the attribution of a  $^{137}\text{Cs}$  peak to the Chernobyl fallout in Chinese cores is meaningful. As these events took place ~10 years apart, future research should incorporate the use of additional tracers that may unambiguously discriminate both sources of radionuclides in this region. Plutonium ( $^{240}\text{Pu}/^{239}\text{Pu}$ ) or caesium ( $^{135}\text{Cs}/^{137}\text{Cs}$ ) atom ratios may provide good candidates to achieve this type of discrimination (Bu et al., 2015; Lan et al., 2020; Zhu et al., 2020).

Further to the East, lacustrine and marine sedimentary sequences studied in Japan allowed to identify three main sources of  $^{137}\text{Cs}$ . The first local  $^{137}\text{Cs}$  source detected in Japan was attributed to the atomic bomb peak in 1945 in the Nagasaki area (Mahara and Kudo, 1995). The peak associated with the atmospheric nuclear tests in 1963 was

then largely recorded across the entire Japanese peninsula (e.g. Lu & Matsumoto, 2009; Hosono *et al.*, 2016) whereas the fallout associated with the Fukushima accident was mainly identified in the vicinity of the Fukushima NPP, in particular in lacustrine sediments of the Miyagi, Fukushima and Ibaraki Prefectures (Cao *et al.*, 2017; Jaegler *et al.*, 2019; Minoura *et al.*, 2014), as well as in sediment samples collected along the Pacific coast off the Fukushima prefecture (e.g. Black & Buesseler, 2014) – (Fig. 4).

According to UNSCEAR (2000), only 23% of the total  $^{137}\text{Cs}$  fallout is estimated to have occurred in the Southern Hemisphere. In contrast to what was reported for the Northern Hemisphere, few studies using both  $^{137}\text{Cs}$  and  $^{210}\text{Pb}_{\text{xs}}$  for dating sediment archives were found in this part of the world. This is mainly the case for Africa and Oceania.

Studies available in the Southern Hemisphere reported the occurrence of a single peak attributed to the thermonuclear tests. However, no consensus was shared in the literature to assign a single year to this peak. Several authors have attributed the year 1963 (e.g. Chile, Antarctica - Urrutia *et al.*, 2007; Christ *et al.*, 2015) to this peak as in the Northern Hemisphere, whereas other authors dated this peak to 1964 (e.g. Chile - Elbert *et al.*, 2013) or even 1965 (e.g. in Chile, Argentina, South Africa or in the Kerguelen Island - Arnaud *et al.*, 2006; Kastner *et al.*, 2010; Boardman & Foster, 2011; Ficetola *et al.*, 2018). This shift of 1 to 2 years in the assigned year for the thermonuclear bomb fallout peak between the Northern and Southern Hemispheres can be attributed to the time required for the mixing of air masses from both Hemispheres and the occurrence of significant  $^{137}\text{Cs}$  fallout transfer to the Southern Hemisphere. However, this question remains debated and additional sedimentary sequences should be collected in the future to improve the assignation of this peak (Guevara and Arribére, 2007) and sediment core dating in the Southern Hemisphere.

#### 4.2. Limitations of the currently published $^{137}\text{Cs}$ research

This worldwide database also underlines the unexpected detection of  $^{137}\text{Cs}$  sources in certain regions of the world. In China, a large number of studies claim to have detected Chernobyl fallout whereas more [regional](#) sources of  $^{137}\text{Cs}$  attributed to the Chinese and Russian nuclear tests conducted in Lop Nor and Semipalatinsk, respectively, are not considered as a potential origin (Huang *et al.*, 2019; Zhao *et al.*, 2020). The potential impact of these tests should be investigated more thoroughly. On the contrary, the attribution of a peak to the Chernobyl fallout should be avoided without clear isotopic evidence ([e.g. plutonium isotopes](#)), as the associated fallout was not observed in a vast region that extends from the Ural Mountains/Eastern Turkey to China. For example, in a lacustrine sediment core collected in Mexico, the occurrence of  $^{137}\text{Cs}$  was attributed to both Chernobyl (Méndez-García *et al.*, 2014) and Fukushima accidents (Caballero *et al.*, 2020). This remains to be confirmed as other studies conducted nearby these areas did not record these  $^{137}\text{Cs}$  sources. They only recorded fallout associated with the global bomb peak in 1963 (e.g. Hansen, 2012). A similar finding [was](#) made in Ghana where both fallout sources associated with Fukushima and Chernobyl accidents were recorded in the Amisa and Sakumo River estuaries (Mahu *et al.*, 2016) whereas no single  $^{137}\text{Cs}$  peak could be identified in sediment collected in the nearby Volta and Pra River estuaries (Klubi *et al.*, 2017). In North America,  $^{137}\text{Cs}$  fallout attributed to Chernobyl was identified in Canada, in the Vermillon Lake (Schindler and Kamber, 2013), as well as in the North Lake in the United States (Hardaway *et al.*, 1998). The attribution of  $^{137}\text{Cs}$  peaks to Chernobyl in Mexico, North America, Africa should be taken with great caution in view of the observations made in the current literature compilation and our knowledge of the fallout dispersion (Evangelou *et al.*, 2016).

380 These very likely incorrect assignments could instead have been induced by the occurrence of some local and  
regional  $^{137}\text{Cs}$  sources or by various processes that may affect the distribution of  $^{137}\text{Cs}$  in sediment cores. For  
example, soil erosion was detected in various studies as one of the major process complicating the  $^{137}\text{Cs}$  peak  
identification in the core. This process may have induced an incorrect assignation through the sudden delivery of  
sediment with higher  $^{137}\text{Cs}$  levels (Foucher et al., 2019; Swales et al., 2002) or in contrast lower levels of  $^{137}\text{Cs}$  in  
385 some sediment layers that may be delivered by subsoil sources, sheltered from atmospheric fallout and depleted  
in this radioisotope (Foster et al., 2005). Furthermore, earlier deposits of  $^{137}\text{Cs}$  on ice and snow were reported to  
have increased the  $^{137}\text{Cs}$  activity in a sediment sequence of Antarctica after ice melting (Sanders et al., 2010). On  
the contrary, certain storm events and the associated flood deposits can lead to the dilution of the  $^{137}\text{Cs}$  signal (Gu  
et al., 2011). In addition to these natural and anthropogenic processes that may lead to an increase or a decrease  
390 of the  $^{137}\text{Cs}$  activity along sedimentary sequences, a large number of studies included in the current database  
reported the occurrence of post-depositional processes. Among them, bioturbation and post-depositional  
mobility/diffusion may disturb the temporal profile of radionuclides with depth along the core and dilute their  
concentrations (Benninger et al., 1998; Larsen et al., 2010; Matter et al., 2010). Finally, in some studies, this  
intense sediment mixing led to the impossibility to establish a chronology, typically when no discrete peak was  
395 clearly detected (Eades et al., 2002) or when inconsistent peaks were observed. The frequency of the occurrence  
of these mixing processes in sediment sequences is difficult to estimate as the analyses of cores that cannot be  
dated remain often unpublished.

#### 4.3 Main recommendations for future studies

Overall, this literature review has demonstrated the frequent lack of metadata in publications dealing with sediment  
400 core dating and analysis. Accordingly, we highly recommend the authors of future studies to provide detailed  
information about the reservoir/coring site characteristics, the catchment properties (when relevant) as well as on  
the coring methodology. In the current synthesis, raw radionuclide data were only provided in tables or in a  
reusable format in 30.7% of the publications. To extend the short-lived radionuclide data lifecycle (Bruel and  
405 Sabatier, 2020; Courtney Mustaphi et al., 2019; Wilkinson et al., 2016) and allow more frequent inter-comparisons  
between sites and methodologies, we strongly encourage the authors to systematically provide the detailed  
radionuclide analysis results in tables associated with the publication or in open access data repositories.

Most of the studies covered in the current compilation were conducted in the Northern Hemisphere. This synthesis  
therefore highlights a massive lack of studies in the South Hemisphere in general, and in Africa in particular. As  
these regions of the world have been undergoing major anthropogenic changes and pressures since the mid-20<sup>th</sup>  
410 century, this should be further explored and investigated through the analysis of sediment cores. The achievement  
of more studies in the Southern Hemisphere will contribute to improve our knowledge of nuclear fallout-related  
events in the southern half of the world where no consensus has been reached at this stage regarding the attribution  
of a single year to the  $^{137}\text{Cs}$  fallout peak.

Finally, the current meta-analysis suggests the potential occurrence of errors in peak attributions in certain regions  
415 of the world. To avoid any dating and subsequent interpretation errors in the reconstructions (e.g. contamination)  
based on the analysis of these archives, we strongly recommend the analysis of complementary tracers that may  
discriminate  $^{137}\text{Cs}$  sources unambiguously (e.g.  $^{241}\text{Am}$ ,  $^{90}\text{Sr}$ , plutonium ( $^{240}\text{Pu}/^{239}\text{Pu}$ ) or caesium ( $^{135}\text{Cs}/^{137}\text{Cs}$ ) atom  
ratios).

## **5. Conclusions**

420 A unique meta-analysis of the sediment core dating research using radionuclides was conducted for the 1977–2020 period. This literature overview provides a worldwide referential to help the scientific community reaching a consensus for dating recent sedimentary archives by identifying the  $^{137}\text{Cs}$  peak(s) that may be found in various regions and environments across the globe. This study documents the occurrence of three main sources of  $^{137}\text{Cs}$  that are the 425 most widely detected in sediment cores (nuclear weapon tests, Chernobyl and Fukushima accidents), as well as 24 additional local and regional releases of  $^{137}\text{Cs}$ , which have been synthetized here. The correct attribution of these sources may improve the establishment of core chronology or the validation of  $^{210}\text{Pb}_{\text{xs}}$  age models. Nevertheless, this meta-analysis outlines the complexity to discriminate between some of these  $^{137}\text{Cs}$  sources and the necessity 430 to use additional tools such as plutonium and caesium isotopic ratios to provide an unambiguous distinction between potential sources and avoid any dating errors. This review also highlights the low proportion of paleo-reconstructions conducted in the Southern Hemisphere in general, and in Africa and Oceania in particular, compared to what has been published for the Northern Hemisphere. It also underlines the necessity to improve the identification of the maximal period of  $^{137}\text{Cs}$  emissions after the thermonuclear tests in the Southern Hemisphere by collecting a larger number of sediment archives across wider areas.

435 Overall, this meta-analysis demonstrates the effectiveness of using the  $^{137}\text{Cs}$  and  $^{210}\text{Pb}_{\text{xs}}$  activities for dating sediment cores and reconstructing environmental changes and their impacts over the 20<sup>th</sup> century. In the future, authors are encouraged to share their data including the radionuclide activities measured in the successive sediment layers and the associated metadata in their publications.

## **Data availability**

440 Data are available on the PANGAEA repository at <https://doi.pangaea.de/10.1594/PANGAEA.931493> (Foucher et al., 2021)

## **Author contribution**

A.F and O.E contributed to the data set compilation. A.F, PA.C, P.S and O.E participated to the results discussion and drafted the main manuscript.

## **445 Competing interest**

The authors declare that they have no conflict of interest

## **Acknowledgements**

The authors are very grateful to the scientific community using fallout radionuclides and especially to those colleagues who published their raw data for dating sediment cores without whom the current overview would not

450 have been possible. The lock-down periods associated with the worldwide covid-19 pandemic also allowed the authors to find time to focus on this demanding literature review.
