Abstract. The Earth energy imbalance (EEI) at the top of the atmosphere is responsible for the accumulation of heat in the climate system. Monitoring the EEI is therefore necessary to better understand the Earth’s warming climate. Measuring the EEI is challenging as it is a globally integrated variable whose variations are small (0.5-1 W m⁻²) compared to the amount of energy entering and leaving the climate system (∼ 340 W m⁻²). Since the ocean absorbs more than 90 % of the excess energy stored by the Earth system, estimating the ocean heat content (OHC) provides an accurate proxy of the EEI. This study provides a space geodetic estimation of the OHC changes at global and regional scales based on the combination of space altimetry and space gravimetry measurements. From this estimate, the global variations in the EEI are derived with realistic estimates of its uncertainty. The mean EEI value is estimated at +0.74±0.22 W m⁻² (90 % confidence level) between August 2002 and August 2016. Comparisons against independent estimates based on Argo data and on CERES measurements show good agreement within the error bars of the global mean and the time variations in EEI. Further improvements are needed to reduce uncertainties and to improve the time series especially at interannual and smaller time scales. The space geodetic OHC-EEI product is freely available at https://doi.org/10.24400/527896/a01-2020.003.

1 Introduction

Over the last decades, greenhouse gases and aerosols concentrations have been increasing in the atmosphere, disrupting the balance in the Earth system between incoming and outgoing radiation fluxes. Part of the outgoing longwave radiation being blocked, the system has reemitted less energy towards space than it has received from the Sun (Hansen et al., 2011; Trenberth et al., 2014). This imbalance at the top of the atmosphere, known as the Earth energy imbalance (EEI), is about 0.5-1 W m⁻² (von Schuckmann et al., 2016). It is challenging to estimate the EEI since it is two orders of magnitude smaller than the mean incoming solar radiation (340 W m⁻²) (L’Ecuyer et al., 2015).
Positive values of the EEI indicate that an excess of energy is stored in the climate system. With its high thermal inertia and its large volume, the ocean acts as a buffer, accumulating most of the excess of energy (more than 90 %, e.g. von Schuckmann et al., 2020) in the form of heat. The other climate reservoirs, the atmosphere, land and cryosphere, play a minor role in the energy storage at seasonal and longer time scales (von Schuckmann et al., 2020b). As a result, the ocean heat uptake (OHU) prevails in the global energy budget on timescales longer than several months. The global OHU (GOHU) is therefore a good proxy of the EEI variations.

The OHU is counted positive when heat enters the ocean and negative when heat leaves the ocean. It is the time derivative of the ocean heat content (OHC). OHC change time series may be inferred by different approaches: (1) direct measurement of temperature/salinity profiles mainly derived from the Argo floats network (von Schuckmann et al., 2020b), (2) re-analysis which combines in situ measurements of temperature/salinity and space measurements of sea level with ocean modelling (Stammer et al., 2016), (3) through the ocean surface net flux from satellite observations (Kato et al., 2018; L’Ecuyer et al., 2015), (4) and the space geodetic approach (introduced in Meyssignac et al., 2019 and this study). These methods are complementary, with their own advantages and limitations (Meyssignac et al., 2019). Direct measurements approach relies on in situ measurements which are unevenly spatially distributed with poor sampling of the deep ocean (below 2000 m depth), marginal seas and below seasonal sea-ice. Re-analyses provide a more complete description of the ocean’s state that is consistent with the dynamics of the ocean but are subject to large biases in the polar oceans, spurious drifts in the deep ocean and inaccurate initial conditions that may obfuscate a significant part of the OHC signal related to EEI (Palmer et al., 2017). Ocean net flux approach consists in assessing the radiative and turbulent fluxes from satellite observations to provide the spatial distribution of net heat fluxes at the ocean surface, but it is tainted with large residuals and uncertainties (Kato et al., 2018; L’Ecuyer et al., 2015). The space geodetic approach aims at measuring the sea level changes due to the thermal expansion and saline contraction of the ocean (also called steric sea level changes) based on differences between the total sea level changes derived from satellite altimetry measurements and the barystatic sea level changes from satellite gravity measurements. This approach offers consistent spatial and temporal sampling of the ocean, with a nearly global coverage of the oceans, excepting the polar regions. It also provides OHC change estimates over the entire ocean water column.

The EEI shows time variations in response to anthropogenic emissions and natural variability like ocean-atmosphere interactions or volcanic eruptions. Different amplitudes and time scales are involved in these time variations from monthly to interannual variations of the order of a few Wm⁻² associated with the coupled natural variability of the ocean and the atmosphere to decadal and longer-term variations of the order of a few tenth of Wm⁻² associated to the anthropogenic and the natural forcing of the climate system. To evaluate these variations and particularly the small decadal and longer-term response of EEI to anthropogenic or natural forcing, EEI should be estimated with an accuracy better than 0.1 W m⁻². This is particularly challenging and it requires a fine characterisation of the errors associated with the EEI estimates.

The originality of this study is to provide the OHC change and EEI from space altimetry and space gravimetry with a comprehensive description of the uncertainty. This space geodetic approach has three major advantages: it covers the ocean down to the bottom, the spatial coverage is nearly global (until 82° poleward) and it is based on a few instruments which
enables an exhaustive description of error sources and a robust propagation of errors from the measurements to the global OHC (GOHC) change estimate. A preliminary estimate of the GOHC 10-year-trend uncertainty of +/-0.32 W m\(^{-2}\) (90 % confidence level -CL-) has been published with this approach (Meyssignac et al., 2019). A central objective of this study is to revisit this uncertainty estimate, extend it to other time spans and reduce it as much as possible. First, we extend the spatial and temporal coverage of OHC change and EEI time series, to provide regional and global estimates of OHC change over the period 2002 to 2016. Second, we rigorously and accurately assess the uncertainty in GOHC change and EEI, propagating the errors from the sea level and ocean mass changes estimates and taking into account the time correlations in errors. To reach these objectives, innovative algorithms have been developed. We present them in this paper.

The physical assumptions underlying the estimation of the EEI from space geodetic measurements are introduced in section 2. Section 3 describes the sea level and ocean mass variations, and thermal expansion data used as input for the computation of OHC changes and the EEI over the 15-year period from August 2002 to August 2016 (sect. 4.1). Error propagation and uncertainty calculation are performed independently (sect. 4.2). Results are gathered in sections 5 and 6 for the OHC change and the EEI respectively, including comparisons with independent estimates mainly based on the in situ Argo network. Conclusions and perspectives for improvement of the EEI record are given in section 7.

In this article, all uncertainties associated are reported within a [5 % - 95 %] confidence level interval (also noted 90 % CL).

2 Physical principle

In the space geodetic approach, OHC changes are estimated from steric sea level changes, which are due to the thermal expansion and the haline contraction of the ocean column of water. Steric sea level changes are calculated as the difference between total sea level changes and ocean mass changes (e.g. Meyssignac et al., 2017; Forget and Ponte, 2015 and references there in). It is expressed by the sea level budget equation (Eq.1.) where the total sea level change (\(\Delta S_{total}\)) is the sum of the ocean mass change (\(\Delta S_{mass}\)) and the ocean steric sea level change. The latter is composed of two terms, the ocean thermal expansion change (\(\Delta S_{thermостeric}\)) and the ocean halosteric change (\(\Delta S_{halостeric}\)).

\[
\Delta S_{total} = \Delta S_{mass} + \Delta S_{thermостeric} + \Delta S_{halостeric},
\]

At global scale, the ocean salinity change is negligible (Llovel et al., 2019, Gregory et al., 2019). Therefore Eq. (1), can be simplified, and the global mean thermosteric sea level change (\(\Delta GMT_{SL}\)) is obtained from the difference between the global mean sea level change (\(\Delta GM_{SL}\)) and the global mean ocean mass change (\(\Delta GM_{MOM}\)).

\[
\Delta GMT_{SL} = \Delta GM_{SL} - \Delta GM_{MOM},
\]
Then, the GOHC change ($\Delta\text{GOHC}$) is derived by dividing the thermal expansion change by the expansion efficiency of heat (EEH), noted $\varepsilon$ at global scale as in Eq. (3) (see Melet and Meyssignac, 2015 for more details):

$$\Delta\text{GOHC} = \frac{\Delta\text{GMSL}}{\varepsilon}. \tag{3}$$

At global scale, on annual and longer time scales, the heat stored by the Earth in response to the EEI is stored essentially in the ocean because the heat capacity of the ocean is much larger than the heat capacity of the rest of the climate system (Palmer and McNeall, 2014; Melet and Meyssignac, 2015). The fraction of energy entering the ocean $\alpha$ is around 0.9. The EEI can now be retrieved from the GOHU, the temporal derivative of GOHC, by dividing it by $\alpha$ the fraction of energy entering the ocean (Eq.(4)). $\alpha$ is set to 0.9, the recent estimate from von Schuckmann et al., 2020. Beforehand, GOHC change is filtered out to remove the signals related to the intrinsic ocean variability, mostly happening in the mixed layer above the pycnocline. For short time scales (< 2-3 years), this signal does not correspond to any response to global warming and therefore must be removed to infer variations in the EEI:

$$\text{EEI} = \frac{\text{GOHU}}{\alpha} = \frac{1}{\alpha} \frac{d\text{GOHC}}{dt}, \tag{4}$$

In this study, total sea level change is observed from space with radar altimetry missions (see section 3.1), ocean mass change is observed from space with the gravimetry missions (see section 3.2) and the global and regional EEH is estimated from in situ observations of ocean temperature and salinity (see section 3.3).

3 Data

3.1 Sea level

In this study we used sea level daily gridded dataset for the global ocean (Taburet et al., 2019; Legeais et al., in prep) that is distributed by the Copernicus Climate Service (C3S) and contains the sea level anomalies around a mean sea surface above the reference mean sea surface computed over 1993-2012, also referred as the total sea level change. Data is available over the entire altimetry area from January 1993 onward. They are provided on a daily basis at a spatial resolution of 0.25° x 0.25°. Thanks to rigorous processing of altimetry measurements based on a two-satellite altimetry constellation, homogeneous altimetry standards applied over time (e.g. geophysical corrections, orbit solutions, etc.) and solid validation activities carried out upstream, C3S sea level products are dedicated to the monitoring of the long-term sea level variations. As C3S sea level grids are not corrected from the global isostatic adjustment (GIA), a correction is applied a posteriori. It is derived from an ensemble mean of regional GIA corrections computed with the ICE-5G model and with various viscosity profiles (27 profiles) used in Prandi et al. (2021) (Spada and Melini, 2019). The average GIA value over oceans is -0.28 mm yr$^{-1}$ close to the generally accepted value of -0.3 mm yr$^{-1}$ (e.g. WCRP Global Sea Level Budget Group, 2018). An additional correction of
+0.1 mm yr\(^{-1}\) is considered for the deformations of the ocean bottom in response to modern melt of land ice (Frederikse et al., 2017).

The description of the errors, and the uncertainties on the long-term stability of the sea level estimate in these products were provided by Ablain et al. (2019) and Prandi et al. (2021) for the global and regional scales respectively. Over the whole altimetry period (January 1993-December 2020), the GMSL shows a significant rise of \(+3.52 \pm 0.35\) mm yr\(^{-1}\). Focusing on the period of interest in this study (August 2002-August 2016), the GMSL increase is \(+3.57 \pm 0.40\) mm yr\(^{-1}\). At the regional scale, the sea level rise distribution ranges between 0 and 6 mm yr\(^{-1}\), with uncertainties ranging from \(\pm 0.8\) to \(\pm 1.2\) mm yr\(^{-1}\), pointing out that the sea level is rising everywhere over the globe. Recent studies also showed that sea level is accelerating at \(0.12 \pm 0.07\) mm yr\(^{-2}\) at the global scale (Ablain et al., 2019) and ranges between -1 mm yr\(^{-2}\) and +1 mm yr\(^{-2}\) at the regional scale (Prandi et al., 2021).

### 3.2 Ocean mass

The Gravity Recovery And Climate Experiment (GRACE) mission, launched in 2002, allowed continuous monitoring of ocean mass change over the study period (Tapley et al., 2004). GRACE was decommissioned in 2017 and its successor GRACE Follow-On (GRACE-FO) was launched in May 2018. This study stands as a proof of concept, demonstrating the capability to deliver space geodetic estimates of the OHC change and EEI and their associated uncertainties. The study period is therefore limited to April 2002-August 2016 when the GRACE data shows the best quality. This restricted period enable to avoid (i) instrumental issues deprecating the quality of the GRACE data at the end of the mission (e.g. Wouters et al., 2014), (ii) the 11-months data gap between GRACE and GRACE-FO, (iii) instrumental issues during the GRACE-FO mission on the accelerometers, (iv) eventual biases between the GRACE and GRACE-FO missions (e.g. Landerer et al., 2020; Chen et al., 2020). Ocean mass variations observed by GRACE are mainly due to freshwater exchanges with the continents (including ice-melting and water cycle) at global scale, and, also, to the ocean circulation at regional scale. However, estimating the rates of global and regional ocean mass change with GRACE data remains a challenging task due to numerous processing choices that can strongly affect the results and lead to a large variety of solutions with significant uncertainty (Uebbing et al., 2019). In this study, we considered the GRACE LEGOS ensemble V1.4 (ftp://ftp.legos.obs-mip.fr/pub/soa/gravimetrie/grace_legos/V1.4/) updated from Blazquez et al., (2018). This ensemble version includes 216 solutions, based on fully normalised spherical harmonic solutions from six different centers and a large variety of choices for post-processing corrections including the corrections of the geocenter motion, the oblateness of the Earth, the atmosphere ocean dealiasing, the filtering of the noise responsible for the characteristic stripes of GRACE gravity data, the leakage correction and the GIA. More details of this update and the appropriate references can be found in the appendix A. This ensemble approach allows a robust estimation of the uncertainties associated with state-of-the-art ocean mass change estimates based on GRACE measurements (see Blazquez et al., 2018 for more details). In addition to spherical harmonics, the ocean mass change can also be estimated from mascon solutions provided by the Jet Propulsion Laboratory (JPL RL06), the Center for Space Research (CSR RL06) and the Goddard Space Flight Center (GSFC RL06). These three mascon solutions use the same post-processing corrections for the geocenter
motion (Sun et al., 2016), for the oblateness of the Earth (C20) and the low harmonic degrees (C30) of the gravity field (Loomis et al., 2019), for the dealiasing of the atmosphere and ocean signals (AOB1B RL06 from Dobslaw et al., 2017) and for GIA (ICE6G-D from Peltier et al., 2018). Comparing these three mascons with the subset of the LEGOS ensemble that use the same post-processing corrections lead to similar ocean mass change estimates (see Fig. 1 in appendix A) which confirms the consistency of the mascon solutions with the spherical harmonics solutions and gives confidence in their representation of mass transport. Within the LEGOS ensemble the subset which uses the mascon post-processing choices shows ocean mass changes in the upper range of the ensemble estimates. This corroborates the major role of post-processing choices on the estimation of global ocean mass change estimates and stresses the need to quantify the associated uncertainty.

When considering the same mask as the altimetry product, the GMOM trend in the LEGOS ensemble reaches 1.83 ± 0.21 mm yr\(^{-1}\) for the period from August 2002 to August 2016, in agreement with the state-of-the-art estimates. Regional variations in ocean mass change are fairly small (up to 3.66 mm yr\(^{-1}\)) when considering the ensemble mean, except at high latitudes and for shallow seas, variations in the ocean bottom pressure due to the ocean circulation or changes in the geoid are relatively small compared to the global ocean mass increase (Piecuch and Ponte, 2011; Piecuch et al., 2013).

### 3.3 Expansion efficiency of heat (EEH)

The EEH expresses the change in ocean density due to heat uptake. It represents the ratio of the thermosteric sea level change over the heat content change under a given heat uptake. As such it allows estimating changes in OHC from changes in thermosteric sea level (following Eq. (3)). The EEH is slightly sensitive to changes in temperature because they affect thermosteric sea level and ocean heat content in the same manner. It is however more sensitive to changes in salinity because salinity changes affect more thermosteric sea level than ocean heat content: the saltier the water, the more seawater expands in response to constant heat uptake and the larger the EEH. The EEH is thus expected to mainly vary with latitude as vertically integrated salt content varies with latitude. In time, the change in EEH is expected to be negligible over the study period, because the warming pattern is unlikely to change much at decadal time scales (Russell et al., 2000; Kuhlbrodt and Gregory, 2012).

In this study, the first regional EEH estimate is calculated down to 2000 m depth from Argo data (Meyssignac et al., in prep.). Monthly 3D in situ temperature and salinity fields from various 11 Argo solutions were used to compute the ratio between GMTSL change and GOHC change. These monthly ratios are averaged over time, then averaged together to provide a global EEH estimate of 0.145 ± 0.001 m YJ\(^{-1}\) representative of the 0–2000 m ocean column for the period 2005-2015, excluding marginal seas and areas located above 66\(^{\circ}\) N and 66\(^{\circ}\) S. This regional extent corresponds to the spatial extent that is regularly sampled by the in situ Argo network. The global EEH estimated here is in good agreement with previous estimates of 0.12 ± 0.01 m YJ\(^{-1}\) (equivalent to 0.52 W m\(^{-2}\)mm yr\(^{-1}\)) representative of the 0–2000 m ocean column over 1955–2010 from in situ observations (Levitus et al., 2012) and 0.15 ± 0.03 m YJ\(^{-1}\) for the full ocean depth over 1972–2008 (Church et al. 2011). Its uncertainty is however much smaller because the EEH computation is based on the Argo network that has a precise estimate of ocean temperature and salinity down to 2000 m depth. This more accurate estimate of the EEH enables to significantly
reduce the uncertainties of the OHC change estimate (see section 4.2. on the error propagation and uncertainty calculation). On the other hand, note that this value of the global EEH is likely biased high by a few percent because we did not consider the ocean bottom layer in our computation. The bottom layer, below 2000m depth, is less salty and would slightly lower our global EEH estimate if included here.

Figure 1 shows the associated spatial grid (3x3 degree) of EEH estimates (allowing at the same time to visualise its spatial availability). The value of the EEH for each cell is the temporal mean of the ratio between the local thermosteric sea level variations and the local OHC variations over the period 2005 - 2015. The EEH grid is applied in this study to calculate changes in OHC at regional scales (see section 4.1. OHC and EEI calculation).

3.4 Ancillary data

For validation purposes, OHC change and EEI are also estimated from in situ ocean temperature and salinity from Argo datasets covering the first 2000m depth range. We considered the IAP, IFREMER, IPRC, ISHII, EN4, JAMSTEC, NOAA, and SIO datasets. Differences in ocean temperature among these products are due to the different strategies in data editing, temporal and spatial data gap filling and instrument bias corrections (see for e.g. Boyer et al., 2016). All Argo products are post-processed homogeneously in the framework of this study for integration of temperature and salinity to derive the ocean heat content (e.g. one single integration scheme, climatology computed over the same period 2005-2015). Regional OHC change is retrieved relying on the thermodynamic equation of seawater (McDougall and Barker, 2011). Although IAP, IFREMER, ISHII, EN4, and NOAA products extrapolate the temperature and salinity profiles over the whole ocean, the ensemble of Argo-based GOHC change is calculated here after applying the most restrictive Argo geographical mask among Argo products (it corresponds to the Argo mask of the SIO product, see Fig. 1 for the spatial extent of the mask). This approach enables to get consistent and comparable GOHC change from the different Argo products. A deep ocean contribution of heat storage of $+0.07 \pm 0.06 \text{ W m}^{-2}$ is added for the layers from 2000m to 4000m (following Purkey and Johnson, 2010; Desbruyères et al., 2016). Argo-based EEI estimates are then derived from Argo-based GOHC change with the same method as for the space geodetic approach described in section 4.1. The different Argo products provide heterogeneous uncertainty estimates.

Different products consider different sources of uncertainty and none of the products provide a comprehensive estimate of the uncertainties (see Table 1 in Meyssignac et al. 2019). The absence of a common reference estimate of the uncertainty in Argo gridded temperature products is an issue that has been identified in the climate community. There is currently a community effort that is undertaken in the World Climate Research Program (the GEWEX EEI assessment, see http://gewex-eei.org/) to tackle this problem. This effort should take a few years and the results are not available yet. For the time being uncertainties on the Argo-based GOHC change and EEI are derived from the ensemble dispersion. This type of uncertainty mainly describes the discrepancy between the various center products involved in the ensemble. It represents the uncertainty associated with different approaches to develop the data quality control and the data processing. It does not comprise any errors related to time and space correlation in temperature measurements or potential systematic temperature and salinity measurement biases among products and potential systematic sampling biases among products. So these uncertainty estimates are likely underestimated.
OHC change estimate is also provided by the Ocean Monitoring Indicator (OMI) from the Copernicus Marine Service (CMEMS) (von Schuckmann et al., 2020a). The yearly indicator is the ensemble mean of 5 GOHC change solutions from reanalyses and optimal interpolations of altimetry data and in situ measurements (including Argo data). The OMI indicator is based on integrated temperature differences along a vertical profile in the ocean, down to 700 m depth, and averaged between 60° S and 60° N. Note that uncertainties on the CMEMS GOHC change are also derived from the ensemble dispersion.

EEI variations are also observed from space by the Clouds and the Earth's Radiant Energy System (CERES) instruments. They enable monitoring the incoming and outgoing radiative fluxes at the top-of-atmosphere. CERES instruments allow retrieving EEI variations (EBAF TOA fluxes, 2019) from weekly to decadal timescales with an uncertainty of ±0.1 W m⁻² but the time-mean EEI is measured with an accuracy of ±3.0 W m⁻² due to calibration issues (Loeb et al., 2018).

Our estimates of OHC change and EEI are validated against independent OHC change and EEI estimates from Argo, reanalyses and CERES in sections 5 and 6.

4 Data Processing

4.1 OHC change and EEI calculation

A dedicated data processing chain was specifically developed in order to calculate the OHC change and the EEI from space geodetic measurements, following the physical principle described in section 2. Changes in OHC at global and regional scales, and the EEI are provided in a dedicated product referred to as “MOHeaCAN v2.1” (see section 7).

The first step consists in preprocessing time series of total sea level and ocean mass change from the specific period. Total sea level and ocean mass change grids are downsampled to a 3x3 degree spatial resolution (~300 km) and averaged on a monthly basis to match the effective spatial and temporal resolutions of GRACE products. The areas not defined in the EEH coefficient are then masked out (section 3.3.).

The second step is dedicated to the calculation of the global time series of OHC change and the EEI. GMSL and GMOM time series are calculated at each time step (monthly) using a weighted average taking into account the sea surface in each cell. The GOHC change is then obtained by making the difference between the GMSL and GMOM time series (Eq. (2)) and dividing by the global value of EEH coefficient (Eq. (3)). GOHC change is expressed per unit of area (J m⁻²), when divided by the surface of the Earth at the top of the atmosphere, for a reference height of the top of the atmosphere at 20 km altitude (the same as EBAF, Loeb et al., 2018). The EEI estimate is then derived from the temporal variations of the GOHC, by calculating the derivative, the GOHU, and adjusting it to account for energy contributions from other climate reservoirs (Eq. (4)). Beforehand, GOHC change time series is filtered out by applying a low pass filter (Lanczos) with a cut-off period of 3 years in order to remove high-frequency content related to the intrinsic ocean variability and the mesoscale activity that is visible in altimetry but not in gravimetry (described in section 2.).

The last step aims at calculating changes in OHC at regional scales. Monthly steric sea level grids change are directly deduced at 3x3 degree spatial resolution from the difference between the collocated sea level and ocean mass change grids. Contrary
to the global scale, the ocean salinity change can not be neglected at regional scales (see Eq. (1)), and halosteric contribution to sea level expansion should be removed to retrieve the regional thermal expansion variations of the ocean. Nevertheless, at this stage of the study, the regional OHC change grids are obtained from the steric sea level grids divided by the grid of EEH coefficients without accounting for ocean salinity change. This has no impact on the estimate of the OHC trend over the full period 2005-2015 because the EEH has been calculated over this period and the salinity effect is thus implicitly accounted for in the local EEH coefficients. However, over other periods or smaller periods included within 2005-2015, the local EEH is expected to be slightly different as the local salinity changes with time and this calculation of the OHC change should be considered as an approximation. The approximation is accurate at the level of a few percent because local changes in salinity are small compared to the total salt content of the water column (according to the Argo record). In this study we have chosen this conservative approach with a constant EEH because the salinity anomaly data shows important inconsistencies at annual and inter-annual time scales among Argo products (e.g. Ponte et al. 2021). Instead of using low-confidence salinity anomaly data we prefer to assume at this stage a constant EEH estimated from salinity climatologies that are more reliable. This approach leads to an estimate of GOHC change with a lower uncertainty but the counterpart is that the level of confidence in regional OHC change is lower. Note that the GOHC change can also be deduced from the regional OHC change grids by summing each grid weighted by the area of each cell. We checked this approach and found that it leads to the same results as with the global approach described before.

4.2 Error propagation and uncertainty calculation at global scale

One of our main objectives is to provide the uncertainty associated with the OHC change and EEI estimates. In this study the error propagation is performed only at global scale. It is much more complex to propagate the uncertainty at regional scales because it requires to describe the spatial correlation of the errors in satellite altimetry and space gravimetry data which is not a simple task. At this time estimates of these errors are not available in the literature but this work is currently ongoing and should be the subject of further publications in the coming years. Meanwhile we focus on the uncertainty at global scale. A rigorous approach is proposed here, consisting in providing the variance-covariance matrix ($\mathbf{\Sigma}$) of the errors for the GOHC change and EEI time series at global scale. To obtain the $\mathbf{\Sigma}$ matrices of the GOHC change and EEI time series, errors must be propagated from the GMSL and GMOM monthly time series as represented in Fig. 2. The first step consists in estimating the variance-covariance matrices for the sea level ($\mathbf{\Sigma}_{GMSL}$) and the ocean mass ($\mathbf{\Sigma}_{GMOM}$) time series. $\mathbf{\Sigma}_{GMSL}$ is inferred from the GMSL error budget of Ablain et al. (2019) over the period 2002-2016. In short, the elementary variance-covariance matrices ($\mathbf{\Sigma}_{error_i}$) corresponding to each error described in the GMSL error budget (Ablain et al., 2019) are first calculated independently of each other. Each matrix is calculated from a large number of random draws (> 1000) of simulated error signals whose correlation is modelled. Their shape depends on the type of errors prescribed, which can be of several kinds: jumps, time-correlated errors, long-term drifts. Assuming errors are independent, $\mathbf{\Sigma}_{GMSL}$ is given by the sum of all $\mathbf{\Sigma}_{error_i}$ (see Ablain et al. 2019 for the details of the calculation).
For the calculation of $\Sigma_{GMOM}$ we use an ensemble approach where the ensemble of GMOM time series ($X_i$) is directly used to calculate the covariance between each time series:

$$\Sigma_{GMOM}(i, j) = cov(X_i, X_j) = E[(X_i - E[X_i])(X_j - E[X_j])],$$  \hspace{1cm} (5)

where $E$ is the mean operator. This approach is reliable when GMOM ensembles are large enough, so that the dispersion between the members of the ensemble adequately represents the GMOM uncertainties. We use this approach with the LEGOS ensemble of 216 ocean mass solutions but we can not apply it with the ensemble of mascon solutions which has only 3 distinct members. For the mascon ensemble, the uncertainty is simply computed as the standard deviation between the three solutions.

The second step consists in calculating the variance-covariance matrices for the GMTSL time series ($\Sigma_{GMTSL}$). The GMTSL is obtained by calculating the differences between the GMSL and the GMOM. We consider the errors in GMSL independent from the errors in GMOM and estimate $\Sigma_{GMTSL}$ as the sum of $\Sigma_{GMSL}$ and $\Sigma_{GMOM}$. Note that this assumption is not verified in reality as some errors are correlated between GMSL and GMOM like the errors related to the GIA correction and the error associated to the positioning of the reference system (in particular to the geocenter position). But the amplitude of these errors is very different in altimetry and space gravimetry. While the error in GIA correction and in the geocenter position are important in space gravimetry (see for e.g. Uebbing et al., 2019; Blazquez et al., 2018), their effect on satellite altimetry is small (see for e.g. Ablain et al., 2019 and reference there in). Thus, on the overall, the correlation in satellite altimetry and space gravimetry of the GIA and the geocenter correction errors is expected to have a small effect and we neglect it here.

In the third step we propagate the errors in the calculation of the GOHC change. As the GOHC change is derived from the GMTSL by dividing it by the global coefficient of EEH $\epsilon$, the uncertainty on $\epsilon$ ($\epsilon_\epsilon$) has also to be considered:

$$GOHC(t) = \frac{GMTSL(t) \pm e_{GMTSL}(t)}{\epsilon \pm \epsilon_\epsilon},$$  \hspace{1cm} (6)

The error propagation for the division of the two uncorrelated variables GMTSL(t) and $\epsilon$ with a respective uncertainty $e_{GMTSL}(t)$ and $\epsilon_\epsilon$ leads to the following form for the variance-covariance matrix of GOHC change time series ($\Sigma_{GOHC}$) (e.g. see Taylor, 1997, eq. (3.8)):

$$\Sigma_{GOHC} = \frac{1}{\epsilon_\epsilon^2} \Sigma_{GMTSL} + \left(\frac{\epsilon}{\epsilon_\epsilon}\right)^2 GOHC \times GOHC^T.$$  \hspace{1cm} (7)

This equation shows that GOHC errors depend on the uncertainty $\epsilon_\epsilon$ but also on the value of $\epsilon$.

The last step is the propagation of errors in the EEI, obtained after filtering and deriving the GOHC with respect to time and adjusting it with $\epsilon$ the fraction of energy entering the ocean. These complex operations do not allow to express the errors of the EEI with a literal expression as for the GOHC change (Eq. (7)). An empirical approach is then proposed to first derive the variance-covariance matrix of GOHU time series ($\Sigma_{GOHU}$). It firstly consists in generating a set of GOHC errors time series ($e_k$) whose variance-covariance matrix is $\Sigma_{GOHC}$. They are obtained by the product of the Cholesky decomposition of $\Sigma_{GOHC}$ ($\Sigma_{GOHC} = AA^T$), and a random vector ($R_k$) following a Gaussian vector of mean 0 and covariance matrix the identity:
\[ e_k = A R_k^t, \] (8)

Each \( e_k \) is then filtered by a low-pass filter at 3 years to provide a set of GOHU errors time series from which the variance-covariance matrix \( \Sigma_{GOHU} \) is easily inferred (see Eq. (5)). The final operation consists in applying the formulation from Eq. (7) for the division of the GOHU by the \( \alpha \) fraction. \( \Sigma_{EEI} \) is obtained simply from \( \Sigma_{GOHU} \) neglecting any errors in \( \alpha \):

\[ \Sigma_{EEI} = \frac{1}{\alpha^2} \Sigma_{GOHU}, \] (9)

Once variance-covariance matrices are known, the statistical parameters (e.g. trend, acceleration) can be fit at any time-spans from a linear regression model \( (y = X\beta + \epsilon) \) applying an Ordinary Least Square (OLS) approach, where the estimator of \( \beta \) with the OLS, noted \( \hat{\beta} \), is:

\[ \hat{\beta} \sim (X^t X)^{-1} X^t y, \] (10)

and where the distribution of the estimator \( \hat{\beta} \) takes into account \( \Sigma \) and follows a normal law:

\[ \hat{\beta} = N(\beta, (X^t X)^{-1} (X^t \Sigma X) (X^t X)^{-1}). \] (11)

This mathematical formalism was fully described in Ablain et al. (2019) to estimate the uncertainties of the GMSL trend and acceleration. It is applied in this study to derive the realistic uncertainties of GOHC and EEI trends. The uncertainty envelope can also be derived from the square root of the diagonal terms of \( \Sigma \).

5 Ocean heat content change: results & validation

5.1 Global and regional OHC change

The GOHC trend is \(+0.70 \pm 0.20 \text{ W m}^{-2}\) for the period from August 2002 to August 2016 (Fig. 3a). It indicates the rate at which oceans accumulate heat and gives an estimate of the average GOHU. This value is significant when compared to its uncertainty of \( \pm 0.20 \text{ W m}^{-2}\). In this trend uncertainty, the contribution from satellite altimetry uncertainty is higher than the contribution from space gravimetry uncertainty. The GMSL error budget provided by Ablain et al. (2019) is by construction comprehensive and conservative (all choices are conservative in particular the representation of the error in wet tropospheric correction and its time correlation are probably slightly overestimated) and leads to GMSL errors that are likely slightly overestimated. In addition, the total GMSL errors have been validated against independent measurements from tide gauges (e.g. Watson et al., 2015) so there is high confidence that the 90 % CL uncertainty in GMSL used here is an upper bound of the real uncertainty in GMSL. GMOM errors are deduced from an ensemble of GRACE solutions (update of Blazquez et al., 2018) accounting for all known sources of errors including instrumental errors (e.g. taken into account using solutions from different centers) and post-processing choices (e.g. geocenter, oblateness, filter, GIA). Although we are confident the current state-of-the-art post processings used in the ensemble of solutions provide a reliable coverage of the real associated uncertainty, we can not rule
out the possibility that the resulting GMOM uncertainty is slightly underestimated because of some unknown small undetected systematic bias among state-of-the-art post processing. Another issue is that there is no validation of GMOM against independent data available yet. The global freshwater budget offers a potential approach to validate the GMOM estimates against independent estimates derived from the sea ice volume changes and the ocean global salinity estimates (e.g. Munk, 2003). But the first results show that estimates of the global ocean salinity are not accurate enough to provide an efficient validation (Llovel et al., 2019). For these reasons, we have a smaller confidence in the GMOM uncertainty estimate than in the GMSL uncertainty estimate leading to a confidence in our GOHC change uncertainty estimate that is between medium and high. Note that compared to previous estimates in Meyssignac et al. (2019) the uncertainty in GOHC change is reduced here. This is essentially due to the updated estimate of the global EEH coefficient with Argo data that leads to a smaller uncertainty than the estimate of Levitus et al. (2012) used in Meyssignac et al. (2019) (see Meyssignac et al., In prep).

Regional OHC trends for the period from August 2002 to August 2016 are generally positive ranging from -1 to +2 $10^3$ W m$^{-2}$ (Fig. 4). As the OHC is an integrative variable, it depends on the area considered in the computation. In this case the difference between the surface considered in the GOHC change and the surface considered in regional OHC change is of the order of 2 $10^4$, explaining the difference of 3 orders of magnitude between the typical GOHC and the typical regional OHC changes. The spatial patterns depicted by the GOHC trends are highly correlated to climate mode fingerprints retrieved for example in steric anomalies (e.g. Pfeffer et al., 2018). These include for instance the Pacific Decadal Oscillation, dividing the North Pacific along a typical northeast - southwest chevron pattern (e.g. Mantua and Hare, 2002), and the El Niño–Southern Oscillation (e.g. Enfield and Mayer, 1997), consisting in a typical west-east oscillation of the temperature in the tropical and South Pacific. The spatial patterns observed in the North Atlantic are likely related to the warming of the Gulf Stream in the Northeast Atlantic and to the cooling of the Atlantic Meridional Overturning Circulation (AMOC) bringing warm waters from the tropical Atlantic to the Northwest Atlantic (e.g. Ruiz-Barradas et al., 2018). The positive anomaly in the Indian Ocean is likely related to the warm pool, recording higher temperature increase during the last decades than the global ocean (e.g. Rao et al., 2012; Weller et al., 2016; Lee et al., 2015).

5.2 Comparison with estimates based on in situ temperature profiles

To evaluate our GOHC change estimate, we compare it with independent estimates over the period 2005-2015. The processing of the Argo gridded ocean in situ temperature products into GOHC change time series is described in section 3.4. The validation is restricted to the period January 2005-December 2015, because the coverage of the Argo network becomes nearly global only after 2005 and because afterwards issues in the Argo salinity products lead to artefacts in the salinity climatology and further in the GOHC change products. Over 2005-2015, the space geodetic GOHC trend of +0.71 ± 0.23 W m$^{-2}$ is in agreement within the uncertainties with the Argo-based GOHC trend of +0.59± 0.13 W m$^{-2}$ and also with the CMEMS GOHC trend of +0.60± 0.25 W m$^{-2}$ (Table 1).

As an indication, the average GOHC trend deduced from another combination of altimetry and gravity measurements has been also calculated using three GRACE mascon solutions (see Table 1). A low value of 0.56 W m$^{-2}$ is obtained for the 2005-2015
time period, but it is still consistent with the MOHeaCAN product as it is in the uncertainty range of the GOHC trend estimated from the MOHeaCAN product (+0.71 ± 0.23 W m$^{-2}$). To check more precisely the consistency between the mascon-based estimate of the GOHC trend and the MOHeaCAN estimate we re-estimate the MOHeaCAN GOHC trend over 2005-2015 using only the sub-ensemble of GRACE spherical harmonic solutions that is based on the same post-processing choices as the mascon solutions. In this case we find a result (+0.61 ± 0.18 W m$^{-2}$) that is closer by less than 0.05 W m$^{-2}$ to the mascon-based estimate. This precise consistency at the level of 0.05 W m$^{-2}$ gives confidence in our estimate. The residual difference could be due to sources of errors that were omitted in the calculation of the spherical harmonic ensemble, such as incomplete leakage errors or differences in the regularisation process of the mascon solutions and the spherical solutions.

The space geodetic GOHC interannual variations of 5 × 10$^7$ J m$^{-2}$ are presented in Fig. 5. We find the interannual variations in GOHC change in agreement with Argo-based estimates for time scales greater than 3 years, low during the period from 2006 to 2011, and high during the period from 2011 to 2015 (Fig. 5). At shorter time scales (lower than 3 years), variations in GOHC change are poorly correlated. At these time scales, part of the signal is due to the internal variability of climate (e.g. ENSO) that may not be detected in the same way by both space geodetic and Argo-based estimates because of their different time and space resolution. In addition, GOHC variations depicted by all datasets suffer from a lack of accuracy at these time scales to analyse any differences in a significant way (see the large uncertainty envelope at sub annual time scales shown in Fig. 5). At regional scale, over the period 2005-2015, space geodetic and Argo-based OHC trends are similar (Fig. 6). Overall there is a fairly good spatial coherence of the observed spatial structures as in the Equatorial Pacific Ocean and in the Northern Atlantic but the amplitude of the signals is systematically higher in the space geodetic OHC trend. In addition some discrepancies are observed in Indian Ocean where space geodetic OHC trends are about two times the Argo-based estimates. Although input data are similar, the OHC trends based on the various Argo datasets also show differences at regional scales up to 2.6 × 10$^3$ W m$^{-2}$ among different Argo products. This is the same order of magnitude as the difference with the regional MOHeaCAN trends (Fig. 6). These analyses on a regional scale provide insights on the regional structure of the signal. They remain preliminary and present several limitations. On the one hand, the contribution of the regional halosteric signal is not taken into account here in the calculation of the space geodetic OHC change. Ocean salinity change may have a significant impact in some local regions (as in the southeast Indian Ocean (Llovel and Lee, 2015), in the northwest Indian Ocean or close to the Arctic ocean). On the other hand, the regional contribution of the deep ocean in the Argo data (restricted to 0-2000m) is not considered. These limitations will be the subject of future work and may lead to a better agreement between the OHC trends observed by space geodetic data and Argo data.

6 Earth Energy Imbalance: results & validation

The space geodetic approach provides the mean EEI estimate and also the temporal evolution of the EEI over the 15-year period from August 2002 to August 2016 (Fig. 3). The mean EEI of +0.74 ± 0.22 W m$^{-2}$ is obtained from the GOHC trend
corrected to account for the energy uptake from land, cryosphere and atmosphere. This mean EEI value represents an enormous amount of energy when it is integrated onto the entire Earth's surface at the top of the atmosphere. For information, it represents a total energy uptake of the Earth of about 350 TW (i.e. about 1000 times the power of the world’s nuclear power plant). Our EEI estimate indicates a positive trend of $0.02 \pm 0.05$ W m$^{-2}$ yr$^{-1}$, representing a non-significant acceleration of the energy uptake by the ocean over 2002-2016. Longer time series or more accurate data are needed to analyse this acceleration. Our EEI estimate also shows large interannual variations of EEI from -0.5 to 2.0 W m$^{-2}$ (Fig. 3) between 2002 and 2016 that are due to climate-change variations of GOHC change or to internal variability. Further studies are needed to determine the causes for these variations. At 3-year time scales the uncertainty of our EEI estimate varies from 0.8 to 1.0 W m$^{-2}$. Such a level of uncertainty shows that the monthly signals in our EEI estimate is for the moment subject to too many errors to be interpreted.

Space geodetic EEI is compared at interannual time scales with Argo-based and CERES-based EEI estimates (Fig. 7). Signals lower than 3 years are filtered out in all EEI time series. EEI means and trends are also removed beforehand from each dataset to compare EEI variations at interannual scales.

The interannual signals are better correlated between the time series from space geodetic and CERES data than with the Argo-based data. Although the amplitude of the space geodetic EEI signal is slightly higher (up to 0.8 W m$^{-2}$), they appear to be fairly well phased between 2006 and 2013 (same phase within a few months). In contrast, the Argo-based EEI have similar amplitudes to those of CERES, but are mostly out of phase. The short time period of the in situ data in particular limits the analysis of these signals. To date, the origin of the discrepancies between these different EEI estimates remains under investigation. They are all impacted by internal variability, in particular ENSO (e.g. mid-2007-mid 2009 (Loeb et al., 2012), 2011) and the high frequency signals (monthly to biannual). Regional signature of the internal variability may not be the same in the different observing systems (owing to their different spatial and temporal resolution) leading to discrepancies in EEI estimates. Observing systems with incomplete coverage may miss some important signals that sign at global scale. Another source of discrepancy among EEI estimates is that we assumed for the geodetic approach and the in situ approach that 90% of the excess of energy due to EEI is captured by the ocean. While this assumption is reasonable at biannual and longer time scales (Palmer and McNeal 2017), it is probably not true at smaller time scales when atmosphere and to a smaller extent land and cryosphere exchange larger portions of energy with the ocean. This too simple assumption may explain some discrepancies between the CERES estimate on one side and the geodetic and the in situ estimates on the other side.

7 Data availability

Changes in OHC at global and regional scales, and the EEI are gathered in the “MOHeaCAN” product v2.1, available online at https://doi.org/10.24400/527896/a01-2020.003 with the complete associated documentation (product user manual and algorithm theoretical basis document).
8 Conclusions and outlook

This study provides the first space geodetic estimate of the Earth energy imbalance and changes in ocean heat content at global scale, with rigorous assessment of the uncertainties using a formal error propagation approach. It is based on the assumption that monitoring heat accumulation in the ocean, with a combination of satellite altimetry and gravimetry measurements, is representative of the vast majority (~90%) of the energy imbalance observed at the top of the atmosphere. The mean value of the EEI derived from this space geodetic approach over the period August 2002 to August 2016 is +0.74 ± 0.22 W m⁻². This figure is fully in agreement with independent data based on in situ measurements (Argo network) within the confidence level of the uncertainty. Furthermore, although this is a preliminary calculation, the OHC change is also calculated for the first time at regional scale thanks to a set of expansion efficiency of heat coefficients estimated from in situ Argo data. The spatial patterns retrieved in the OHC trends are highly correlated to climate mode fingerprints observed in steric anomalies (e.g., Pfeffer et al., 2018). They also correlate well with regional OHC trends derived from in situ Argo data, despite known limitations in these regional estimates (e.g., deep ocean in Argo data, salinity ocean change not corrected in altimetry and gravimetry approach).

The rigorous uncertainty estimate proposed here has still a few limitations. It does not account for the loss of spatial coverage imposed by the Argo geographical mask in the computation of the expansion efficiency of heat. It does not include either the errors related to the estimation of the global EEH value over the first 2000 m depth only (i.e., the effect of the deep ocean on the EEH value is neglected). Furthermore, no error on the fraction of energy entering the ocean α is included in the EEI uncertainty. Finally, the approach depends on the knowledge of the GMSL and GMOM error budget. These error budgets can be improved further. In particular, an effort must be made to better describe the errors in spatial gravity measurements, especially to include the uncertainties related to the differences in the harmonic and mascon approaches in the error budget. The consistency between the processing of altimetry and gravimetry data could still be improved for instance by homogenising the GIA datasets used to correct the gravimetry signals and the sea level from altimetry. Also atmospheric effects should be harmonised. Indeed, altimetry data are currently processed with the dynamical atmospheric correction (Carrère and Lyard, 2003) while only the inverse barometer correction is applied in gravimetry processing (Blazquez et al., 2018). Another area for improvement is the extension of the spatial and temporal scales of the OHC change and EEI estimation. While altimetry and GRACE data are available together since August 2002, the datasets provided in this study are limited in time (August 2002-August 2016) and space (Argo mask) as the objective of this study is to demonstrate the feasibility of such an approach (proof of concept) using reliable GRACE measurements and EEH data over the Argo geographical mask. However, in the future, the OHC change and EEI time series could be extended in time using the GRACE-FO data already available from August 2018. This requires managing issues related to the 11-month gap between GRACE and GRACE-FO data (July 2017-June 2018) and the degradation of GRACE data quality after August 2016. The OHC change could also be estimated outside the current Argo mask by extrapolating the EEH coefficient grid to the full ocean using ocean reanalyses.
This study emphasises that the synergy between spatial data (altimetry and gravity) and in situ data (Argo Network) is essential to obtain accurate estimates of OHC change. The former contributes to observing the total OHC variations over the whole water column and with a very good spatial and temporal resolution since 2002, while the latter provides a quasi-global coverage since 2005 and allows access to the vertical structure of the thermal expansion of the ocean down to 2000 m depth. The capacity of both observing systems to provide independent estimates of the EEI since 2005 is absolutely essential. It enables independent comparisons which is the unique method to robustly check and validate the final EEI estimates. By pointing to discrepancies among different EEI estimates from different observing systems, intercomparisons foster further development to understand the causes for discrepancies. As we understand these discrepancies, the different estimates will improve and we can expect significantly more precise and more robust estimates of the EEI in the coming decade. It is crucial that the space geodetic observing system and the Argo network continue the monitoring and improve their coverage and accuracy in the years to come to support this effort.

Appendix A

The GRACE LEGOS ensemble V1.4:

GRACE LEGOS V1.4 is an ensemble of 216 global water mass transfer solutions derived from GRACE and GRACE-FO mission covering the period from August 2002 to December 2020 at monthly time scale and with a spatial resolution of 1 degree. The total amount of water remains constant from one month to another for each solution. The ensemble is based on L2 spherical harmonic solutions from 6 different centers: COST-G RL1.2, CNES RL5.0, CSR RL06, GFZ RL06, JPL RL06, and TUGRAZ ITSG2018. Atmosphere and ocean dealiasing models are restored using AOD1B RL06 (Dobslaw et al., 2017) except for the CNES solution where ERA interim and TUGO models where used. Ocean dealiasing model is restored and C0 coefficients are corrected in the spherical harmonics to compensate for the total amount of water vapor in the atmosphere expressed in C0 GAA (Chen et al., 2019). The ensemble includes also a large variety of choices for post-processing corrections including: 3 geocenter motion (Lemoine and Reinquin (2017), Uebbing et al., (2019), and Sun et al., (2016)), 3 oblateness of the Earth ((Cheng et al., 2013), Lemoine and Reinquin (2017), and Loomis et al., (2019)), 2 GIA correction (ICE6G-D (Peltier et al., 2018) and Caron et al., (2018)). In order to reduce the anisotropic noise DDK filters are applied to the L2 solutions, including DDK5 and DDK6 (Kusche et al., 2009) except for the CNES solution where a truncated single value decomposition scheme is used for the inversion instead of a classical Cholesky inversion. This method reduces the noise drastically but on the other hand the coefficients of high degree where information is scarce are normalized to the mean coefficients (Lemoine et al., 2016). Solid Earth displacement due to the largest Earthquakes (Sumatra 2004 and 2012, Tohoku-Oki 2010 and Chili 2010) are corrected following (Tang et al., 2020). Moreover, a new method to convert from spherical harmonics to equivalent water height is applied (Blazquez et al. in prep). This method consists in using high spatial a priori solutions to reduce leakage and Gibbs effects. The spherical harmonics solution is separated in the a priori part using external data as land/ocean masks, glacier
mass trends (Hugonnet et al., 2021) and lake volume change (Crétaux et al., 2016) and the rest of the harmonics solution which contains less signal and must be filtered.

Figure 1: Comparison of global mean ocean mass changes from satellite gravimetry based on spherical harmonics solutions (LEGOS ensemble V1.4, in grey) and mascon solutions over August 2002-August 2016 for the global ocean. The mean of the full spherical harmonic ensemble is shown in red. The mean of the spherical harmonic ensemble subset consistent with mascons is shown in orange. The mean of the three mascon solutions considered in this study is shown in blue.

Competing interests

The authors declare that they have no conflict of interest.

Acknowledgments

This work has been supported by ESA in the framework of the MOHeaCAN project (Monitoring Ocean Heat Content and Earth Energy ImbalANce from Space): eo4society.esa.int/projects/moheacan/. This work is also supported by the CNES for the dissemination of the products. We would like to thank in particular Françoise Mertz and Caroline Mercier for making the data available on the ODATIS portal and AVISO. Julia Pfeffer and Anne Barnoud are supported by the European Research
Council (ERC) under the European Union’s Horizon 2020 research and innovation program (GRACEFUL Synergy Grant agreement No 855677). Jonathan Chenal is grateful to the French Ministry of Ecological Transition for its funding.
