Abstract. Methane, ethane, and propane are among the most abundant hydrocarbons in the atmosphere. These compounds have many emission sources in common and are all primarily removed through OH oxidation. Their mixing ratios and long-term trends in the upper troposphere and stratosphere are rarely reported due to the paucity of measurements. In this study, we present long-term (2006-2016) northern hemispheric ethane, propane, and methane data from airborne observation in the Upper Troposphere - Lower Stratosphere (UTLS) region from IAGOS-CARIBIC project. The methane and propane observations provide additional information for understanding northern hemispheric ethane trends, which is the major focus of this study. The linear trends, moving averages, non-linear trends and monthly variations of ethane, methane and propane in 2006-2016 were presented for the upper troposphere and lower stratosphere over five regions (whole Northern Hemisphere, Europe, North America, Asia and rest of the world). The growth rates of ethane, methane, and propane in the upper troposphere are -2.24, 0.33, and -0.78 %/yr, respectively, and in the lower stratosphere they are -3.27, 0.26, and -4.91 %/yr, respectively, in 2006-2016. This dataset is of value to future global ethane budget estimates and the optimization of current ethane inventories. The data are publicly accessible at <https://doi.org/10.5281/zenodo.6536109> (Li et al., 2022).

1. Introduction

25 Ethane (C_2H_6) is among the most abundant non-methane hydrocarbons (NMHC) present in the atmosphere. Major sources of ethane to the atmosphere are via natural gas and oil production (~62%), biofuel combustion (20%), and biomass burning (18%). Interestingly, 84% of its total emissions are from the Northern Hemisphere (NH) (Xiao et al., 2008). Oxidation by hydroxyl (OH) radicals is the major atmospheric loss process for tropospheric ethane, while in the stratosphere the
30 reaction with chlorine (Cl) radicals provides an additional loss process (Li et al., 2018). Due to the seasonal variation of ethane emissions and the photochemically generated OH radicals, ethane has a clear annual cycle in mole fractions, showing higher levels in winter. Its global lifetime is circa three months, with a minimum in summer (~2 months) and a maximum in winter (~10 months) (Xiao et al., 2008; Helmig et al., 2016; Li et al., 2018). Ethane oxidation forms acetaldehyde, which
35 in turn contributes to the formation of PAN (peroxyacetyl nitrate) or peracetic acid depending on the levels of NO_x (Millet et al., 2010). PAN acts as a reservoir species of nitrogen oxides (NO_x) and can strongly affect tropospheric ozone distributions by transporting NO_x from the point of emission to remote locations. Furthermore, PAN is known to be a secondary pollutant like ozone with negative impacts on regional air quality and human health (Rudolph, 1995; González Abad et al., 2011; Fischer et al., 2014; Monks et al., 2018; Kort et al., 2016; Tzompa-Sosa et al., 2017; Dalsøren et al., 2018; Pozzer et al., 2020).

Many studies have reported ethane trend analysis based on either ground-based sampling or FTIR (Fourier Transform Infrared Spectrometer) measurements. A summary of these studies is shown in Table 1. In the troposphere (Table 1a), a decreasing trend of ethane during 1986-2008 and an
45 increasing trend during 2009-2014 were reported in the literature. The trends of C_2H_6 partial column at four European sites (Jungfraujoch, Zugspitze, Harestua and Kiruna) during 1996-2006 were between about -1.09 to -2.11%/yr (Angelbratt et al., 2011). Simpson et al. (2012) concluded a strong global ethane decline of 21% over 26 years (1984-2010), with a stronger decline occurring from 1984 to 1999 (-7.2 ± 1.7 ppt/yr) than from 2000 to 2010 (-1.9 ± 1.3 ppt/yr). Franco et al.
50 (2015) showed the ethane trend at Jungfraujoch to be -0.92%/yr during 1994-2008, followed by a strong positive trend of 4.9%/yr during 2009-2014, which may be related to the intensifying emissions from shale gas exploitation in North America. Helmig et al. (2016) calculated a mean ethane growth rate of 2.9-4.7%/yr from 2009 to 2014 at 32 NH ground measurement sites and

concluded that North American oil and gas development was the primary source of the increasing
55 emission of ethane. Franco et al. (2016) compared the ethane total column change at six sites across
NH for the period of 2003-2008 and 2009-2014, and also revealed a sharp increase of 3-5%/yr
during 2009-2014 compared with 2003-2008, which was associated with oil and gas industry
emission. Hausmann et al. (2016) presented a positive ethane trend of ca. 4.6%/yr at Zugspitze (47°
N) and a negative trend of ca. -2.5%/yr at Lauder (45° S) for 2007-2014, and inferred an ethane
60 increase from oil and gas emission of 1-11 Tg/yr for 2007-2014. Angot et al. (2021) showed an
increasing trend in ethane of ca. 5.6%/yr at GEOSummit (73°N) for 2010-2014, followed by a
temporary pause of ethane growth in 2015-2018. Sun et al. (2021) presented a negative ethane
trend of $-2.6 \pm 1.3\%/yr$ over 2015-2020 in a densely populated eastern Chinese city Hefei.

In contrast to tropospheric ethane trends, trends in the stratosphere have been far less investigated.
65 The stratospheric ethane trends were reported to follow a decreasing trend in 1995-2008 and an
increasing trend in 2009-2015 (Table 1b). Gardiner et al. (2008) presented the annual trend in
stratospheric ethane column (relative to year 2000) at six sites and these varied from 0.43 to -
3.31%/yr until the year 2005. Franco et al. (2015) reported ethane trends at 8-16 km measured at
Jungfraujoch of $-1.75 \pm 1.30\%/yr$ for 2004-2008 and $9.4 \pm 3.2\%/yr$ for 2009-2013, indicating an
70 ~11% sharp increase since 2009. Helmig et al. (2016) showed that the UTLS column ethane (8-
21km) measured at Jungfraujoch was decreasing by $-1.0 \pm 0.2\%/yr$ from 1995 to 2009, and started
a sharp increase at a rate of $6.0 \pm 1.1\%/yr$ from 2009 until 2015, while the difference in growth rate
between the two time periods is smaller for the mid-tropospheric column (3.6-8 km): $-0.8 \pm 0.3\%/yr$
(1995-2009) and $4.2 \pm 1.0\%/yr$ (2009-2015).

75 Previous investigations of the distribution, emissions, lifetime, and atmospheric trends of ethane
have been mostly based on surface-based measurements. These have been either from a
regionally focused intensive field measurement campaign (e.g. Kort et al. (2016)) or from
networks of remote sampling stations (e.g. Franco et al. (2015), Helmig et al. (2016)). The
advantage of surface sites is that they are easily accessed and maintained, however, such
80 measurements inevitably reflect the local or regional situation, and changes in emissions
immediately upwind of a measurement location can affect the results, masking any underlying
long-term global trend. In addition, most ethane measurement sites are located in high-income
countries, such as North America and Europe, while ethane observations in the rest of the world

are sparse. This too hinders the assessment of global ethane trends, for while one country's
85 emission may be declining another's could be increasing rapidly. For the aforementioned reasons,
it is advantageous to assess the global long-term ethane trend from the upper troposphere and
even the stratosphere where emissions can be expected to be well mixed by atmospheric
circulations. In particular, the trend of ethane in the more isolated and remote stratosphere is of
interest when assessing long-term changes.

90 In this study, we use airborne observations covering the Northern Hemisphere (NH), including
over regions where ground measurements are not set up or not possible. We present long-term
northern hemispheric and geographically delineated (North America, Asia, Europe, Rest of the
world) ethane trends in the upper troposphere and lower stratosphere for the decade 2006-2016
derived using airborne measurements. In addition, the trends of methane and propane collected
95 from the same observations are examined to better understand the observed variation of NH ethane
trends, as they have common sources and sinks in the atmosphere. This study focuses on describing
the dataset itself, therefore, an in depth interpretation is outside the scope. All the data used in this
study are publicly available at <https://doi.org/10.5281/zenodo.6536109>. These data can be used for
further analysis on global and regional trends, emissions and lifetime of methane, ethane, and
100 propane, their contributions to climate change, troposphere-stratosphere exchange, and
improvement of current inventories and atmospheric models.

2. Materials and Methods

2.1 IAGOS-CARIBIC observation

105 The IAGOS-CARIBIC project (In-service Aircraft for a Global Observing System-Civil Aircraft
for the Regular Investigation of the atmosphere Based on an Instrument Container) is an aircraft-
based scientific project with the aim of monitoring long-term global atmospheric physics and
chemistry (Brenninkmeijer et al., 2007). The flight altitudes are at ~10 km, which is in the Upper
Troposphere-Lower Stratosphere (UTLS) region. A custom-built whole air sampler collects
110 pressurized air samples during each flight, and these samples are subsequently measured in the
laboratory with Gas Chromatography (GC) coupled with three detectors: GC-ECD (for carbon

dioxide, nitrous oxide, and sulphur hexafluoride) (Schuck et al., 2009), GC-FID for methane and volatile organic compounds (including ethane and propane)(Baker et al., 2010), and GC-AED for volatile organic compound measurements after 2017 (data not used in this study) (Karu et al., 2021) (Karu et al., 2021). The precision of ethane and propane data used in this study is 0.2% and 0.8%, respectively (Baker et al., 2010), and of methane 0.17% (Schuck et al., 2009). Details regarding operational and analytical procedures, calibration scales, and quality assurance are documented in the cited references, and summarized as follows.

Each IAGOS-CARIBIC flight normally consists of four flight sequences with a total number of 116 air samples collected by whole air samplers (flasks). The inlet and outlet of each flask are connected by multi-position valves which can be automatically switched with programming. A pumping system and pressure sensors are connected to the inlet valves to guarantee the final pressure in each flask to be around 4.5 bar. The outlet valves are connected to ambient air. Prior to pressurization, each flask is flushed with ambient air for 10 times (about 5-10 min). The average filling (sampling) time of each flask is about 45s (range 0.5-1.5 min) depending on the flight altitude, resulting a spatial resolution of 7-21km.

Methane (CH_4), ethane (C_2H_6), and propane (C_3H_8) were measured with a HP 6890 GC with a polymer Porapak Q 3/4" column (10 ft, 100/120 mesh) installed in a single oven. Nitrogen (N_2 , purity 99.999%) was used as carrier gas at a constant flow rate of 50ml/min. The GC was operated at oven temperature of 220°C with flow rates of synthetic air of 250ml/min and hydrogen of 80ml/min. Water vapor in samples was removed by passing through a drying tube at the start of the analysis. The calibration standards and reference gas cylinders were ordered from NOAA (for methane), and the National Physical Laboratory (for ethane and propane) which are certified against World Meteorological Organization (WMO) Global Atmosphere Watch (GAW) program scale, and they are regularly renewed within every three years which warrants the stability of calibration gases. Three additional calibration standards samples were measured in between samples of each flight sequence in order to monitor the quality of measurements and reduce uncertainty.

In total 6,607 Northern Hemispheric samples were collected during Feb 2006-Feb 2016. 74 samples were collected at altitude lower than 8,000 m and Potential Vorticity (PV) <2 PVU (Potential Vorticity Unit), where can be largely influenced by surface emissions. Therefore, those

samples were excluded from trend analyses. The remaining 6,533 samples were divided into two categories: upper tropospheric samples (altitude $\geq 8,000$ m and PV < 2 PVU), and lower stratospheric samples (PV ≥ 2 PVU). To investigate the changes above the tropopause, the lower stratospheric samples were classified into the lower part of the lower stratosphere ($2 \text{ PVU} \leq \text{PV} < 6 \text{ PVU}$) and the upper part (PV ≥ 6 PVU). All samples are categorized into four regions based on their sampling locations: North America (NAM), Asia (ASI), Europe (EUR), and Rest of the world (ROW). The coordinate of each region is shown in Table S1 and geographical distribution of samples is shown in Figure S1 in the Supplementary Material. In later analyses, we used the term “whole NH” to refer to the combination of four regions. Table 2 shows the total sample number collected in 2006-2016 of 20 sub-regions, i.e. 4 categories (upper troposphere, lower stratosphere, lower stratosphere-lower part, lower stratosphere-upper part) and 5 regions (whole NH, EUR, NAM, ASI, ROW). The later sections will further investigate the trends and seasonality of ethane, methane and propane in these 20 sub-regions. It is noted that the region designated must not correspond to the source region, only the geographical location of the data points.

2.2 Trend analysis

We have applied three trend analysis methods in this study: linear fit, moving average, and non-linear trend.

- (1) Linear fit was applied to each sub-region throughout the entire time period (2006-2016). The growth rates of ethane, methane and propane of each sub-region by linear fit are shown in Table 2. These growth rates were referred as “linear trend” in the later sections.
- (2) Moving average was achieved with Python (version 3.9.7) pandas package DataFrame.rolling function using a rolling sum with a window length of 20 observations.
- (3) Non-linear trend analysis using the “Prophet” algorithm (Taylor and Letham, 2018). The “Prophet” algorithm has been applied on the analysis of non-continuous time-series datasets (Li et al., 2022), as is the case for aircraft data. The trend analysis model has four components: trend (non-periodic changes), seasonality (periodic changes), holiday effects, and error (idiosyncratic changes). In this study, effects of holidays are not included. We used a linear model with change points for the trend component, and the trend function

consists of growth rate, adjustments of growth rate, and offset parameter. The flexibility of trend (e.g. overfitting or underfitting) can be adjusted by the parameter “changeoint_prior_scale”. A change point represents the moments where the data shifts directions. The value of the parameter “changeoint_prior_scale” represents the strength of change points, more change points will be automatically detected when the value of this parameter increases. The uncertainty interval was set to be 95%. The code of trend analysis in Python for this study can be found in the Supplementary Material. Figure S2 shows the ethane trend and seasonality at Iceland estimated by “Prophet” algorithm. Compared with the trend and seasonality estimated by the NOAA algorithm (www.esrl.noaa.gov/gmd/ccgg/mbl/crvfit/crvfit.html) using the same dataset in Figure 1(b) of Helmig et al. (2016), the seasonality of ethane is captured by both algorithms and the results match with each other. The non-linear trend is estimated as the average value of ten fitting levels on the trend (i.e. “changeoint_prior_scale” = 0.1, 0.2, 0.3, ..., 0.9, 1.0). The uncertainty of the non-linear trend analysis is estimated by resampling methods. For the dataset of each sub-region, we randomly resampled the dataset 20 times, with each time consisting 90% of the samples of the dataset. We then run the “Prophet” algorithm for each of the 20 sub datasets, using the average value of ten fitting levels as the trend of each sub dataset. The range of the 20 trends from the resampled datasets is assumed as the uncertainty of non-linear trend analysis for each sub-region.

190

3. Results and Discussion

3.1 Overview of IAGOS-CARIBC observations

The overview of geographical distribution, altitude, PV, ethane, methane and propane of all 6,607 samples collected in 2006-2016 is shown in Figure 1. Samples were collected in a broad range of latitude (0.2 – 77.4°) and longitude (-122.2 – 141.8°) (Figure 1a). 57.9% of the samples were collected in the latitude bands of 30-60°, 25.6% were from latitude 0-30°, and 16.5% from latitude above 60°. Samples were collected at altitude range of 946.4 – 12,525.1 m, with 98.8% being

collected above 8,000 m (Figure 1b). PV values of all the samples range from -0.32 – 12.17 (Figure
200 1c). For the trend analyses in the later sections, samples collected at altitude lower than 8,000 m
and $PV < 2$ PVU were excluded. Figures 1 d,e,f show the observed ethane, methane and propane
mole fractions, their linear trends over 2006-2016, and their moving average. The observed mole
fractions of ethane, methane and propane are in the range of 5.5 – 2982.2 ppt, 1579.7 – 1926.8 ppb,
and 1.0 – 2090.0 ppt, respectively. Both ethane and propane showed decreasing trends using linear
205 fit over 2006-2016, and methane had an increasing growth rate over the same period. The exact
growth rates of ethane, methane, and propane are not reported here, however, they are reported in
the later sections where regional trends are investigated.

3.2 Upper tropospheric trends

210 3.2.1 Linear trends in the upper troposphere

Figure 2 shows the upper tropospheric observations, linear trends and moving average of ethane
(Figures 2 a,b,c,d,e), methane (Figures 2 f,g,h,i,j) and propane (Figures 2 k,l,m,n,o) over five
regions: whole Northern Hemisphere (Figures 2 a,f,k), Europe (Figures 2 b,g,l), North America
(Figures 2 c,h,m), Asia (Figures 2 d,i,n), and rest of the world (Figures 2 e,j,o). The growth rates
215 of ethane, methane and propane over each region are shown in Table 2 a.

The upper tropospheric ethane shows decreasing trends over all regions for 2006-2016, with the
most decrease in ROW (-26.7 ppt/yr, -5.19 %/yr) and the least decrease in ASI (-6.9 ppt/yr, -
1.17 %/yr). The whole NH upper tropospheric ethane decreased at a rate of -14.9 ppt/yr (-
2.24 %/yr) over 2006-2016. Unlike the large variations in linear trends of ethane among regions,
220 the upper tropospheric methane shows more homogeneous increasing trends among all regions
(range 5.2-6.7 ppb/yr, 0.29-0.37 %/yr) due to its longer atmospheric lifetime. The whole NH
upper tropospheric propane decreased at rate of -0.7 ppt/yr (-0.78 %/yr), which is dominated by
the decrease in ROW (-7.5 ppt/yr, 14.7 %/yr). The upper tropospheric propane mole fractions
were increasing at rates of 0.3 – 3.2 ppt/yr (0.33 – 2.1 %/yr) in EUR, ASI and NAM.

225

3.2.2 Non-linear trends in the upper troposphere

The non-linear trends of upper tropospheric ethane, methane, and propane at regional scales, estimated by the “Prophet” algorithm and their associated uncertainties are shown in Figure 3. Ethane and methane share common sources in gas and oil emissions, and ethane, methane, and propane react with OH radicals as their major sinks in the troposphere.

In early 2010, a peak is clear to be seen for all three compounds in the whole NH upper troposphere, which may indicate a decrease in OH radicals. This peak is also pronounced in ASI for all three compounds, however, the methane peak in ASI has large uncertainty.

Ethane and propane in EUR are noticeably higher than other regions due to lower sampling altitudes in EUR (Figure S3, mean \pm one standard deviation, $10,197 \pm 857$ m) compared to other regions (NAM: $10,982 \pm 557$ m; ASI: $10,621 \pm 942$ m; ROW: $11,054 \pm 580$ m). Whereas methane in EUR is at similar level to other regions due to methane’s longer atmospheric lifetime.

Large uncertainties occur when the sampling number was low. For example, the trend uncertainties for ethane, methane and propane in ASI were large during Jan 2009-Nov 2011, because most ASI samples were collected during Jun-Oct 2010, and there was a 1.5 year gap between Jan 2009 and Jun 2010 when no sample was collected (Figure 2).

3.2.3 Monthly variation in the upper troposphere

The monthly variations of the observed upper tropospheric ethane, methane and propane mole fractions (2006-2016) over five regions (whole NH, EUR, NAM, ASI and ROW) are shown in Figure 4. The observed monthly variations are driven by the emissions and atmospheric hydroxyl radical (OH) cycle (the major sink for tropospheric ethane, methane and propane). The whole NH upper tropospheric ethane, methane and propane mole fractions show peaks in June and July. The upper tropospheric NAM and EUR ethane mole fractions increase from October/November peaking in April, decrease from April until October. This is consistent with the FTIR observation (Franco et al., 2015). The upper tropospheric ASI and ROW ethane peaks in June, two months later than NAM and EUR. Methane shows small monthly variations in EUR, NAM and ROW, suggesting that the emissions play a greater role and thus compensate the influence of the seasonal cycle of OH radical. The upper tropospheric methane in ASI has shown higher mole fractions in summer (June-September) due to deep convection of upward transport of surface air

with higher methane into the upper troposphere during Asian monsoon (Baker et al., 2012). The monthly variations of propane are more variable compare to ethane due to the shorter lifetime of propane and probably more variable emission sources of propane.

260 **3.3 Lower stratospheric trends**

The sources and sinks of ethane, methane and propane in the stratosphere are different as in the troposphere. There is no known large emission source of ethane, methane and propane in the stratosphere. Stratospheric samples have a wider source footprint and are influenced by troposphere-stratosphere exchange, and chemical reaction. In the stratosphere, the OH radical
265 concentration on average decreases by a factor of 10 compared with tropospheric OH levels, whereas chlorine (Cl) radicals are more abundant and therefore plays a greater relative role in ethane, methane and propane oxidation (Li et al., 2018). The loss of ethane in the stratosphere by reaction with Cl radicals is about 40 times more than that by OH radicals (reaction rate of ethane with Cl is about 400 times faster than with OH at 250K (Atkinson et al., 2001), and stratospheric
270 OH is about ten times more abundant than stratospheric Cl (Li et al., 2018)), whereas the ethane loss in the troposphere by Cl is negligible compared with by OH due to the small amounts of tropospheric Cl (OH:Cl around 10,000) (Lelieveld et al., 1999; Gromov et al., 2018)). The reaction rates of ethane, methane and propane with Cl radicals are about 572:1:1330 at 298K (Atkinson et al., 1997), indicating that propane and ethane are more sensitive to the changes in stratospheric Cl
275 radicals.

3.3.1 Linear trends in the lower stratosphere

Figure 5 shows the lower stratospheric observations, linear trends and moving average of ethane (Figures 5 a,b,c,d,e), methane (Figures 5 f,g,h,i,j) and propane (Figures 5 k,l,m,n,o) over five
280 regions: whole Northern Hemisphere (Figures 5 a,f,k), Europe (Figures 5 b,g,l), North America (Figures 5 c,h,m), Asia (Figures 5 d,i,n), and rest of the world (Figures 5 e,j,o). The growth rates of ethane, methane and propane over each region are shown in Table 2 b.

The growth rates of lower stratospheric methane over all five regions (range 0.22-0.51 %/yr) are consistent with the upper tropospheric methane (range 0.29-0.37 %/yr) (Table 2). In contrast, the

285 difference between the lower stratospheric and upper tropospheric propane growth rates is large,
because propane has a higher sensitivity to stratospheric chlorine and shorter lifetime compared
to methane. The lower stratospheric ethane has similar growth rates in the whole NH, EUR and
ROW compared with the upper troposphere, whereas the difference occurs in NAM and ASI. The
Asian summer monsoon may be a reason to explain the different growth rates in ASI, although
290 further investigation on the change in troposphere-stratosphere mixing and stratospheric chlorine
in NAM is needed.

3.3.2 Non-linear trends in the lower stratosphere

The observed lower stratospheric ethane over the whole NH shows two exceptional peaks in
295 2010 and 2013 (Figure 6 a). The peak in 2010 is not seen at regional levels (NAM, ASI, EUR),
which suggests global upward transport of the upper tropospheric ethane (peaking in 2010-2011)
into the stratosphere and the important contribution from ROW. The second peak in 2013 can be
due to the regional emission transport from the troposphere into the lowermost stratosphere as
such a peak is observed simultaneously over NAM, ASI and ROW, or due to changes in
300 stratospheric sinks (e.g. OH or Cl radical concentration) as such peaks are seen for all three
compounds.

Methane trends in the lower stratosphere show large variability during 2010-2014 over the whole
NH, ASI and ROW, similar variability is present in the upper tropospheric methane trends
(Figure 3), indicating a fluctuated upwards transport of surface emissions into the upper
305 troposphere and stratosphere.

3.3.3 Monthly variation in the lower stratosphere

The lower stratospheric ethane mole fractions do not show strong seasonality, except that NAM
has a seasonal trend with one month later shift compared to the upper tropospheric NAM trend.
310 The lower stratospheric ASI ethane shows the same timing peak in June with upper tropospheric
ASI ethane which potentially indicates the intrusion of tropospheric air masses into the stratosphere
due to Asian summer monsoon (Xiong et al., 2009; Park et al., 2007). There is little seasonality
evident in the ethane mole fractions in the stratosphere. Since stratospheric aircraft measurement
campaigns are generally of short duration (several weeks), a direct comparison to previous data is

315 not possible, however, vertical column data obtained by ground based FTIR for 8-21km reported
by Helmig et al. (2016) also showed no clear seasonal variation.

The lower stratospheric methane is observed to reach the lowest in March-May over all five
regions. Propane in the lower stratosphere reaches the highest in June-August over most regions
except ASI.

320

3.3.4 Trends in the lower and upper parts of the lower stratosphere

Because the potential vorticity of the lower stratospheric samples has a broad range (2-12.2
PVU), the lower stratosphere is further classified into two parts: lower part ($2 \leq PV < 6$ PVU) and
upper part ($PV \geq 6$ PVU), to investigate the changes of trends within the lower stratosphere. It is
325 noted that the sample number of each sub-region gets smaller (95-1,656 samples per region;
Table 2) by applying this classification, thus the trends have larger uncertainties and should be
interpreted with caution.

The linear trends of methane over all five regions, and ethane over four regions (except ASI)
show little difference between the lower and upper parts of the lower stratosphere (Table 2 c,d;
330 Figures S4-5). Larger differences ($\Delta > 2\%$) in growth rates of ethane in ASI, and propane over
all five regions are found.

The non-linear trends of ethane, methane and propane in the upper and lower parts of the lower
stratosphere are similar over most regions (Figures S6-7). A significant difference occurs for
ethane in ASI during 2006-2013 when the lower part ethane had a sharp increase in 2006-2007,
335 then followed a plateau in 2007-2013, whereas the upper part ethane had a continuous decrease in
2006-2013. It's noted that the sample number in upper part of the lower stratosphere over ASI is
the minimum among all the sub-regions (Table 2).

3.4 Limitations and implications

340 Despite the usefulness, uniqueness and high quality of our datasets, several limitations of our study
should be noted. (a) Representativeness of the presented trends. Although our flight sampling is
frequent and covers a large area of the NH, the spatial and temporal distributions of our samples

are not even. This may cause the trends being influenced by specific regions where more samples were collected. (b) Nature of samples. Our samples were collected in the UTLS region and can be
345 influenced by atmospheric transport (e.g. troposphere-stratosphere exchange), surface sources, and chemical destruction processes. Therefore, the trends represent the net effects of these factors making the interpretation with regard to single factors difficult. It is noted that our aircraft samples have significantly different spatial distributions compared with the studies summarized in the Introduction section, therefore, any comparison should be carefully made. When comparing
350 surface and airborne datasets from multiple locations to assess global atmospheric changes, it will become increasingly important to ensure comparability of data quality. A process that has begun through the grounding of a World Calibration Center for VOCs, although this dataset predates this initiative. (c) PV choice of identifying upper tropospheric and stratospheric samples. In this study, we used $PV=2$ to define the tropopause, whereas other approaches exist. It is shown that on large
355 space and time scales in the extratropics, the WMO thermal tropopause corresponds to a surface of constant potential vorticity (PV), although there exist systematic differences on smaller scales (Stohl et al., 2003; Wirth, 2000).

Implications. (a) Observations of ethane, methane and propane were often restricted at regional scale or short-duration. We have presented a long-term (10 years) airborne observations of
360 ethane, methane and propane in the UTLS region at northern hemispheric scale. This dataset is unique and can be used to examine long-term troposphere-stratosphere exchange, chemical and dynamical changes in the UTLS region, and improve model performance. To the best of our knowledge, such long-term aircraft observations are only available from IAGOS-CARIBIC project (our study) and CONTRAIL project (Machida et al., 2008; Sawa et al., 2015). (b) The
365 “Prophet” algorithm is an open source software, and suitable for non-continuous time-series datasets. Unlike the commonly used linear fit approach for trend analysis, the “Prophet” algorithm is robust to missing data and the influence from outliers is minimized. It better captures the inter-annual variability and is not influenced by the time period of choice. (c) Other analysis approaches such as machine learning techniques can be used on our dataset to enlarge the spatial
370 and temporal distributions. Combining our dataset with space-borne observations will provide a better view of global distributions and trends of trace gases.

4 Data availability

The IAGOS-CARIBIC observational data of ethane, methane, and propane in the period February
375 2006 – February 2016 can be accessed at <https://doi.org/10.5281/zenodo.6536109> (Li et al., 2022).
Co-authorship may be appropriate if the IAGOS-CARIBIC data are essential for a result or
conclusion of a publication.

5 Conclusions

380 In this study, we present upper tropospheric and lower stratospheric ethane trends from airborne
observations over the period 2006-2016 with reference to methane and propane. The linear
trends, moving averages, non-linear trends and monthly variations of ethane, methane and
propane were examined for 20 sub-regions (4 categories: the upper troposphere, the lower
stratosphere, the lower part of the lower stratosphere, and the upper part of the lower
385 stratosphere; and 5 regions under each category: whole NH, EUR, NAM, ASI and ROW). The
linear trends of methane were similar in all sub-regions (range 0.22-0.51 %/yr increase), whereas
ethane and propane had more variable trends due to their shorter atmospheric lifetime. The
observed growth rates of ethane, methane, and propane over 2006-2016 in the upper troposphere
are -2.24, 0.33, and -0.78 %/yr, respectively, and in the lower stratosphere are -3.27, 0.26, and -
390 4.91 %/yr, respectively. The dataset is publicly available and is valuable for future studies to
evaluate and improve atmospheric models and emission inventories, and understand long-term
changes in troposphere-stratosphere exchange and in sources and sinks of ethane, methane and
propane.
