Abstract.

The largest uncertainty in future projections of sea level change comes from the uncertain response of the Antarctic Ice Sheet to the warming oceans and atmosphere. The ice sheet gains roughly 2000 km³ of ice from precipitation each year and loses a similar amount through solid ice discharge into the surrounding oceans. Numerous studies have shown that the ice sheet is currently out of long-term equilibrium, losing mass at an accelerated rate and increasing sea level rise. Projections of sea-level change rely on accurate estimates of the contribution of land ice to the contemporary sea level budget. The longest observational record available to study the mass balance of the Earth's ice sheets comes from satellite altimeters. This record, however, consists of multiple satellite missions with different life-spans, inconsistent measurement types (radar and laser) and of varying quality. To fully utilize these data, measurements from different missions must be cross-calibrated and integrated into a consistent record of change. Here, we present a novel approach for generating such a record that implies improved topography removal, cross-calibration and normalization of seasonal amplitudes from different mission. We describe in detail the advanced geophysical corrections applied and the processes needed to derive elevation change estimates. We processed the full archive record of satellite altimetry data, providing a seamless record of elevation change for the Antarctic Ice Sheet that spans the period 1985 to 2020. The data are produced and distributed as part of the NASA MEaSUREs ITS_LIVE project (Nilsson et al., 2021, DOI: <https://doi.org/10.5067/L3LSVDZS15ZV>).

38 1 Introduction

39 The single largest uncertainty in multi-centennial projections of sea level change comes from the uncertain
40 response of the Antarctic Ice Sheet to warming oceans and atmosphere (Oppenheimer et al, 2019). Reductions in
41 uncertainty will come primarily from developing our understanding of the ice sheet’s response to changes in ocean
42 and atmosphere over the observational record. Given the inaccessibility and size of the ice sheet, satellite
43 observations provide the most comprehensive means to assess ice sheet change. One of the most valued
44 observational records comes from a handful of satellite altimeters that, in combination, provide a near-continuous
45 record of elevation-change from 1992 (McMillan et al., 2014; Schröder et al., 2019; Shepherd et al., 2018, 2019;
46 Zwally et al., 2015, 2021). These observations have provided invaluable insights into how the topography of
47 Antarctica has changed over the past 30 years, revealing rapid thinning of key West Antarctic glaciers (Konrad et
48 al., 2017) that have the potential to thin and retreat irreversibly (Joughin et al., 2014; Rignot et al., 2014). Previous
49 studies of the polar ice sheets that used data from a single satellite mission have been hampered by relatively short
50 records over which to assess change. Records longer than 10 to 20 years are needed to reduce the overall
51 uncertainty in elevation change assessments and to reduce the impact of short-term variability on the climate
52 series (Wouters et al., 2013). Therefore, the creation of long-term records is essential for the separation of short-
53 term variability from long-term change. Such records require piecing together observations from numerous
54 satellite instruments, with unique measurement characteristics and sources of error. Previous studies have tried to
55 overcome these issues by either comparing inter-mission rates of elevation change (avoiding merging the records)
56 or merging the records at relatively coarse resolution (>50 km) (Davis, 2000; Khvorostovsky, 2012). More
57 recently, progress has been made to construct synthesized records of ice sheet elevation at higher resolution
58 (Schröder et al., 2019; Shepherd et al., 2019; Wingham et al., 2006). Many issues still remain unsolved, including
59 the proper accounting of radar-penetration, slope induced errors, and resolving time-variable and static
60 topography. In this study, we provide new and modified algorithms to mitigate the impact of these issues on the
61 elevation change record. In support of the “Inter-mission Time Series of Land Ice Velocity and Elevation”
62 (ITS_LIVE), a “NASA Making Earth System Data Records for Use in Research Environments” (MEaSUREs)
63 project, we revisit the processing and cross-calibration of more than 30 years of altimetry measurements over
64 Antarctica to provide a state-of-the-art climate record of ice sheet topographic change. Specifically, we combine
65 data from four conventional pulse-limited radar altimeters (Geosat, ERS-1, ERS-2, and Envisat), a dual antenna
66 radar altimeter capable of operating in both Synthetic Aperture Radar Interferometric mode and pulse-limited
67 mode (CryoSat-2), and a small-footprint waveform (ICESat) and photon counting (ICESat-2) laser altimeters,
68 yielding the most comprehensive record of Antarctic elevation change to date (Figure 1).

74

75

76

Figure 1: Spatial and temporal coverage of the seven satellite altimetry missions used to produce the elevation change synthesis. Concentric dashed circles and labels (orange) indicate orbital limits of each mission (Geosat 72°, ERS-1/2 and Envisat – 81.5°, ICESat 86° and CryoSat-2/ICESat-2 88°). Antarctic drainage basins 1-27 are show in black (Zwally et al., 2012). Orbital limits and drainage basins are plotted over ITS_LIVE velocities (Gardner et al., 2018) merged with the inSAR phase-based estimates (Mouginot et al., 2019).

77 **2 Data**

78 **2.1 Geosat**

79 The U.S Navy launched the GEOdetic SATellite (Geosat) in March 1985, which operated until September 1989,
80 providing limited Antarctic coverage between $\pm 72^\circ$ latitude. The main goal of the mission was to provide the U.S
81 Navy with detailed information about the marine gravity field. Geosat operations consisted of two separate
82 missions, where the initial 18 months was the classified “Geodetic Mission” (GM), in a 135-day repeat orbit,
83 ending in September 1986, and the “Exact Repeat Mission” (ERM), in a 17-day repeat orbit, lasting until the end
84 of the mission. The mission carried a Ku-band (13.5 GHz) pulse-limited altimeter providing measurements every
85 670 m along-track (10 Hz), with a pulse-limited diameter of ~ 3 km. In this study we used “Ice Data Record”
86 (IDR) from the Radar Ice Altimetry Group at NASA Goddard Space Flight Center (GSFC) providing geolocated
87 and corrected surface elevations. Only records with a valid retracking correction and waveforms containing a
88 single return echo were used in the study to reduce noise in the derived surface elevations. We detected the
89 presence of a bias in the Automatic Gain Control (AGC) parameter of 1.23 dB between the Geodetic Mission
90 (GM) and the Exact Repeat Mission (ERM) phases. This is most likely due to the change in orbit and did not
91 affect any of the other parameters, including the surface elevation change.

92 **2.2 ERS-1 and ERS-2**

93 The European Space Agency (ESA) launched the European Remote Sensing (ERS) satellites in 1991 (ERS-1) and
94 1995 (ERS-2) respectively. They operated continuously between $\pm 81.5^\circ$ latitude until 1996 and 2003,
95 respectively. Both missions carried conventional pulse-limited Ku-band (13.6 GHz) radar altimeters, with a pulse-
96 limited footprint of ~ 1.5 km, and an along track resolution of 370 m (20 Hz sampling rate). The two missions
97 operated in a 35-day repeat orbit, though ERS-1 had several shorter mission phases early on that deviated from
98 the standard repeat-track orbit. For this study the “REprocessing of Altimeter Products for ERS (GDR): 1991 to
99 2003” (REAPER), detailed in Brockley et al. (2017) is used to obtain surface elevation measurements. This
100 product contains updated corrections and improved calibrations. For each satellite record we separated the data
101 from the two operational modes, ‘ocean’ and ‘ice’, excluding any data used for calibration. The product provides
102 different retracking solutions from which we have chosen to use the ICE1 retracker, otherwise known as the
103 “Offset Center of Gravity” (OCOg) retracker (Wingham et al., 1986) using a 30% threshold of the maximum
104 waveform amplitude. The Ku-chirp and the ICE-1 20 Hz quality flags, available in the product, were used to
105 exclude poor quality observations from the analysis.

106 **2.3 Envisat**

107 The “Environmental Satellite” (Envisat) was launched by ESA in 2002 as a successor to the ERS mission and was
108 officially decommissioned in 2012. Envisat was launched into a 35-day repeat orbit, operating with a pulse-limited
109 radar altimeter with the same footprint, radar frequency, and sample frequency as the earlier ERS missions. For
110 Envisat we used the “RA-2 Geophysical Data Record” (GDR) version 2.1. Only data collected during the period
111 2002 to 2010 were used due to changes in orbit initiated in October of 2010. The GDR product, as with the
112 REAPER product, includes elevations determined using the ICE-1 retracker with a 30% threshold of the

113 maximum waveform amplitude, which we used for this analysis. We applied the same quality filter on the GDR
114 records as with the ERS product, using the Ku-chip and ICE-1 quality flags.

115 **2.4 ICESat and ICESat-2**

116 The National Aeronautics and Space Administration (NASA) launched the Ice, Cloud, and land Elevation Satellite
117 (ICESat) in 2003, which operated from 2003 to 2009, in a 96-day repeat orbit. The mission carried a novel laser
118 altimeter providing a 70 m beam-limited ground footprint, with 170 m along-track sampling (40 Hz). We used
119 the latest version of the GLAS06 product (release 34), which has been corrected for the “Gaussian-Centroid-
120 Offset” (Borsa et al., 2014), detector saturation and converted to heights above the WGS84 ellipsoid. We did not
121 apply any inter-campaign bias to the ICESat elevations, as there is no consensus that these are required (Borsa et
122 al., 2019). The records are further edited to remove poor quality observations, using the accompanying quality
123 flags ($\text{elev_use_flh} > 0$, $\text{sat_corr_flg} > 2$, $\text{sigma_att_flg} > 0$, $\text{i_numPk} > 0$).

124

125 The ICESat-2 mission is a follow on mission to ICESat and was launched in October 2018 with the goal of
126 continuing the long-term altimetry measurements of polar regions (Markus et al., 2017). It carries a new and novel
127 photon counting laser altimeter that uses a 532 nm laser with a pulse repetition rate of 10 kHz and that operates
128 in a repeat-track configuration over the continental ice sheets. In contrast to its predecessor’s single beam, ICESat-
129 2 collects ground measurements using six individual laser beams arranged in three pairs. Each of the beam pairs
130 is separated by 3 km and each inter-pair beam by 90 m across track. This configuration allows for a direct estimate
131 of the across track surface slope that was not directly possible with ICESat’s single beam configuration. The beam
132 limited footprint for each beam is 12 m in diameter sampling every 0.7 m along-track with a repeat frequency of
133 91 days. In this study surface elevation from the ATL06 product was used following the approach outlined in
134 Smith et al. (2019, 2020). Here a segmentation filter (difference filter) was used to remove poor quality
135 observations, if differences between consecutive points exceeds a threshold of 2 m the point was rejected. Further
136 editing was done using the ATL06 quality flag, keeping only data designated to be of good quality
137 (“*atl06_quality_summary* = 0”).

138 **2.5 CryoSat-2**

139 ESA’s CryoSat-2 mission launched in 2010 with the primary purpose of monitoring changes in Earth’s Sea and
140 land ice. This satellite carries a new type of Doppler/delay radar altimeter (Raney, 1998) equipped with a dual
141 antenna configuration allowing for interferometric measurements of surface elevations. The altimeter system,
142 referred to as SIRAL, operates in two different modes over the ice sheets; a Synthetic Aperture Radar
143 Interferometric (SARIn) mode over the marginal areas and a Low-Resolution Mode (LRM) [a conventional Ku-
144 band pulse-limited radar (identical to ERS and Envisat)] over the ice sheet interiors. The Doppler/delay radar
145 allows for increased along-track resolution compared to conventional pulse-limited altimetry. The SARIn-mode
146 has an effective resolution of 350 m along-track and 1500 m across-track, compared to the LRM-modes 1500 m
147 along and across track resolution. Further, the dual antenna configuration allows for mapping of the exact position
148 of the surface echo location, by estimation of the across-track look angle from the difference in path length of the
149 signals between the two antennas. In contrast to previous missions, CryoSat-2 operates in a drifting orbit, with a
150 369-day repeat and a 30-day sub-cycle. The drifting orbit offers improved spatial coverage compared to repeat-

151 track orbits at the expense of larger across track distances. We processed both the LRM and SARIn modes using
152 the ESA L1b Baseline-C product for the time span 2010-2018 using a custom CryoSat-2 processor described in
153 Nilsson et al. (2016). For the LRM-mode we have chosen to use a 10% threshold of the maximum waveform
154 amplitude for retracking, similar to Schröder et al., (2019).

155 **3 Methods**

156 To generate a continuous record of elevation change for Antarctica several corrections and processing steps need
157 to be applied to the altimetry data. The details of the different steps are provided in this section and a summary of
158 the corrections their order of application is provided below:

- 159 1. Application of geophysical corrections and parameter editing for each mission [Section 2].
- 160 2. Correcting for slope-induced error in the radar altimetry using an ancillary elevation model [Section
161 3.1].
- 162 3. Removal of the static topography to extract time-variable elevation change [Section 3.2.1].
- 163 4. Correcting the radar altimetry data for changes in near-surface scattering conditions [Section 3.2.2].
- 164 5. Cross-calibration and integration of the multiple sensors and modes into a continuous time series
165 [Section 3.2.3].
- 166 6. Normalization of seasonal amplitudes for each sensor using a reference mission [Section 3.2.4].
- 167 7. Interpolation, extrapolation and filtering to create a three-dimensional data product [Section 3.2.5].

168 **3.1 Slope-induced error correction**

169 The largest source of error in radar altimetry over ice sheets is associated with the effects of surface slope inside
170 the beam-limited radar footprint. This error stems from an inability to locate the surface from which most of the
171 echo power originates (off Nadir). Because of this, the echo is assigned the location of the sub-satellite point on
172 the Earth surface. This introduces a slope-dependent measurement error on the order of 0-100 m (Brenner et al.,
173 1983), which varies with the magnitude of the surface slope. There are a few ways of minimizing the slope-
174 induced error (Bamber, 1994; Roemer et al., 2007). For this study we used the “relocation method” described in
175 (Nilsson et al., 2016). The relocation method corrects both the range and the coordinates to the echolocation (from
176 nadir) using topographical information, such as surface slope, aspect and curvature. This method has been shown
177 to improve surface-elevation retrievals compared to other approaches (e.g. Schröder et al., 2017). To compute the
178 required surface slope, aspect and curvature, we used the “bedmap2” digital elevation model from Fretwell et al.
179 (2013) resampled to 2 km horizontal resolution.

180 **3.2 Elevation change estimation and algorithms**

181 Surface elevation changes are determined as follows: The local mean topography within a specified search radius
182 is removed from each mission and mode, leaving only the elevation anomalies that contain the time variable
183 signal. Artificial trends and seasonal amplitudes in elevation anomalies, that are introduced by changes in surface
184 scattering characteristics, are reduced proportionally to the correlation with the received radar waveform shape.
185 Inter-mission biases in seasonal elevation anomalies are further minimized using a normalization scheme that
186 references all seasonal elevation change amplitudes to those observed by CryoSat-2. A cross-calibration scheme

187 is applied to adjust and merge elevation change from all missions and modes into a continuous monthly time
188 series. Lastly, interpolation is used to generate a consistent gridded product with 1920 m horizontal resolution at
189 monthly time steps from 1985 to 2020. The details of each step are provided in the following sub-sections.

190 **3.2.1 Removal of time-invariant topography**

191 To create time series from observations of surface elevations, the time-invariant topography must be removed to
192 obtain the change signal. This can be done by directly modelling the topography at any given position, e.g., by
193 fitting a mathematical surface using least-squares, while accounting for the spatial and temporal trends. This rather
194 simple approach, however, has some inherent limitations. When solving for time-invariant topography one must
195 account for discrepancies between observations originating from: (1) *differences in the orbital geometry of the*
196 *missions*, (2) *differences in ascending versus descending range estimates* and (3) *differences in measurement*
197 *density*. To account for (1) we employ an iterative prediction-point adjustment to solve for the topography given
198 a pre-defined grid of a specified dimension for ascending and descending tracks separately for each mission or
199 mode. For each grid-node, the closest data points inside a specified search radius are used to compute a new
200 centroid location, when 5 or more data points are available. This centroid location is used in the next iteration as
201 the new prediction point. This allows us to conveniently follow the reference orbits (locations of highest data
202 density) to solve for the topography along the satellite ground tracks. Issue (2) has been handled in different ways
203 (e.g., Flament et al., 2012; McMillan et al., 2014; Moholdt et al., 2010). We have chosen to solve (2) by separating
204 the individual datasets in ascending and descending orbits, solving for the topography at the same center date with
205 the inclusion of a linear trend. The differing number of available observations (3) in each independent solution is
206 handled by allowing for a different number of coefficients in the mathematical surface-topography model that is
207 fit to the data. We have provided three different mathematical models of topography (including time) that vary
208 spatially depending on the number of data points available in the local search area at the grid-node.

209 For locations with 15 or more observations a biquadratic surface (six coefficients) is modeled. When 5 to 14
210 observations are available a bilinear surface (three coefficients) is modeled. If there are less than 5 observations
211 the local mean (one coefficient) is removed and the slopes estimated independently in each direction (x and y).
212 The linear temporal term in the design matrix is used to center the data to a specific time and is always included,
213 except if $n < 5$ points. A robust least squares approach, M-estimator (Hubert' T weighting function), is used to
214 solve for the model coefficients (Holland et al., 1977).

215
216 Time-invariant surface topography is estimated at each prediction point and removed from the original
217 observations inside each local search radius (excluding the linear term). This produces topographic residuals
218 varying only with time. Using this approach, it is common for the search radius of different along-track centroids
219 to overlap. This can produce situations where a node, with corresponding elevation data, might already have been
220 provided with a solution. To ensure that the best time-invariant topography solution is retained, the new correction
221 is only applied if the estimated root-mean-square (RMS) of the residuals (w.r.t. the time-invariant topography) is
222 lower than the previously computed solution for the data point in question.

223
224

225 We select different search-radii for the repeat-track (ERS 1/2, Envisat, ICESat, Geosat) and drifting-track
 226 (CryoSat-2) missions. The radius is empirically determined by investigating the residual RMSE from the
 227 algorithm over different types of surfaces. We found that, on a 500 m grid spacing, a search radius of 500 m
 228 provided a good trade-off between the accuracy and computational efficiency of the algorithm for the repeat-track
 229 missions. For CryoSat-2 and Geosat, we found that a higher search radius of 1000 m was needed to provide results
 230 with a comparable RMSE. This larger search radius allows for more ground tracks to be included in the inversion,
 231 reducing the variance of the model residuals. The inclusion of a linear temporal trend in the fit is key to effectively
 232 remove the ascending/descending bias, and to center all data to a common epoch (center date of each mission or
 233 mode).

234 3.2.2 Surface and volume scattering correction

235 The microwave pulses transmitted by spaceborne radar altimeters at Ku-band frequency (~13.6 GHz) are sensitive
 236 to changes in the dielectric properties of the ice sheet surface (as determined by changes in the snow grain size,
 237 temperature, density, water content, among others). Large scale temporal and spatial changes in the scattering
 238 horizon induce changes in measured range, and thus surface elevation, and can introduce long-lived biases in the
 239 derived elevation change rates (Arthern et al., 2001; Davis et al., 2004; Khvorostovsky, 2012; Nilsson et al., 2015;
 240 Wingham et al., 1998). To mitigate this effect, we use a retracking algorithm that tracks the leading edge of the
 241 return waveform (i.e., a maximum amplitude threshold between 10% and 30%). Such retrackers have been shown
 242 to be less sensitive to changes in ice sheet surface properties (Helm et al., 2014; Nilsson et al., 2016; Schröder et
 243 al., 2017). Another key step is removing elevation variability that is correlated with changes in the received radar
 244 waveform shape (Flament and Rémy, 2012; McMillan et al., 2014; Paolo et al., 2016; Simonsen et al., 2017;
 245 Zwally et al., 2005). The shape of the waveform is intricately linked to the medium in which it is propagated or
 246 reflected. Removing the correlation between changes of the shape of the radar waveform with elevation can
 247 largely reduce these artificial signals. For this study we approximated the shape of the radar waveform following
 248 the definition of Flament et al., (2012) and Simonsen et al., (2017), using the backscatter (Bs), the leading-edge
 249 width (LeW) and the trailing edge slope (TeS).

250
 251 The spatially-variant scattering correction was estimated by computing the local sensitivity gradient (SG) between
 252 each waveform parameter and elevation residuals using a multi-variate least squares inversion. The SG-
 253 parameters were estimated for ascending and descending tracks separately. All waveform parameter time series
 254 were centered and normalized using the mean and standard deviation. Further, parameters were detrended by
 255 applying a difference operator, forming the following least-squares model:

$$\nabla \left(\frac{h - \bar{h}}{\sigma_{dh}} \right) = SG_{Bs} \cdot \nabla \left(\frac{Bs - \overline{Bs}}{\sigma_{Bs}} \right) + SG_{LeW} \cdot \nabla \left(\frac{LeW - \overline{LeW}}{\sigma_{LeW}} \right) + SG_{TeS} \cdot \nabla \left(\frac{TeS - \overline{TeS}}{\sigma_{TeS}} \right) \quad (1)$$

256
 257 where ∇ is the difference operator, h the elevation residual (elevation relative to time-invariant topography), σ the
 258 standard deviation and the overbar represents the average value of the parameter.

259
 260

261 The SG-parameters were inverted for using the same adaptive search-center approach as described in Sect. 3.2.1.
 262 The estimated SGs were then used to correct each observation within the search cap using the linear combination
 263 of the original waveform parameters and the estimated coefficients. Finally, we apply a linear space-time
 264 interpolation to estimate corrections at locations where the multi-variate fit did not provide a satisfactory solution.
 265

266
 267 Figure 2. Original and scattering corrected area integrated time series for Lake Vostok in East Antarctica, which
 268 has been shown to have a height trend close to zero over recent decades (Richter et al., 2014). A discrepancy in
 269 uncorrected height trends is observed for the various mission due to differences in altimetry processing, orbit
 270 configuration and the quality of the geophysical corrections. Envisat and ERS-2 (Ice) show the largest uncorrected
 271 magnitude in both trend and seasonal signal. Corrected height change records show significantly lower seasonal
 272 amplitudes and trends that are close to zero.

273
 274 To determine the optimal search radius for generating the scattering correction, we performed a sensitivity study
 275 over Lake Vostok in East Antarctica (Figure 2). Lake Vostok was selected due to its low surface slope, on average
 276 0.03°, and highly stable surface (Richter et al., 2014), minimizing the impact of the static and time variable
 277 topography in the analysis. After varying the search radius from 1 to 5 km, we found that the 1 km solution
 278 provided the most accurate trend and seasonal amplitude for all missions and modes. We also found that the
 279 absolute magnitude of both the trend and amplitude increased linearly as the search radius increased. We interpret
 280 this result as a decrease in efficiency of the correction, possibly due to de-correlation with increasing
 281 spatial/temporal scales. The use of a 1 km search radius is also computationally efficient as less data are used in
 282 the inversion. Applying these lessons to the ice sheet wide processing, we found that the correction has a minor
 283 impact on the estimated trend for the CryoSat-2 SARIn-mode and the Geosat missions. We also found that the
 284 application of the correction to the SARIn and Geosat data increased the seasonal amplitude of the local (single
 285 grid cell) time series (Section 3.2.4). Given that there is no physical justification for an increase in seasonal
 286 amplitude, we chose not to apply the correction to the Geosat mission and the SARIn-mode data. For the other
 287 missions, the magnitude of the correction varied across missions and modes of operation, where the largest

288 changes in trend and amplitude were found for Envisat and ERS-2 ice mode, and the lowest for CryoSat-2 LRM.
 289 By examining the changes in trend and amplitude we found significant spatial patterns, also varying across each
 290 mission and mode, as shown in Figure 3. These patterns show strong correlations to both surface slope/roughness
 291 and signals of metrological origin (Armitage et al., 2014) and are mostly driven by katabatic winds and the re-
 292 distribution of snow. The wind effect can be observed in the RMSE plots for Envisat and for ERS-2 Ice as banned
 293 structures East Antarctic sector following the main ridge lines.
 294

295
 296 Figure 3: Change in elevation change rate and RMSE (seasonal amplitude) of the local time series after correction
 297 for temporal changes in scattering (penetration depth). Spatial patterns linked to surface conditions can be clearly
 298 observed. These effects are most prominent for Envisat and ERS-2.
 299

300 3.2.3 Cross-calibration and integration

301 Removal of the time-invariant surface topography is done internally to each dataset such that elevation residuals
 302 are not aligned to the same surface (see Section 3.2.1). To align elevation anomalies to a common reference we
 303 first solve for inter-mission offsets. These offsets vary regionally (Khvorostovsky, 2012; Wingham et al., 2009;
 304 Zwally et al., 2005), depending on the underlying topography, physical interactions of the radar with the surface,
 305 and differing retracking methodologies. In contrast to previous studies (e.g., Davis, 2005; Khvorostovsky, 2012;
 306 Li et al., 2006; Schröder et al., 2019; Wingham et al., 2006, 2009; Zwally et al., 2005), we estimate these offsets
 307 using a least-squares adjustment. This approach allows for a simple, yet consistent, alignment of multiple relative
 308 elevation anomalies without requiring full overlap between missions to solve. The technique follows the approach
 309 of Bevis et al. (2014), using the entire multi-mission record to constrain the solution while accounting for trend,
 310 seasonality and inter-mission/mode offsets. The trend is represented by a polynomial, with a maximum order of
 311 six; a four-term Fourier series to account for seasonality; and Heaviside functions to solve for the inter-mission
 312 offset between missions and modes. The design matrix can be written as:

$$h(t) = \sum_{i=1}^{n_p-1} p_i(t - t_r)^{i-1} + \sum_{k=1}^{n_f} s_k \sin\left(\frac{2\pi t}{T_k}\right) + c_k \cos\left(\frac{2\pi t}{T_k}\right) + \sum_{j=1}^{n_j} b_j h \quad (2)$$

313

314 where n_p is the model order, t is the time in decimal years, t_r is the reference time in decimal years ($t_r =$
315 2013.95), T_k is the seasonal period reference ($T_1 = 1$ and $T_2 = 0.5$), n_f is the number of Fourier series terms ($n_f =$
316 4) and n_j is the number of missions and modes ($n_j = 10$).

317
318 Here, we add offsets for ten different missions and modes in the least squares model (Geosat, ERS-1 Ocean/Ice,
319 ERS-2 Ocean/Ice, Envisat, ICESat, CryoSat-2 LRM/SARIn and ICESat-1) to all data falling within the search
320 radius. To determine the order of the polynomial we use the Bayesian Information Criterion (BIC: Fabozzi et al.,
321 2014; Schwarz, 1978) to select the polynomial that produces the lowest BIC-value estimated from monthly binned
322 data.

323
324 The cross-calibration is performed on a 2 km polar-stereographic grid (EPSG: 3031) using a variable search radius
325 of 1-10 km surrounding each grid-cell. The radius is increased until 70% of the time series is filled (monthly) or
326 the maximum radius is reached. If the maximum search radius is reached and the 70% criteria is not meet, we
327 continue processing using all available data. In most cases the search radius is in the range of 2-10 km. Outliers
328 in the original time series were initially removed using a 1-year running median filter where values larger than
329 ten times the median absolute deviation (MAD) are rejected. The model is then fit to the time series using a robust
330 least-squares inversion as in Sect. 3.2.1. Solutions are rejected if the absolute value of the linear rate is larger than
331 20 m a⁻¹ or if the RMS of the time series relative to the model is larger than 4 m. If any of the derived offsets are
332 larger than 100 m the offset is set to zero. The offsets estimated from the least-squares inversion are then subtracted
333 from the time series providing an initial cross-calibrated record of elevation change. Further, a last outlier step is
334 performed where the model is used to filter the time series by omitting observations exceeding ten-times the MAD
335 of the model-residuals.

336
337 This approach has several advantages; it allows a first order calibration of non-overlapping time series while also
338 aligning overlapping missions and modes to their common mean. To account for time series that do not fully
339 conform to our choice of a linear model, a secondary cross-calibration is performed for the four mission-specific
340 offset coefficients (ERS-1 to ERS-2, ERS-2 to Envisat/ICESat, Envisat/ICESat to CryoSat-2 and CryoSat-2 to
341 ICESat-2), using the post-fit model residuals. This approach was chosen as it facilitates the estimation of any
342 residual offsets after removal of the majority of the trend and seasonality, making it simple to estimate the overall
343 bias between the mission groups. The offsets for groups ERS-1 to ERS-2, ERS-2 to Envisat/ICESat and CryoSat-
344 2 to ICESat-2 were estimated by taking the median difference between the two datasets over their respective
345 overlapping time periods. This approach was found to be suboptimal for the Envisat/ICESat to CryoSat-2 offsets
346 due to the short period of overlap (less than 4 month) and large changes during the time period 2009-2011. To
347 overcome this limitation, we applied three different methods, generating five different independent
348 Envisat/ICESat to CryoSat-2 offsets at each search node. Method 1: We fit two second order polynomials to the
349 two residual time series and compute the median offset between the two functions over a one-year overlap (2010-
350 2011), and the difference between the two intercepts of the polynomials. Method 2: We applied a Kalman
351 Smoother with a state-space model consisting of a constant local level and a random-walk trend (Kalman, 1960;
352 Shumway and Stoffer, 1982) that better accommodates the variability in the time series. The filter was initialized
353 with a variance rate of 1 mm² a⁻³ (Davis et al., 2012), with the observational noise given by the RMSE of each

354 residual time series. Initial state-values of the filter were set to zero for both the level and trend with large initial
 355 uncertainties ($1e6$). The filter parameters were then optimized using the expectation-maximization (EM)
 356 algorithm (Shumway and Stoffer, 1982) with five iterations. The same approach as in Method 1 was used to
 357 generate the two estimates of the offset based on the one-year overlap, and the differencing of the two intercepts.
 358 Method 3: Here the offsets were determined by computing the median difference between the two missions over
 359 the 2010-2011 time period. To determine which of the offsets produces the best cross-calibration, we apply each
 360 offset and compute linear rates of change from 2003 to 2019. These rates are then compared to rates estimated
 361 from unbiased ICESat/ICESat-2 measurements produced by Smith et al., (2020), and the offset with the smallest
 362 absolute difference was selected. Finally, the selected offsets rate difference (radar minus laser) is checked against
 363 the difference computed without a residual cross-calibration. If the applied offset did not improve the rate
 364 compared to the ICESat/ICESat-2 record, then the residual offset was set to zero. Following Schröder et al.,
 365 (2019), we remove outliers in the offsets using a 100×100 km 5-MAD moving spatial filter. The intermission
 366 offsets are then interpolated using a gaussian kernel with a 20 km correlation length using the nine closest data
 367 points. This produces a spatially consistent field of offsets for the cross-calibration of the elevation residuals. Then
 368 the offsets estimated from the initial least-squares adjustment, and the offsets estimated from the secondary
 369 residual calibration are then applied to create a fully calibrated local time series. Finally, the individual calibrated
 370 elevation time series for each mission/mode are averaged to monthly estimates of elevation change for each spatial
 371 grid cell, with an associated standard error. Once, the time series have been calibrated a seasonal amplitude
 372 correction is applied to the data to normalize amplitudes between missions. This is described in more detail in
 373 Section 3.2.4. Finally, the monthly normalized time series are then combined and integrated into a continuous
 374 record using the weighted average of the data within each overlapping temporal bin. Weights are specified as the
 375 inverse variance of each mission's accuracy, and the random error estimated from the monthly averaging
 376 procedure (see 4.1).

377

378
 379 Figure 4. Maps of the residual cross-calibration offset and the corresponding error for the three main inter-mission
 380 transition periods. One should note that here ICESat has been grouped with Envisat in the initial calibration.

381
 382
 383
 384
 385

386 The initial least-squares adjustment provided good alignment between overlapping modes (ocean/ice mode) and
387 missions (Envisat-ICESat), and a first order correction for the three weakly overlapping missions that allows for
388 better estimation of the residual biases from the detrended data. Initial offsets were determined to be as large as
389 10-15 m in areas of rapid change such as Pine Island Glacier. However, the least-squares adjustment was shown
390 to be inadequate when large non-linear elevation changes are present. The magnitude of the estimated residual
391 cross-calibration error (after least-squares adjustment) (Figure 4) show that most overlapping regions have a
392 clear correlation with temporal coincident elevation change rates. This pattern is evident in the Envisat to
393 CryoSat-2 transition (Figure 4) for Dronning Maud Land (Basins 5-8), Wilkes Land (Basins 12-13),
394 Bellingshausen Sea (Basins 23-25) and the Amundsen Sea sector (Basins 20-23) (Figure 10: 2010-2012). For
395 the ERS-2 to Envisat transition, we find a clear correlation between the magnitude of the offsets and the changes
396 in elevation due to variations in surface mass balance in Wilkes's land (Basins 12-13 seen in Figure 1), over the
397 2001-2003 time period (Schröder et al., 2019).

398 3.2.4 Normalization of seasonal amplitude

399 The radar signal's interaction with the surface and sub-surface firn-layers can create artificially large seasonal
400 amplitudes and trends, as described in Sect. 3.2.2. We correct for these as best possible using information
401 contained in the waveform parameters. However, in many cases these corrections are unable to fully correct the
402 artificial signals. This behavior can be seen in Schröder et al., (2019) and in our data, even after the scattering
403 correction has been applied there exists intermission variations in seasonal amplitude (Figure 5). To further reduce
404 this effect, we apply an amplitude correction (h_n) to each mission to normalize the seasonal signal over the entire
405 record. We normalized the seasonal amplitudes of the ERS 1 & 2 and Envisat records to match amplitudes
406 computed from the CryoSat-2. CryoSat-2, which is retracked with a much lower threshold of the maximum
407 waveform amplitude (10%) for LRM and a maximum gradient threshold for SARin, has been shown to be less
408 sensitive to changes in surface properties and produces seasonal amplitudes of the same magnitude as ICESat
409 (Figure 5) (Nilsson et al., 2016). "After removal of the long-term trend, the amplitude normalization was computed
410 for each mission, except for ICESat and CryoSat-2, according to:

411

$$h_n = \left(1 - \frac{a_i}{a_r}\right) \cdot [\alpha_c \cos(2\pi t) + \alpha_s \sin(2\pi t)] \quad (3)$$

412

413 where (a_i) is the amplitude of the mission ($a^2 = \alpha_c^2 + \alpha_s^2$), (a_r) is the reference amplitude estimated from
414 CryoSat-2 data and $\alpha_{c,s}^2$ are the coefficients for the seasonal model. The correction is applied by subtracting it
415 from each individual time series and the normalization has the effect of producing more homogeneous amplitudes
416 over the entire altimetry record. The application did not introduce any noticeable shift in the phase of the seasonal
417 signal.

418

419 ICESat and the CryoSat-2 LRM mode show similar magnitude in amplitude and supports the choice of using
420 CryoSat-2 as reference where the difference is most likely explained by the lower temporal sampling of ICESat.
421 The slightly lower seasonal amplitude of ICESat-2 is mostly likely due to the short time span used to estimate the
422 amplitude (2-years), as seen in Figure 5.

423

424 Figure 5. Top: Median seasonal amplitude of the different missions and modes for the CryoSat-2 LRM (top) and
 425 SARin (bottom) mode masks (South of 81.5° S for LRM). The blue bars show the original seasonal amplitude
 426 with no corrections applied, the orange bars show the amplitude once the mission dependent scattering correction
 427 has been applied, and the green bars show the normalized amplitude after adjustment using CryoSat-2 as reference.

428 3.2.5 Interpolation, extrapolation and filtering

429 Collocation (a.k.a. ordinary kriging; Herzfeld, 1992; Nilsson et al., 2016) was used to interpolate the monthly
 430 elevation change estimates onto a 1920 m grid using a maximum search radius of 50 km and a 20 km correlation
 431 length. The 1920 m was chosen to be consistent with the ITS_LIVE grid that accommodates nesting of datasets
 432 at multiple resolutions. An adaptation to Nilsson et al. (2016) is that the local average is replaced by an estimate
 433 from a linear model regressed against both surface elevation (bedmap2) and surface velocity from Gardner et al.
 434 (2018), available at (<https://its-live.jpl.nasa.gov>), following the approach of Hurkmans et al. (2012) as seen below:
 435

$$436 \quad m_0 = \beta_0 + \beta_1 h_{DEM} + \beta_2 \log(v) \quad (4)$$

436

437 where (h_{DEM}) is elevation values from the DEM (bedmap2) and (v) are the surface velocity values. The minimum
 438 surface velocity is capped at 50 m per year to avoid introducing noise in the interior parts of the ice sheet and the
 439 logarithm is applied to linearize the range of velocity values.

440 For the interpolation, the spatial variance is taken to be the mean of the random error estimated from the monthly
441 averaging procedure. The noise term (diagonal of the error matrix), used in the collocation to weight each
442 observation, is taken as root-sum-square (RSS) of the variance of the cross-calibration error, mission accuracy
443 and the random error (see Section 4.1). Further, a minimum error of 5 cm is given to all observations based on
444 ICESat and ICESat-2 crossover analysis (Section 5.1, Table 1). Prior to the interpolation we remove erroneous
445 observations using a 100 km radius spatial filter centered at the location of each data value. In this procedure,
446 following Smith et al. (2020), we remove spatial gradients inside each 100 km cap by fitting a biquadratic surface
447 and if the observation exceeds a specific threshold it is removed. This threshold is dependent on the local surface
448 roughness and elevation change rate, where the surface roughness is estimated from the bedmap2 DEM. If the
449 surface roughness is larger than 60 m and the absolute elevation change rate is less than 0.2 m a^{-1} (Smith et al.
450 2020), then the filter threshold is set to 3-MAD otherwise set to 30-MAD (gross-outliers). This has the effect that
451 the filter is more aggressive in regions of steep topography (Antarctic Peninsula and the Transantarctic Mountains)
452 while preserving signal in areas of rapid change. In the temporal domain, and after spatial interpolation, a 12-
453 month median filter is applied to remove outliers exceeding the 10-MAD threshold. Rejected values in the time
454 series are filled using a gaussian kernel with a correlation length of 3-months.

455
456 Differences in satellite orbits cause spatial coverage to vary from $81.5^\circ - 88^\circ \text{ S}$ (excluding Geosat that only reached
457 72° S). The large gap in coverage between the maximum latitude reached and the south pole is referred to as the
458 pole hole. To create a spatially complete record of elevation change we use extrapolation to fill the pole hole for
459 each monthly time epoch. We first average each monthly spatial field to a coarse 20 km resolution, corresponding
460 to the average correlation length of the elevation anomalies. We then fill the CryoSat-2 and ICESat/-2 pole holes
461 using our collocation/kriging algorithm (with velocity and elevation terms set to zero), similar to Zwally et al.
462 (2015), using the 200 closest 20 km averaged values, with a correlation length of 100 km, and provide each
463 averaged observation with the aggregated error within each cell. For the 81.5° S missions (ERS 1/2 and Envisat)
464 the unobserved area is about eighteen times larger than the area for CryoSat-2 and ICESat/-2. This makes our
465 extrapolation approaches less useful. To overcome this issue, we remove a linear trend and the annual seasonal
466 signal estimated over the ICESat, CryoSat-2 and ICESat-2 period for each grid-cell over the 1992-2020 period.
467 The residuals to this model are more homogeneous in the far field. We then extrapolate these residuals to the
468 entirety of the 81.5° pole hole for each month using the same spatial kriging/collocation algorithm as previous
469 used (velocity and elevation set to zero). After the monthly residuals have been gridded and filled, we add back
470 the linear trend and seasonality estimated from the CryoSat-2 and ICESat/2 model for each location. For both
471 approaches we multiply the predicted errors from the algorithm with a factor of three to avoid errors that are too
472 small (e.g., less than 5 cm as estimated from ICESat-2 as in Table 1.). The estimated errors for the pole-hole are
473 to be considered only as a guide. These errors are based on the error-statistics of the surrounding 20 km averaged
474 data and errors being extrapolated inward to the pole, such as data from the Transantarctic mountains. This can
475 provide a somewhat unrealistic looking spatial pattern for the estimated error field, but which is still based on
476 observations.

477
478 Interpolated elevation anomalies can easily be included or excluded in any future analysis using the *data_flag*
479 field that is included with the data product: 0 = no data, 1 = high quality data, 2 = low quality data, 3 = pole hole.

480 The “low quality data” index is based on a minimum bedmap2 surface roughness criteria that is set to the
481 approximate size of the range gate window of the radar altimeters (roughness threshold for Geosat: 30 m, ERS-
482 1/2 and Envisat: 120 m, and CryoSat-2: 240 m). We also provided the ESA COP DEM
483 (<https://spacedata.copernicus.eu/web/cscda/dataset-details?articleId=394198>) resampled to our 1920 m grid using
484 a box-filter (averaging) to allow the user to investigate time-evolving topography. Center date of the DEM is circa
485 2010-2015 which is in line with our provided center or reference date of 2013-12-16.

486

487 To estimate volume changes at the basin scale (Figure 1), we replaced the interpolated values flagged by the
488 surface roughness criterion with values estimated from a hypsometric relationship (Moholdt et al., 2010; Nilsson
489 et al., 2015b). Here, the monthly values of elevation change (excluding the values flagged by roughness) were
490 binned using the median value within 100 m elevation intervals according to the hypsometry provided by the
491 DEM (bedmap2). As in Morris et al. (2020), a linear model was fit to these binned values and used to extrapolate
492 values to areas flagged as “low quality data”. This was done only for the purpose of this paper and is not applied
493 to the final data product. This choice was made to allow the users to select a suitable method given their interest
494 or constraints.

495 **4 Error propagation and validation**

496 **4.1 Uncertainties of elevation change time series and data**

497 An internal crossover analysis was performed to determine the relative accuracy of each mission and mode in a
498 similar manner as Brenner et al. (2007) and Schröder et al. (2019). We estimated the standard deviation of all
499 crossovers with a time difference of less than 31-days. Crossovers were binned as a function of surface slope at
500 intervals of 0.04° (Figure 6). The relative accuracy of each mission or mode was determined from the standard
501 deviation at zero slope by fitting an error function (inside an interval of 0 - 0.4°) as shown in Table 1. To derive
502 the uncertainty of each time series epoch we use the spatiotemporal variability inside each monthly time interval,
503 in the form of the standard deviation. This provides a random error for each monthly value that varies both in
504 space and in time and encompasses measurement related errors driven by topography, retracking and range
505 corrections etc. To quantify the total cross-calibration error for each time series we use the standard deviation of
506 each grouped mission offsets (Section 3.2.3) and add them in quadrature to estimate the total cross-calibration
507 error, similar to Schröder et al. (2019). We then have the total error (σ_m) for each month in each time series by
508 summing the individual error sources as:

$$\sigma_m^2 = \sigma_i^2 + \sigma_c^2 \quad (5)$$

509

510 where (σ_m) the error due to the elevation change variability within each monthly interval for each time series and
511 (σ_c) is the total cross-calibration error for each time series. The estimated total error (σ_m^2) is the provided RMS-
512 error in the product (varying both by location and time).

513

514
 515 Figure 6. Standard deviation (cm) of intra-mission and intra-mode crossovers for the Antarctic Ice Sheet as a
 516 function of surface slope (degrees). Precision decreases quasi-linearly as surface slope increases.

517
 518 Table 1. Sensor and mode errors ($\sigma_{mission}$) as a function of the random (σ_{noise}) and slope dependent (σ_{slope})
 519 errors. Slope (α) is in degrees. Modelled error ($\sigma_{mission}$) is based on fitting the following function to the intra-
 520 sensor, intra-mode crossover data: $\sigma_{mission} = \sigma_{noise} + \sigma_{slope}\alpha^2$

521
 522

Mission	σ_{noise} (cm)	σ_{slope} (cm)
Geosat	36	793
ERS-1 (Ice)	36	159
ERS-1 (Ocean)	26	114
ERS-2 (Ice)	34	147
ERS-2 (Ocean)	22	89
Envisat	15	97

534 4.2 Validation of rates of elevation change

535 To validate the data product, we computed elevation change rates and compared them to rates derived from near-
 536 coincident Operation IceBridge (OIB: MacGregor et al. (2021)) and pre-OIB data spanning the period 2002 to
 537 2019 using the Airborne Topographic Mapper (ATM: MacGregor et al. (2021)) laser altimeter. Elevation change
 538 rates for ATM were derived following the approach of Nilsson et al. (2016), where a linear model was solved at
 539 each measurement location using a search radius of 175 m. Following the approach of McMillan et al. (2014) and
 540 Wouters et al. (2015), the local slope was used to correct the measurements to the reference track, indicated as

541 Track_Identifier = 0 in the product. Solutions were rejected if they contained less than two campaigns of ATM
542 data, the magnitude of linear rate was larger than 10 m a^{-1} , the standard deviation of the solution exceeded 1 m a^{-1} ,
543 or if the solution contained less than 10 measurements, and if the time span was less than two years. The
544 elevation accuracy of the ATM sensor family has an estimated error of less than 9 cm (Brunt et al., 2017),
545 corresponding to an accuracy of roughly 0.5 cm a^{-1} over the 18-year measurement period. Operation IceBridge
546 coverage is concentrated to the western parts of the Antarctic Ice Sheet, providing very limited coverage in the
547 East. To overcome this limitation, we also use elevation change rates estimated by Smith et al. (2020) that are
548 based on crossover analyses of satellite laser altimetry (ICESat and ICESat-2: 2003-2019) that has an error of
549 roughly 10 cm. This corresponds to an error in the rate of elevation change of about 0.6 cm a^{-1} , which is consistent
550 with the error observed for ATM. These errors and their impact are discussed further in Section 5.

551

552 4.3. Area integrated error estimation

553 Area integrated error for each drainage region, based on the outlines from Zwally et al. (2012) (shown in Figure
554 1), are estimated loosely following the approach of Nilsson et al. (2016). The total area integrated error is divided
555 into three main components: the systematic bias, the random error and the rate error estimated in the fitting
556 procedure. These are then combined in quadrature to produce the total error according to:

557

$$\sigma_{tot}^2 = \sigma_s^2 + \frac{\sigma_r^2}{n} + \frac{\sigma_{\dot{h}}^2}{n-k} \quad (6)$$

558

559 where σ_s is the systematic bias, σ_r the random error, $\sigma_{\dot{h}}$ the rate error, n is the number of uncorrelated elevation
560 change estimates (see below) and k is the degrees of freedom in the least squares model ($k = 2$). The systematic
561 bias and the random error are taken as the average and standard deviation of the difference in rate between the
562 JPL (this study) and ICESat-ICESat-2 (Smith et al. 2020) products for the 2003-2019 period. We compute the
563 error in the estimated rate using the variance-covariance matrix in the least square fitting procedure according to:

564

$$\sigma_{\dot{h}}^2 = \bar{\sigma}_m^2 \cdot \text{diag}[(X^T X)^{-1}]_{\dot{h}} \quad (7)$$

565

566 where $\bar{\sigma}_m$ is the average monthly uncertainty from our product inside the time interval of interest, X is the design
567 matrix of the linear model, X^T is the transpose of the design matrix, diag the diagonal elements of the array and
568 $()^{-1}$ the inverse of the dot products. The subscript \dot{h} is the location of the rate error in the diagonal array. To
569 account for spatial autocorrelation σ_r and $\sigma_{\dot{h}}$ are divided by n . n is estimated by dividing the total area of each
570 drainage region with the correlation area: $n = A/\pi\rho^2$ where A is the area of the region and ρ is the correlation
571 length. The errors for each drainage region are summarized in Table 2. The intrinsic quality of each mission was
572 determined through internal crossover analysis (Section 4.1) of each mode and mission and is summarized in
573 Table 1 and Fig. 6. Analyzing the correlation length of the laser-only versus JPL elevation change differences we
574 find an ice sheet wide correlation length-scale on the order of 20-100 km. To be conservative, a correlation length
575 of 100 km was used to compute n .

576

577 Table 2. Regionally averaged errors for the synthesized JPL record of elevation change, computed relative to the
578 unbiased ICESat to ICESat-2 estimate of Smith et al (2020). Errors were determined by differencing 2003-2019
579 linear rates of elevation change between products. The bias (mean $-\sigma_s$) and error (standard deviation $-\sigma_r$) are
580 computed for each drainage basin (1-27: Figure 1). Antarctic Ice Sheet (AIS), Antarctic Peninsula (AP), West
581 Antarctic Ice Sheet (WAIS) and East Antarctic Ice Sheet (EAIS) statistics are determined using area weighted
582 averages.
583

Region	Bias (mm a ⁻¹)	Error (mm a ⁻¹)	Area (km ²)	Corr. length (km)

584 5 Results

585 5.1 Accuracy of synthesis

586 Previous studies have relied on near co-incident airborne measurements to validate land ice elevation changes
587 derived from multi-mission synthesis (McMillan et al., 2014; Nilsson et al., 2016; Simonsen and Sørensen, 2017;
588 Wouters et al., 2015). This approach, however, is limited in both the spatial and temporal coverage. For Antarctica,
589 airborne validation data has been collected during austral summer, mostly over rapidly thinning glaciers, such as
590 Pine Island and Thwaites, in the Western part of the ice sheet, with significant spatial coverage starting in 2002.
591 The derived errors from these local comparisons are then extrapolated to the entire ice sheet, into regions
592 exhibiting very different surface and metrological conditions. With the launch of ICESat-2 in September 2018 we
593 now have, for the first time, the ability to compare long-term unbiased laser derived rates of elevation change on
594 a continental scale. For this analysis we compare our synthesized rates of elevation change to those estimated by
595 Smith et al. (2020) for the period 2003-2019 for each basin (Zwally et al., 2012) (Figure 1). The results of this
596 analysis are summarized in Table 2. We find an ice sheet wide error of $-0.8 \pm 7.8 \text{ mm a}^{-1}$ (Figure 7e) with a
597 quadratic and linear increase as a function of surface slope in the systematic bias and random error, respectively
598 (Figure 7f-g). To determine the validity of this comparison we also compared ICESat /-2 rates with rates from
599 ATM over the time period 2003-2018. Good agreement was found between the two datasets with an average
600 difference $2.3 \pm 22 \text{ cm a}^{-1}$ (Figure 7c) over regions with an observed rate of elevation change from ATM ranging
601 from -15 to 2 m a^{-1} . The main discrepancies between our product and the ICESat /-2 derived elevation change
602 are concentrated over areas of high-relief and over regions with large magnitude changes, such as Pine Island and
603 Thwaites glaciers (Figure 7a). Here, differences larger than 10 cm a^{-1} can be found, and for the main trunk of Pine
604 Island glacier we find a difference of $2 \pm 10 \text{ cm a}^{-1}$ (Figure 7a). The magnitude of the ATM error compared to
605 ICESat /-2 product is larger. This is mostly due to the fact that the data comparison locations are in areas of rapid
606 change. The correlation between the two laser datasets and our product is greater than 0.8 in both cases.

607
 608 Figure 7. Elevation change validation and comparison using rates derived from ICESat - ICESat-2 and airborne
 609 ATM data over the time period of 2003-2019 and 2001-2019, respectively. (a) shows the spatial distribution of
 610 the elevation change differences from this study (JPL) differenced with rates derived from Smith et al. (2020). (b)
 611 shows the comparison of rates derived from JPL with ATM at locations indicated in (d) with green flight lines.
 612 (c) shows the comparison between ICESat - ICESat-2 derived rates with ATM. (e) depicts the ice sheet wide
 613 histogram of elevation change differences. (b,c,e) include the distribution mean (μ), standard deviation (σ),
 614 correlation (ρ), and number of observations (n). (f-g) the bias (mean) and error (standard deviation) as a function
 615 of surface slope for the JPL - ICESAT-1/2 validation.

616
 617 The relative precision of the different satellite altimeters used in this study range from 5-40 cm over low slope
 618 surfaces (Table 1 and Figure 6). Earlier missions such as Geosat, ERS-1 and ERS-2 are roughly three times less
 619 precise than later missions (Envisat, ICESat/2 and CryoSat-2). However, it was also found that the ERS-1/2 ocean
 620 mode was $\sim 30\%$ more precise than ice mode data, bringing it closely in line with the later missions. Unfortunately,
 621 the data coverage of the ocean mode is far lower than the ice mode. For CryoSat-2, the lower relative precision
 622 of the SARIn mode can be attributed to the spatial coverage, with SARIn operating over rougher terrain compared
 623 to the LRM mode that operates over the interior of the ice sheet with a higher along-track resolution (i.e., smaller
 624 footprint). Similar effects were also seen in Schröder et al. (2019). The laser altimetry missions show the lowest
 625 noise levels, on the order of 5 cm over flat areas ranging up to 20 cm for slopes $< 0.8^\circ$, with ICESat-2 showing a
 626 factor-of-two improvement in precision over its predecessor (ICESat) over all surface slopes.

627 5.7 Comparison to other studies and datasets

628 Previous long-term Antarctic Ice Sheet elevation change products have been produced by Dresden University of
629 Technology (Schröder et al., 2019: TUD) and the Centre for Polar Observation & Modelling (Shepherd et al.,
630 2019: CPOM). These products vary in both resolution and processing methodologies. The TUD product is
631 provided at a spatial resolution of 10 km and as monthly elevation change estimates. In contrast, the CPOM
632 product provides elevation change estimates every 5-years at 5 km resolution and basin wide time series of mass
633 change at quarterly resolution. The TUD dataset is comprised of Seasat, Geosat, ERS-1/2, Envisat and CryoSat-
634 2, while CPOM consists of data from ERS-1/2, Envisat and CryoSat-2. To allow for a fair comparison between
635 the different products we used our provided product without hypsometric extrapolation for the analysis.

636
637 The errors reported for our elevation change synthesis are slightly larger than those reported by TUD; this is due
638 to the difference in retracking and the fitting procedure used to derive the error estimates. Comparing all three
639 data products to the ATM validation data we find the best agreement with the JPL synthesis. (JPL: 4 ± 19 cm a⁻¹,
640 TUD: 6 ± 20 and CPOM: $+4 \pm 53$ to -16 ± 61 cm a⁻¹). The JPL and TUD estimates were computed from the same
641 ATM dataset and given the same editing criteria, while values from CPOM are the reported values from Shepherd
642 et al. (2019). Applying the same analysis to the 2007-2011 and 2011-2016 elevation change solutions provided
643 by CPOM, we found values of 29 ± 41 cm a⁻¹ (2007-2011) and -8 ± 30 cm a⁻¹ (2011-2016) for the comparison
644 with ATM, and a weighted average of -2.2 ± 33 cm a⁻¹ comparing data from overlapping locations. To further
645 compare the noise level in the different datasets we use the elevation change from the common 1992-2016 time
646 period (as CPOM only provides rates in five-year intervals) of all products and compare against ICESat-ICESat-
647 2 elevation change rate from 2003-2019. To reduce the impact of difference in time span, we initially compare
648 only to data between 81.5° and 90° S (pole hole), as this spatial domain only contains ICESat and CryoSat-2
649 measurements and is thus the most closely aligned in time with the ICESat-ICESat-2 estimate. We also perform
650 an ice sheet wide analysis, though the time spans are not identical. To compute the noise level, we simply
651 difference the three rate fields with the ICESat-ICESat-2 derived rates and computed the average and standard
652 deviation of the differences. This provided the following ice sheet wide results: -0.32 ± 1.70 (JPL), -0.45 ± 1.92
653 (TUD) and -0.33 ± 2.59 (CPOM) cm a⁻¹. For the pole-hole region, 81.5° and 86° S, the following results were
654 obtained: -0.33 ± 1.17 (JPL), -1.37 ± 1.57 (TUD) and -1.90 ± 3.15 (CPOM).

655
656 Comparing the long-term rates for the overlapping time period 1992-2016, we find an overall good agreement for
657 the three original products. Comparing only values North of 81.5° S, we determine volume change rates of -58, -
658 48 and -59 km³ a⁻¹ for JPL, TUD and CPOM, respectively. Differences are well within the errors for all the three
659 products. Studying the differences in spatial patterns (Figure 8), using the JPL derived rate as the reference, we
660 find that the TUD and JPL products agree well over East Antarctica in Basins 10-17 while a larger difference can
661 be seen in Basin 3 closer to the Weddell Sea. Larger differences between JPL and CPOM compared to JPL versus
662 TUD can be observed in East Antarctica (EAIS). This is likely a result of different methodologies for correcting
663 changes in the radar scattering. Dividing the estimates into different regions we find the following volume change
664 estimates for the 1992-2017 period: WAIS (JPL: -108, TUD: -100 and CPOM: -106 km³ a⁻¹), EAIS (JPL: 61,
665 TUD: 48 and CPOM: 43 km³ a⁻¹) and AP (JPL: -11, TUD: 4 and CPOM: 5 km³ a⁻¹). The regional estimates agree

666 well among products, with the largest discrepancies found in the Antarctic Peninsula. Here, both the TUD and
 667 CPOM products provide a positive volume change compared to the JPL-product, highlighting the challenge in
 668 obtaining accurate estimates from this region. Comparing the JPL and TUD products with rates from Smith et al.
 669 (2020) (ICESat/-2) over the time period 2003-2017 (again using the original JPL product with no hypsometric
 670 extrapolation) we find that the two products agree well over WAIS (JPL: -165, TUD: -164, LA: -200 km³ a⁻¹), but
 671 lower in magnitude compared to ICESat/-2 due to the larger radar footprint. For EAIS (JPL: 83, TUD: 51, LA:
 672 85 km³ a⁻¹) a disagreement of roughly 40% is observed between the TUD and JPL products, where LA and JPL
 673 values are practically identical. In the AP (JPL: -19, TUD: -7, LA: -39 km³ a⁻¹) both products are lower in
 674 magnitude compared to ICESat/-2, on the order of 50-80% due to limitations in measuring over high relief
 675 topography.
 676

677
 678 Figure 8: Comparison of overlapping long-term rates from the Technical University of Dresden (TUD) and Center
 679 for Polar Observation and Modelling (CPOM) altimetry product with rates from this study (JPL).
 680

681 To understand how well these products can capture (and provide insight into) the change/variability of physical
 682 processes of the ice sheets, we compared our result with modeled changes in surface elevations (“zs”) from the
 683 IMAU firm densification model (FDM: Ligtenberg et al. (2012)) that is forced by 6 hour mass balance components
 684 (snowfall, rain, sublimation and snowmelt), average surface temperature, and 10 m windspeed, from the Regional
 685 Atmospheric Climate Model, version 2.3p2 (van Wessem et al., 2018). The firm model only simulates changes in
 686 surface elevation due to changes in surface processes and does not account for thinning or thickening resulting
 687 from changes in ice dynamics (flow). To minimize dynamic signals, we mask areas with surface velocities larger
 688 than 30 m a⁻¹ using the velocity field provided by the ITS_LIVE project (Gardner et al., 2018) merged with Phase-
 689 Based estimates (Mouginot et al., 2019). The surface elevation long-term trend and acceleration fields (1992-
 690 2016), seen in Fig. 9, show that for Dronning Maud Land and Enderby Land (Basins 4-11) there is generally good
 691 agreement in both the spatial pattern and the sign of the observed and modelled rate of elevation change. For these
 692 regions, the observed change can be attributed to an increase in accumulation (Boening et al., 2012). However,

693 the magnitude between the modelled and measured rates of change differs by roughly 50%. The altimetry derived
 694 volume change for basins 4-11, over the time period 1992-2016, is estimated at $46 \text{ km}^3 \text{ a}^{-1}$ compared to a modelled
 695 change of $27 \text{ km}^3 \text{ a}^{-1}$. This disagreement becomes even more prominent for Wilkes Land (basins 12-14) where the
 696 difference between modelled and observed rates of change are larger and of opposite signs (Figure 9). For these
 697 three basins, the estimated difference in volume change is on the order of $36 \text{ km}^3 \text{ a}^{-1}$ based on the difference in the
 698 modelled change of $-25 \text{ km}^3 \text{ a}^{-1}$ compared to $11 \text{ km}^3 \text{ a}^{-1}$ from altimetry. The magnitude and sign of these results
 699 are consistent within all three altimetry products compared to the FDM. Further, comparing the differences in the
 700 magnitude of the seasonal amplitude for 1992-2016, we find that the TUD product has an annual amplitude that
 701 is $\sim 50\%$ larger than the JPL product (5.1 ± 15 versus 2.7 ± 4.9 cm). Our estimated value of 2.7 ± 4.9 cm compares
 702 well with the 2.9 ± 4.1 cm average FDM amplitude for the period 1992-2016. This analysis was not applied to the
 703 CPOM product as their provided basin time series are in units of mass, after a firm correction has been applied.

704
 705 Figure 9: Spatial fields of rates (left column), acceleration (middle column) and seasonal amplitudes (right
 706 column) from our product (JPL: top row) and modelled values from the IMAU firm densification model (FDM:
 707 bottom row). Areas of fast flow ($>30 \text{ m a}^{-1}$) have been masked out to minimize heigh changes caused by changes
 708 in ice flow. The altimetry data has been smoothed with a 50 km median filter to highlight large scale spatial
 709 patterns.

710
 711
 712

713 **5.8 Basin-scale time-evolving volume change**

714 Analyzing the 1992-2020 record of surface elevation (Table 3 and Figure 10-11), including the area between 81.5°
715 and 90° S, we determine an average rate of volume change of $-68 \pm 11 \text{ km}^3 \text{ a}^{-1}$ over the entire ice sheet, with large
716 losses from the West Antarctic Ice sheet (WAIS: $-113 \pm 6 \text{ km}^3 \text{ a}^{-1}$), and gains for East Antarctic Ice Sheet (EAIS:
717 $+75 \pm 5 \text{ km}^3 \text{ a}^{-1}$) which experienced large snow-fall events in 2009 and 2011 (Boening et al., 2012). The Antarctic
718 Peninsula (AP) is the most challenging region to measure elevation change, due to its extreme surface relief and
719 sparse data coverage. We anticipate that any estimate derived from conventional satellite radar altimetry will be
720 biased positive due to the inability to measure low elevation signals. That said, we estimate an overall negative
721 trend for the AP of $-27 \pm 8 \text{ km}^3 \text{ a}^{-1}$ for the 29-year record (1992-2020) (Figure 10-11) that align closely with other
722 estimates (Groh et al., 2021; Rignot et al., 2019; Shepherd et al., 2018; Zwally et al., 2021), but is highly dependent
723 on the applied hypsometric extrapolation (Section 3.2.5). On decadal time scales we find that the large glaciers
724 systems of Pine Island, Thwaites, Smith and Kohler (Basins 21 and 22) show relatively stable mass loss since the
725 early parts of the satellite era, with signs of accelerated thinning since 2007-2009 (Figure 11). WAIS has seen
726 almost a doubling of its mass loss in the last decade (2011-2020) compared to the two previous decades (Figure
727 11). EAIS has reverted back to its previous long-term decadal rate of $\sim +8 \text{ km}^3 \text{ a}^{-1}$, in line with the observed 5-
728 year trend from Geosat over Dronning Maud Land (Figure 11,12), down from $+84 \text{ km}^3 \text{ a}^{-1}$ following the anomalous
729 snow-fall during the 2001-2011 period. AP was in balance and saw little observable change in the first decade
730 (1991-2010), but increased its mass-loss by a factor of ten in the period of 2001-2011. The mass loss in the last
731 decade was slowed by roughly 50% due to a positive mass balance anomaly during the period 2016-2018. Over
732 the Geosat time period from 1985 to 1989, and for latitudes $< 72^\circ \text{ S}$, a general stable and small positive rate of 6
733 $\pm 16 \text{ km}^3 \text{ a}^{-1}$ was found for the EA1 region (Basins 4-11, Figure 12). This rate remained stable between 1985 and
734 2009 ($\sim 10 \text{ km}^3 \text{ a}^{-1}$) until the onset of a precipitation event in 2009. For the EA2 region (Basins 12-15, Figure 1) a
735 shift in both sign and magnitude was observed for the 1985-1989 period compared to the long-term positive rate
736 for EA1. The mass loss over the 1985-1989 period was $-70 \pm 22 \text{ km}^3 \text{ a}^{-1}$, and found to be mostly driven by the
737 Totten glacier system in Basin 13 (Figure 10). This rate is based, however, on heavy extrapolation over the Totten
738 region, due to poor data coverage for the last two years of the mission, and should be treated with caution. Trends
739 for EA2 showed a stable negative rate (~ -25 - $30 \text{ km}^3 \text{ a}^{-1}$) until 2001-2003 when a large positive change occurred
740 due to an increase in SMB (Figure 10c). The region reverted back to long-term negative trend after 2006 mostly
741 modulated by changes in SMB.

 758 Figure 10. Rates of Antarctic Ice Sheet elevation change. Elevation change rate (a) and acceleration (b) for the
 759 1992-2020 period and average rates for (c) 3-year, (d) ICESat – ICESat-2 and (d) 10-year intervals. (*) indicates
 760 a five-year interval for Geosat.

761
 762 Regionally, concentrated rates of thinning from accelerated glacier flow (Gardner et al., 2018; Rignot et al., 2019)
 763 are found to spread inland over time due to a regional dynamic imbalance (Shepherd et al., 2019). The marginal
 764 areas surrounding the Getz ice shelf (Basin 20) also exhibit negative rates of elevation change but are more
 765 localized to the narrow glacier outlets due to inland topographic barriers and time since initiation of thinning
 766 (Figure 10-11). This area saw a large break in the overall long-term trend around 2010 when rapid onset thinning
 767 was observed and attributed to short-term variations in both the surface mass balance and ice dynamics (Chuter
 768 et al., 2017; Schröder et al., 2019; Gardner et al., 2018). Basin 18, which contains the Kamb Ice Stream,
 769 experienced a relatively steady gain in volume over the last three decades resulting from the stagnation of the
 770 Kamb Ice Stream some 200 years prior (Catania et al., 2006) (Figure 10-11). Totten Glacier (Basin 13), part of
 771 the EAIS, has been losing mass since the late 1970's (Schröder et al., 2019) with the average trend mostly governed
 772 by ice dynamics and short-term variability and acceleration driven by changes in precipitation (Li et al., 2016). A
 773 major change in trend was observed in 2010 when a large-scale thinning of the entire is observed, likely in
 774 response to a change in precipitation and possibly changes ice dynamic driven by changes in ocean conditions
 775 (Khazendar et al., 2013; Li et al., 2016). The activation or reversal in trend of both the Totten and Denman glaciers
 776 in early 2009-2010 has disrupted the long-term equilibrium or gain that has been observed for most parts of Wilkes
 777 Land (Basins 12 and 13, Figure 1). A departure from the long-term trend can now be observed for large parts of
 778 Wilkes Land in the form of large-scale negative acceleration spreading inland (Figure 10). In Dronning Maud

779 Land and Enderby Land (Basins 5-8), the previously mentioned snow-fall events in 2009 and 2011 (Boening et
780 al., 2012) are clearly observed in the regional elevation change trends. This pattern is most prominent along the
781 Weddell Sea coast where the accumulation signal, in the form of precipitation, shows an earlier event in 2006
782 (Basins 3 and 4) (Figure 10 and 11). The glaciers flowing into the Bellingshausen Sea have shown a complex
783 pattern of change over the last 29 years. Here, Palmer Land (Basin 24) shows a steady increase in surface elevation
784 over the initial 15 years of the record, following a long-term positive anomaly in precipitation from 1992.
785 However, a reversal in this pattern was observed around 2007 where patterns of thinning (McMillan et al., 2014;
786 Schröder et al., 2019; Shepherd et al., 2019; Wouters et al., 2015) (Figure 10) can be observed localized to the
787 major low-elevation outlet glaciers in the regions. The change can be largely attributed to a change in precipitation
788 amount, with lesser contributions from changes in ice dynamics resulting from enhanced melting by the ocean
789 (Gardner et al., 2018; Hogg et al., 2017). However, in the southern part of the Bellingshausen Sea, near Ferrigno
790 glacier in Basin 23, we find a relatively stable trend during most of the record until 2009 when a large acceleration
791 in ice loss can be observed. This acceleration can only be partially attributed to changes in ice dynamics (Gardner
792 et al., 2018; Wouters et al., 2015) and it is likely that changes in precipitation is the major driver of change. Large
793 changes in both spatial and temporal variability can be observed in the AP region in the last three decades, where
794 large scale reversals of signals can be observed over different time periods. Here, we find a large-scale positive
795 elevation change anomaly in Basin 23-26, superimposed on a long-term negative trend, over the time periods
796 1998-2000, 2004-2006 and 2016-2018. These changes are linked to changes in the short-term variability of SMB
797 in the region due to increased precipitation. Examining the rates derived over the ICESat-2 time period (2018-
798 2020) a large positive elevation change signal can be observed over the WAIS region, in contrast to the overall
799 negative long-term trend. This anomaly is directly linked to large scale snow-accumulation, resulting from an
800 extreme precipitation event in the austral winter of 2019 which has been attributed to the landfall of atmospheric
801 rivers (Adusumilli et al., 2021).

Figure 11. Basin (Zwally et al., 2012) and ice sheet monthly elevation change time series for the period of 1992 to 2020.

808 **6 Discussion**

809 We provide a new elevation change product for the Antarctic Ice Sheet that synthesizes over three decades of data
810 from seven different satellite altimeters. To do this we applied slope corrections to all pulse-limited radar altimetry
811 datasets, substantially reducing the overall error in both measured elevation and elevation change rates as can be
812 seen in the crossover quality analysis. Our methodology explicitly separates the time-variable and the static
813 topography in the inversion for elevation change and is one of the major improvements over previous studies
814 (Flament et al., 2012; McMillan et al., 2014; Moholdt et al., 2010). Removing the time-invariant topography from
815 the time-variable elevation allowed us to more easily accommodate varying spatial scales of correlation inherent
816 to the different processes affecting the altimetry retrievals of elevation. This can be conceptualized by noting that
817 correlation lengths are less than <10 km for the time-invariant topography, while elevation change signal are
818 correlated at length scales greater than 50 km in some places. We performed extensive testing over Lake Vostok
819 in East Antarctica and concluded that the optimum search radius for estimating time-invariant topography was
820 500 m for repeat track missions and 1000 m for drifting-track missions. An extensive investigation was also
821 undertaken to determine the optimum radius for maximizing correlation between the waveform parameters and
822 the time-variable elevation change. From this analysis it was determined that a 1000 m search radius provided the
823 best results in both minimizing the trend and RMS of the residuals. Both spatial and temporal patterns of changes
824 in the scattering horizon (penetration depth) (Figure 2 and 3) of the radar signal further highlights the importance
825 of this correction, which can reach magnitudes of several cm a^{-1} (Figure 3). This correction also has a significant
826 impact on the magnitude of the seasonal signal at continent wide scales and can produce reduction of upwards of
827 50% in the seasonal amplitude of the elevation change signal (Figure 3 and 5).

828
829 Cross-calibration of the different missions is likely the most challenging barrier to generating a continuous and
830 accurate record of elevation change. In this study we have taken a somewhat different approach to Schröder et al.
831 (2019) and Shepherd et al. (2019). Here, we work entirely in residual space, after the removal of time-invariant
832 topography. We first apply a least-squares approach to provide an initial inter-mission adjustment. This
833 adjustment is mainly to align overlapping data and modes such as ICESat and Envisat. The approach also has
834 advantages of removing long-term trends and seasonality, allowing us to estimate any remaining offset by
835 examining the residuals to the least-squares model. We find here that the Envisat and CryoSat-2 transition is
836 troublesome, as only a few months of data overlap exist due to the later change in orbit of the Envisat mission and
837 the large ice sheet-wide changes that occur around this transition. To overcome the sampling problem and the
838 variable elevation change behavior observed for different locations, we investigated several methods to estimate
839 Envisat/CryoSat-2 offsets. Given the availability of high-accuracy ICESat and ICESat-2 elevation change rates
840 we were able to determine which offset provided the most appropriate trend compared to the laser altimetry
841 reference. One should note that we do not use the laser altimetry data to scale or generate the offset, its merely an
842 independent guide to select the most suitable offset produced from the different alignment approaches. This
843 method provides volume changes that are well in line with both the CPOM and TUD products, which provides us
844 with confidence in our approach. Further, it is unfortunate that Envisat changes orbit in late 2010 as it would have
845 allowed almost 2 years of overlap with CryoSat-2. Hopefully this data can be included in the future versions once
846 the issue of how to satisfactorily handle the change in orbit can be addressed. This work is currently being
847 undertaken. As of now, including post orbit change data in the synthesis has the effect of introducing noise in the

848 Envisat time series and spurious offsets, severely limiting the use of the data. For the Geosat data we include a
 849 caveat for the quality of the cross-calibration. A cross-calibration has been applied but the quality of this
 850 adjustment can vary due to the long gap separation between Geosat (ending in 1990) and the next altimetry mission
 851 (ERS-1: starting in 1992). We recommend that care be taken here and suggest that for regional studies that a
 852 manual post-calibration be applied. The suggestion would be to follow the approach outlined in Sect. 3.2.3 using
 853 Eq. (2) varying the degree of the polynomial until satisfactory results are obtained, as seen in Fig. 12.
 854

855
 856 Figure 12. Monthly elevation change time series for the area measured by Geosat (72° S latitude limit) for the
 857 period 1985-2020. The large difference in RMS seen in the Geosat time series for full ice sheet is mostly driven
 858 by observations collected over the Antarctic Peninsula. The regional Geosat time series were recalibrated to
 859 allow for better alignment with the long-term record, as suggested in Section 6. This as the local offset estimated
 860 at each grid-cell for Geosat might not be of sufficient quality everywhere.
 861

862 Another important altimetry correction in the processing is the amplitude normalization, using CryoSat-2 as a
 863 reference. Fig. 5 illustrates that even after applying corrections for the change in scattering horizon (e.g.,
 864 penetration bias), the different missions show inconsistent seasonal amplitudes with the older pulse-limited
 865 mission that have seasonal amplitudes that are more than twice that of newer missions (e.g., Envisat, CryoSat-2,
 866 and ICESat/2). This is most likely linked to the higher level of noise in the older sensors (~ 30 cm vs ~ 10 cm). The
 867 larger noise levels make it difficult to separate the change in a shifting scattering horizon with time-invariant
 868 topography. Hence, there is need to normalize the different seasonal amplitudes over the different missions, as
 869 there is no physical justification for why they should differ. Here we found that both the ICESat and CryoSat-2
 870 mission showed remarkable good agreement in seasonal amplitude with surface elevation change simulated by
 871 the RACMO firn densification model (Ligtenberg et al., 2012). In the end we selected CryoSat-2 as the reference,

872 as it provides both higher spatial and temporal sampling compared to ICESat. ICESat-2 was not considered as we
873 believe that the record currently is too short (only 2 years was used in this study) to provide a viable estimate of
874 seasonal climatology. It should be noted that this correction removes the mean difference in amplitude between
875 missions but does not modulate the seasonal-phase or the inter-annual variability in the amplitude within a single
876 mission.

877
878 Large data gaps exist at latitudes exceeding the maximum orbital coverage; this gap is referred to as the pole hole.
879 In our product we fill the pole hole to provide a spatially complete field to aid in the estimation of ice sheet wide
880 mass balance and to make the data more usable for modeling efforts. However, we do recognize that our chosen
881 interpolation method may not be appropriate for regions such as AP and Basins 15-17, which are comprised of
882 highly variable topography. Therefore, we provide a mask layer (*data_flag*) that identifies *high quality*, *low*
883 *quality* (high topographic relief), and *pole hole* data. After some investigation we found that applying the
884 hypsometry method to extrapolating monthly estimates of elevation change produced an improved estimate of
885 basin scale volume changes when compared to the ICESat-ICESat-2 product. This methodology is not applied to
886 distributed product. We leave it up to the user of the product to apply their own methodology for extrapolation,
887 but we recommend that the hypsometric method when generating basin scale mass balance estimates.

888
889 Elevation change rates near the pole hole are relatively small, due to low precipitation amounts (Wingham et al.,
890 2006) and few dynamically active glaciers. Changes in mass within the pole hole only amount to few tens of
891 gigatons of change (Shepherd et al., 2019), once corrected for firn-air-content. Hence, the interpolation of data to
892 fill the pole hole only contributes a small part of the overall volume change. In our estimate the overall volume
893 change is estimated to be $26 \text{ km}^3 \text{ a}^{-1}$ South of 81.5° S over the full 2003-2018 time period using the least-squares
894 adjustment method and $34 \text{ km}^3 \text{ a}^{-1}$ when adding the residual cross-calibration. This aligns well with the value
895 estimated from the ICESat-ICESat-2 product of $37 \text{ km}^3 \text{ a}^{-1}$ for the area $81.5^\circ\text{-}86^\circ \text{ S}$ over the period 2003-2019.
896 Studying the other two publicly available altimetry synthesis we find that their pole-hole volume estimates are
897 biased in the negative direction (compared to the ICESat-ICESat-2 product) and can be quite large: -65 (CPOM)
898 and -12 (TUD) km^3a^{-1} . This indicates that using either a constant offset or mission-only derived trends for cross-
899 calibration might not be sufficient for these areas, as a small error can have a large impact when integrated over
900 a large region. This further points to the effectiveness of using the least-squares adjustment for cross-calibrating non-
901 overlapping records.

902
903 Previous altimetry studies of Antarctic mass balance have relied heavily on airborne laser altimetry to provide
904 validation and estimates of the overall volume change uncertainty (McMillan et al., 2014; Wouters et al., 2015).
905 However, airborne data are both limited in spatial and temporal coverage, making it extremely difficult to estimate
906 volume change uncertainties on continental scales. We, for the first time, have used long-term (16-years) unbiased
907 laser altimetry derived rates of elevation change from Smith et al. (2020) to produce ice sheet wide uncertainties
908 for our product. This is especially important for East Antarctica where very little validation data exists from either
909 in-situ or airborne campaigns. Though the rates here are on the order of cm per year, they occur over massive
910 spatial scales and contribute significantly to the overall ice sheet volume change. 16-years of high-accuracy laser
911 data allows us to validate these cm trends as the measurement error reduces as a function of time. This dataset

912 allows us to quantify and validate changes at the mm a^{-1} level, which was previously not possible in East
913 Antarctica. The overall uncertainty estimates of $-0.8 \pm 7.8 \text{ mm a}^{-1}$ is heavily dominated by the small difference in
914 the interior areas of the ice sheet, which rapidly increase closer to the coast with errors reaching 25 mm a^{-1} . In
915 general, the analysis shows that radar altimeters underperform, relative to laser altimeters, in areas of steep
916 topography where change signals are largest. Further, we observe that in East Antarctica, the radar record in many
917 places produces small negative rates, compared to slightly positive rates from laser, indicating residual issues with
918 time-variable radar penetration biases. These issues are of course known to the scientific community (Arthern et
919 al., 2001; Davis, 1993; Lacroix et al., 2009; Legresy and Remy, 1997; Nilsson et al., 2015a) and is an area of
920 active research. However, with this new laser altimetry dataset we now have at least the possibility of quantifying
921 this type of uncertainty across nearly the entirety of the ice sheet.

922
923 Comparing the estimate from this study with the TUD (Schröder et al. 2019) and CPOM (Shepherd et al., 2019)
924 products we find good agreement over the 1992-2016 time period, with differences within the error budgets of
925 the respective products. This agreement is a good indicator that all three products provide consistent results given
926 the different processing methodologies for areas below 81.5° S . Analyzing further, we find that the main
927 difference between products is in the overall noise levels. Given the different comparisons we find that, on
928 average, our product has lower noise and agrees most closely with the laser-altimetry validation data. We attribute
929 this improvement in noise characteristics to the improved processing techniques.

930
931 Another, important improvement is the normalization of the seasonal signal across missions. Though this
932 correction is not perfect, it has lowered the magnitude of the average seasonal signal to a level comparable to the
933 simulated values of elevation change from the RACMO FDM product (Ligtenberg et al., 2012). Accurate
934 quantification of the “seasonal breathing” of the Antarctic ice sheet is important component to estimated rates of
935 snowfall. However, we do find discrepancy between the altimetric and modelled rates of change for East
936 Antarctica, with rates of change differing in places by 200% to 300% for the 1992-2016 period. We further find
937 that the direction of change can have opposite sign between modeled and observed rates, as can be seen in the
938 Wilkes Land region. This indicates that the current generation of firn densification models, though highly
939 successful in representing the main components governing ice sheet mass balance, still cannot fully capture all
940 the complex interactions driving changes in surface elevation. This of course has large implications for estimating
941 the East Antarctica mass balance as the correction for firn-air-content can be as large as 100% of the measured
942 altimetry signal in some basins (Smith et al., 2020). However, several new firn models are expected to become
943 available within the near future, which will greatly help the community to quantify both the error in these models
944 and to help improve our understanding of the processes driving the ice sheet mass balance.

951 **7 Data and code availability**

952 Data can be found at [Nilsson et al., 2021; <https://doi.org/10.5067/L3LSVDZS15ZV>]. The code and algorithm
953 used to generate the product are part of the “Cryosphere Altimetry Processing Toolkit” (captoolkit) and can be
954 found here: <https://github.com/nasa-jpl/captoolkit>

955 **8 Summary and conclusion**

956 In this study we have provided a 36-year record (1985-2020) of elevation change for the Antarctic ice sheet
957 derived from seven altimetry missions combining both laser and radar measurements. Elevation changes were
958 derived from measurements of surface elevation by first removing the time-invariant topography for each mission
959 and applying corrections for varying surface scattering characteristics that affect radar altimetry. The different
960 sensors and modes were cross-calibrated and merged into a continuous record of elevation change, using a
961 combination of interpolation and extrapolation techniques to construct a consistent spatiotemporal dataset for the
962 scientific community.

963
964 Our dataset indicates that between 1992 and the later parts of 2000’s, the Antarctic ice sheet was in near balance,
965 with modest EAIS gains equaling WAIS losses. In the later parts of the 2000’s accelerated WAIS losses outpaced
966 EAIS gains, leading to significant net decrease in ice sheet volume. This accelerated loss has been attributed to
967 increased ocean melting and changes in precipitation (Shepherd et al., 2018). East Antarctica has also seen
968 changes over the last 30 years, where large swaths of Wilkes Land are now showing accelerating negative
969 elevation change starting around the year 2010 and likely stemming from changes in precipitation/firn, and
970 possibly ice dynamics from the Denman and Totten glacier systems. The Dronning Maud Land region has started
971 to show extensive elevation gain due to significant increases in snowfall beginning around 2009. However, one
972 of the main questions still remains: is EAIS losing or gaining mass? With these long-term improved datasets, in
973 combination with accurate firn-modelling, we may soon be able to answer this question. The western parts of
974 Antarctica have seen both consistent and accelerated mass loss over the entire altimetry record dominated by the
975 glacier systems of Pine Island and Thwaites. These areas now show drawdowns for hundreds of kilometers inland,
976 and currently show no signs of slowing down. The Antarctic Peninsula also shows signals of major mass loss, but
977 the long-term accuracy of those estimates is hard to quantify due to inherent limitations of radar measurements
978 over these types of rugged terrain. We can, however, say with confidence that large changes due to a complex
979 mix of atmosphere and ocean forcing have accelerated mass loss in the Bellingshausen Sea over the length of the
980 record (Gardner et al., 2018; Hogg et al., 2017; Wouters et al., 2015). This region was relatively stable for two
981 decades but started to show a large change in behavior from its original trend in the 2008-2010 period.

982
983 It is our hope that the newly produced ITS_LIVE synthesized record of Antarctic Ice Sheet elevation change will
984 improve understanding of the underlying processes driving the patterns of elevation change, with the hope that
985 such understanding will lead to improved projections of ice sheet and sea level change.
986

987 **Competing interests**

988 The authors declare that they have no conflict of interest.

989

990 **Author contributions**

991 J.N. and A.S.G. conceptualized the study. J.N. conducted the analysis, wrote the majority of the main text and
992 made all figures. J.N., A.S.G. and F.S.P all contributed to conceptualization and algorithms development. All
993 authors contributed to the writing and editing of the manuscript.

994

995 **Financial support**

996 The authors were supported by the NASA MEaSUREs, and the NASA Cryosphere Science Program
997 (NNH16ZDA001N-ICESAT2), and the Jet Propulsion Laboratory, California Institute of Technology, through an
998 agreement with the National Aeronautics and Space Administration.

999 **Acknowledgements**

1000 The authors were supported by the ITS_LIVE project awarded through NASA MEaSUREs program, and the
1001 NASA Cryosphere program through participation in the ICESat-2 science team. We thank the NASA and the
1002 European Space Agency (ESA) for distributing their radar altimetry data. The author would like to thank Sebastian
1003 Bjerregaard Simonsen for the discussions and data support during the early part of the study, it was immensely
1004 helpful. Further, we would also like to thank Ludwig Schröder for his help with obtaining the Geosat, data and
1005 Veit Helm and the anonymous reviewer for their helpful comments which greatly improved the manuscript. The
1006 research described in this paper was carried out at the Jet Propulsion Laboratory, California Institute of
1007 Technology, under a contract with NASA.
