## 6 Abstract

7 Using data collected by the Hyperspectral Imager for the Coastal Ocean (HICO) on the International Space Station  
8 between 2010 – 2014, hyperspectral reflectance of various floating matters in global oceans and lakes are derived for  
9 the spectral range of 400 – 800 nm. Specifically, the entire HICO archive of 9,411 scenes is first visually inspected to  
10 identify suspicious image slicks. Then, a nearest-neighboring atmospheric correction is used to derive surface  
11 reflectance of slick pixels. Finally, a spectral unmixing scheme is used to derive the reflectance spectra of floating  
12 matters. Analysis of the spectral shapes of these various floating matters (macroalgae, microalgae, organic particles,  
13 whitecaps) through the use of a Spectral Angle Mapper (SAM) index indicates that they can mostly be distinguished  
14 from each other without the need of ancillary information. Such reflectance spectra from the consistent 90-m resolution  
15 HICO observations are expected to provide spectral endmembers to differentiate and quantify the various floating  
16 matters from existing multi-band satellite sensors and future hyperspectral satellite missions such as NASA's Plankton,  
17 Aerosol, Cloud, and ocean Ecosystem (PACE) mission and Surface Biology and Geology (SBG) mission.

18

19 **Keywords:** Remote sensing, hyperspectral, HICO, OCI, PACE, SBG, floating matters, *Ulva*, *Sargassum*, *Noctiluca*,  
20 *Trichodesmium*, *Microcystis*, brine shrimp, oil slicks, whitecaps, marine debris.

## 21 1. Introduction

22 Since the debut of the first proof-of-concept Coastal Zone Color Scanner (CZCS, 1978 – 1986), satellite ocean color  
23 missions have evolved from the original goal of mapping phytoplankton biomass and primary production to many  
24 other applications. Because of improved spectral resolution and instrument sensitivity, mapping various floating  
25 matters also becomes possible (IOCCG, 2014). These floating matters range from living to non-living, including  
26 *Sargassum* macroalgae, *Ulva* macroalgae, cyanobacterium *Microcystis*, cyanobacterium *Trichodesmium*,  
27 dinoflagellate *Noctiluca*, aquatic plants, brine shrimp cysts, oil slicks, pumice rafts, [sea snots](#), marine debris, among  
28 others (Qi et al., 2020; [Hu et al., 2022](#)).

29 Currently, mapping floating matters using optical remote sensing requires the detection of a spatial anomaly using the  
30 near-infrared (NIR) bands, and then discrimination of the anomaly by comparing its spectral characteristics with  
31 known spectra of floating matters (Qi et al., 2020), or by using ancillary information (e.g., in certain regions a spatial  
32 anomaly can only be caused by a certain type of floating algae). Spectral discrimination requires the knowledge of

33 spectral [signatures](#) of various floating matters. However, despite scattered laboratory or field measurements of certain  
34 types of floating matters, hyperspectral data of these floating matters are mostly unavailable. Although medium-  
35 resolution (300-m) sensors such as the Ocean and Land Colour Imager (OLCI) has been used to show spectral  
36 variations of floating matters (Qi et al., 2020), the data are not hyperspectral, therefore certain spectral features may  
37 have been missed. [For example, various pigments \(e.g., chlorophyll-\*a\*, \*b\*, \*c\*, Fucoxanthin, Zeaxanthin, phycocyanin,](#)  
38 [carotenoid, etc.\) have been found in natural populations of microalgae \(i.e., phytoplankton, Bidigare et al., 1990;](#)  
39 [Bricaud et al., 2004\) and macroalgae \(e.g., Bell et al., 2015; Wang et al., 2018\). These pigments often have narrow](#)  
40 [absorption and reflectance features that can be missed by multi-band sensors, therefore requiring more spectral bands](#)  
41 [or hyperspectral data to perform spectroscopic analysis.](#)

## 60 2. Data and Methods

61 HICO Level-1B (calibrated radiance) data were obtained from the NASA Goddard Space Flight Center  
62 (<https://oceancolor.gsfc.nasa.gov>). [Of the total collected >10,000 scenes, 9,411 were available through this data portal.](#)  
63 [They were all](#) downloaded, and the following 4 steps were used to derive spectral reflectance of various floating  
64 matters.

Deleted: All

Deleted: scenes

65 Step 1 is to generate quick look Red-Green-Blue (RGB) and False-color RGB (FRGB) images with Rayleigh corrected  
66 reflectance ( $R_c$ , dimensionless) in three HICO bands using the same methods as in Qi et al. (2020) [and in the NOAA](#)  
67 [OCview online tool \(Mikelsons and Wang, 2018\).](#) In the FRGB images, a near-infrared (NIR) band is used to represent

77 the green channel, thus making floating matters often appear greenish due to their elevated NIR reflectance. Here,  $R_{rc}$   
78 was generated using the NASA software SeaDAS (version 7.5). Mathematically, it is derived as

$$\begin{aligned} 79 \quad R_{rc} &= (R_t - R_r) / (t \ t_o \ t_{O_2} \ t_{H_2O}), \\ 80 \quad R_t &= \pi L_t^* / F_o \cos(\theta_o), \\ 81 \quad R_r &= \pi L_r / F_o \cos(\theta_o), \end{aligned} \tag{1}$$

82 where  $L_t^*$  is the at-sensor total radiance after vicarious calibration and adjustment of two-way gaseous absorption (e.g.,  
83 Ozone),  $L_r$  is at-sensor radiance due to Rayleigh scattering,  $F_o$  is the extraterrestrial solar irradiance,  $\theta_o$  is the solar  
84 zenith angle,  $t$  is the diffuse transmittance from the image pixel to the satellite,  $t_o$  is the diffuse transmittance from the  
85 sun to the image pixel,  $t_{O_2}$  and  $t_{H_2O}$  are the two-way transmittance due to absorption by atmospheric  $O_2$  and  $H_2O$ ,  
86 respectively. For simplicity, the wavelength dependency is omitted here.

87 Step 2 is to determine image slicks through visual inspection of both RGB and FRGB images. Fig. 1a shows an FRGB  
88 image captured in the central western Atlantic, where an elongated greenish slick is identified.

89 Step 3 is to derive surface reflectance ( $R$ , dimensionless) of the slick pixels (i.e., those containing floating matters)  
90 and nearby water pixels. While the latter is straightforward because  $R$  at each pixel is a standard output of the SeaDAS  
91 software, the former is problematic because standard atmospheric correction in SeaDAS fails over floating matters  
92 due to their elevated NIR reflectance. Such elevated NIR reflectance violates the atmospheric correction assumptions  
93 (i.e., negligible reflectance in the NIR, or fixed relationships between the red and NIR wavelengths) for slick pixels.  
94 Therefore, a nearest-neighbor atmospheric correction (Hu et al., 2000) was used to estimate  $R$  of the slick pixels.  
95 Specifically, from the SeaDAS output of  $R_{rs}$ , we have

$$96 \quad R = \pi R_{rs} = (R_t - R_r - R_a) / (t \ t_o \ t_{O_2} \ t_{H_2O}), \tag{2}$$

97 where  $R_{rs}$  is the surface remote sensing reflectance ( $sr^{-1}$ ),  $R_a$  is the at-sensor aerosol reflectance (and reflectance due  
98 to aerosol-molecule interactions as well as due to sun glint and whitecaps). The difference between  $R$  and  $R_{rc}$  in Eqs.  
99 (2) and (1), respectively, is the removal of  $R_a$  in (2). Estimation of  $R_a$  at each pixel represents the “core” of any  
100 atmospheric correction scheme. The SeaDAS estimation of  $R_a$  is valid over water pixels, but not valid over the slick  
101 pixels. Therefore,  $R_a$  over water pixels was used as a surrogate to represent  $R_a$  over the nearby slick pixels, from which  
102  $R$  over slick pixels was derived. This is why such an approach is called “nearest-neighbor” atmospheric correction  
103 (Hu et al., 2000). In this context, the slick pixel is called “target”, and the nearby water pixel is called “reference”.  
104 Their surface reflectance are called  $R^T$  and  $R^R$ , respectively. Fig. 1b shows examples of  $R^T$  and  $R^R$ .

**Figure 1. Demonstration of how surface reflectance of floating matter ( $R^{FM}$ ) is derived. (a) FRGB image on 1 July 2012 showing several greenish image slicks in the Amazon River plume. The image covers a region of about 40 km  $\times$  24 km, with the “Target” (6.65914°N, 51.2395°W) and “Reference” (6.64847°N, 51.2411°W) pixels marked with a red “x” and a black “x”, respectively. (b) Their corresponding  $R^T$  and  $R^R$ , with the latter derived from SeaDAS and the former derived from a nearest-neighbor atmospheric correction. (c)  $R^{FM}$  derived from  $R^T$  and  $R^R$  using Eq. (4), with  $\chi$  being estimated to be 10%.**

The final step, Step 4, is to perform spectral unmixing of  $R^T$ . This is because floating matters often cover only a small portion a pixel (Hu, 2021a). In this step, the derived  $R^T$  from Step 3 is assumed to be a linear mixture of two endmembers: floating matter ( $R^{FM}$ ) and water ( $R^W$ ):

$$R^T = \chi R^{FM} + (1 - \chi) R^W = \chi R^{FM} + (1 - \chi) R^R \quad (3)$$

Here,  $\chi$  is the subpixel portion of floating matter which can vary between 0.0% and 100%,  $R^W$  is assumed to be  $R^R$ . Then, the final product,  $R^{FM}$ , is derived as

$$R^{FM} = R^R + (R^T - R^R) / \chi \quad (4)$$

In the right-hand side of Eq. (4), the only unknown is  $\chi$ . In practice, assuming  $R^{FM}$  at 750 nm  $\approx$  0.3 as revealed by independent measurements of floating macroalgae (Hu, L. et al., 2017; Wang et al., 2018),  $\chi$  is estimated through linear unmixing as

$$\chi = [R^T(754) - R^R(754)] / [0.3 - R^R(754)] \quad (5)$$

Here, with  $R^T(754)$  varying between  $R^R(754)$  and 0.3,  $\chi$  ranges between 0.0% and 100%. Plugging this mixing ratio into Eq. (4) will derive  $R^{FM}$ . Fig. 1c shows the example of how  $R^{FM}$  is derived from  $R^T$  and  $R^R$  of Fig. 1b once they are known from Step 3, with  $\chi$  being estimated to be 10%.

Once  $R^{FM}$  is derived, a spectral angle mapper index (SAM, Kruse et al., 1993) was used to determine whether different floating matters were spectrally different. SAM was used because it is based on spectral shape only. SAM is the angle between two spectral vectors, defined as (Kruse et al., 1993):

$$\text{SAM (degrees)} = \cos^{-1}[(\sum x_i y_i) / (\sqrt{\sum x_i^2} \sqrt{\sum y_i^2})]. \quad (6)$$

141 Here,  $x$  and  $y$  represent two spectral vectors with the  $i^{\text{th}}$  band from 1 to  $N$ . An SAM of  $0^\circ$  indicates identical spectral  
 142 shapes between  $x$  and  $y$  regardless of their difference in magnitudes, while an SAM of  $90^\circ$  indicates completely  
 143 different spectral shapes. An SAM of  $< 5^\circ$  indicates that the two spectra are very similar (Garaba and Dierssen, 2018).

### 144 3. Results: HICO reflectance spectra of floating matters

145 The approach above was applied to the visually identified image slicks to derive  $R^{\text{FM}}(\lambda)$ . These include: 1) *Sargassum*  
 146 *fluitans/natans* in the Atlantic (including the Caribbean Sea and Gulf of Mexico), 2) *Ulva prolifera* in the western  
 147 Yellow Sea (near Qingdao, China), 3) *Kelp* in South Atlantic, 4) *Trichodesmium* around Australia, in the Gulf of  
 148 Mexico and Persian Gulf, in the South Atlantic Bight, Bay of Bengal, near Hawaii and Pagan Island (middle Pacific),  
 149 5) Cyanobacteria of *Microcystis* in Taihu Lake, Lake Woods, and Lake of Victoria, 6) Red *Noctiluca scintillas* (RNS)  
 150 in the East China Sea, and coastal waters off Japan, 7) Brine shrimp cysts in the Great Salt Lake, 8) Oil slicks in the  
 151 Gulf of Mexico, 9) Whitecaps (foam) in the Arabian Sea, Caspian Sea, and Bohai Sea, 10) Ice in Lake Baykal, 11)  
 152 some unknown algae features. For convenience, they are grouped into 4 figures: Fig. 2 for macroalgae (*Sargassum*,  
 153 *Ulva*, and kelp), Fig. 3 for microalgae (*Trichodesmium*, *Microcystis*, red *Noctiluca scintillas* or RNS), Fig. 4 for organic  
 154 particles and ocean/lake bubbles, and Fig. 5 for unknown algae scums.

156 Figure 2: Surface reflectance ( $R$ , dimensionless) of macroalgae: (a) pelagic *Sargassum fluitans/natans*, (b) *Ulva prolifera*, (c)  
 157 kelp. The dashed lines in (a) and (b) denote  $R$  from water tank experiments of Wang et al. (2018) and Hu, L. et al. (2017),  
 158 respectively.

161 Figure 3. Surface reflectance ( $R$ , dimensionless) of floating scums of microalgae: (a) *Trichodesmium*, (b) *Microcystis*, (c)  
 162 red *Noctiluca* near Yangtze River of the East China Sea and in Sagami Bay of Japan. The dashed line in (a) denote field  
 163 measured  $R$  by McKinna (2010).

 191 **unknown types of algae in Taganrog Bay (note the difference from Fig. 5c) and in Japan coastal waters.**

193 Of all spectra presented in Figs. 2–4, one common feature for all floating macroalgae and microalgae (except red  
194 *Noctiluca*) is the red-edge reflectance (i.e., the sharp increase from about 670 nm to the NIR wavelengths). Such a  
195 common feature is due to both chlorophyll-*a* absorption around 670 nm and high reflectance in the red and NIR  
196 wavelengths due to macroalgae mats or microalgae scums (Kazemipour et al., 2011; Launeau et al., 2018). The lack  
197 of such a red-edge feature in some of the red *Noctiluca* reflectance spectra (Fig. 3c) is possibly due to the lack of  
198 chlorophyll-*a* pigment because red *Noctiluca* is heterotrophic (i.e., it does not contain pigments unless it feeds on other  
199 algae). Other than the common red-edge reflectance, the contrasting spectral shapes of the various types of floating  
200 macroalgae and microalgae are due to their different pigment compositions (see below). In contrast, the non-leaving  
201 floating matters do not show red-edge reflectance or other pigment-induced spectral features in the visible wavelengths  
202 (Fig. 4). In Fig. 5, in addition to pigment absorption, high scattering due to high concentrations of algae particles  
203 together with sharp increases of water absorption from the red to the NIR wavelengths lead to the local reflectance  
204 peak around 700 nm (Fig. 5) and, depending on the particle concentrations, the peak wavelength may be slightly  
205 shifted, for example from 700 to 710 nm.

## 206 4. Discussion

### 207 4.1. Uncertainties in the derived R<sup>FM</sup>

208 There are several assumptions used in the nearest-neighbor atmospheric correction and spectral unmixing (Eq. 4).  
209 Violations of these assumptions will cause errors in the derived  $R^{FM}$  spectra. For example, if the atmosphere over the  
210 floating matter pixel is different from over the nearby water, the nearest-neighbor atmospheric correction may not be  
211 applicable. In practice, however, because the target and reference pixels are very close ( $< 1$  km), such a violation is  
212 unlikely. In Step 4, the water within the FM-containing pixel is assumed to be the same as the nearby water. Because  
213 of the close proximity of the two pixels, this assumption should be valid for most cases unless the FM-containing pixel  
214 is at an ocean front where different water masses converge. The departure of  $R^{FM}(754)$  from the assumed 0.3 will also  
215 lead to errors in the estimated  $\chi$  (and therefore  $R^{FM}$ ). However, as long as  $R^W$  (i.e.,  $R^R$ ) in Eqs. (4) & (5) is  $\ll R^{FM}$ , the  
216 shape of  $R^{FM}$  is still retained, although the magnitude departs from the “truth” in proportional to the departure of  
217  $R^{FM}(754)$  from 0.3. Indeed, the condition of  $R^W \ll R^{FM}$  can be satisfied for  $\lambda > 600$  nm for most floating matters unless  
218 the water is extremely turbid. Even for turbid waters, for certain floating matters where  $R^{FM}$  is elevated at  $\lambda > 530$  nm  
219 (e.g., red *Noctiluca*, brine shrimp cysts, ice), the shape of the derived  $R^{FM}$  should still be valid for  $\lambda > 530$  nm. Indeed,  
220 when  $R^W$  is  $\ll R^{FM}$ , even a simple subtraction of  $R_w$  or TOA radiance between the target pixel and reference pixel, as  
221 demonstrated in Gower et al. (2006), may retain the spectral shapes of floating matters.

222 Another uncertainty source can come from the assumption of linear mixing between floating matters and water (Eq.  
223 (3)). For macroalgae, the linear mixing up to the reflectance saturation level has been shown in laboratory experiments  
224 (Hu. L et al., 2017; Wang et al., 2018). As long as the macroalgae stay on the very surface of water (as opposed to be  
225 submerged under the surface), this assumption should be valid not just for macroalgae but for all floating matters. For  
226 the same reason, if certain portions of kelp are submerged in water, large uncertainties may result from the linear

227 [unmixing scheme](#). Under high-wind conditions, the strong mixing may result in submerged algae (especially for  
228 microalgae), thus violating the linear mixing rule. However, the cases presented in Figs. 2 - 5 were selected very  
229 carefully to avoid high wind speed ( $> 5 \text{ m s}^{-1}$ , where wind speed was obtained from the National Centers for  
230 Environmental Prediction). Therefore, such mixing induced uncertainties are unlikely.

231 Additional uncertainties may come from the HICO radiometric calibration, which affects  $R_t$  and all derivative products.  
232 Through the use of the Marine Optical Buoy (MOBY) and other clear-water sites, HICO has been calibrated  
233 vicariously (Ibrahim et al., 2018), which resulted in significant improvements in the retrieved  $R_{rs}$  over water as  
234 compared with data without vicarious calibration. However, after the vicarious calibration, while the spectral shape  
235 of  $R_{rc}$  over water appears correct, the shape of  $\Delta R_{rc}$  over land appears to be biased low at  $\lambda > 800 \text{ nm}$ . Without vicarious  
236 calibration, the opposite is observed. This is possibly due to the non-linear effects in the detector response to incoming  
237 light, and currently there appears no reliable way to address this issue (A. Ibrahim, personal comm.). Similarly,  
238 calibration for  $\lambda < 450 \text{ nm}$  may be subject to larger errors than for  $\lambda$  between 450 and 800 nm. Therefore,  $R^{FM}$  in the  
239 range of 800 – 900 nm is omitted here, and interpretation of 400 – 450 also requires more caution. Similarly, the  
240 spectral wiggling between 700 and 800 nm (e.g., Fig. 3b) appears to come from residual errors in correcting water  
241 vapor absorption and oxygen absorption in the atmosphere. Therefore, although the spectral wiggling does not affect  
242 the overall shape of the red-edge reflectance, it may not be used for algorithm development to discriminate floating  
243 matter types.

244 Indeed, with all these possible sources of uncertainties, such HICO-derived  $R^{FM}$  can still be used for spectral  
245 discrimination of different floating matters without ambiguity, as shown below.

#### 246 4.2. Implications for spectral discrimination

247 Spectral discrimination can be performed through either visual inspection or the use of certain type of similarity index  
248 (e.g., SAM, Eq. 6). Here, results of the SAM analysis are presented in Table 1, followed by descriptions of visual  
249 inspection to interpret the spectral similarity or difference. Because nearly all floating algae show typical red edge  
250 reflectance, discrimination of different algae type is focused on wavelengths  $< 670 \text{ nm}$ . [To discriminate floating algae  
251 from non-living floating matters \(e.g., marine debris\), on the other hand, the inclusion of 670 nm is critical.](#)  
252 Furthermore, because HICO data are noisy for wavelengths  $< 450 \text{ nm}$ , the SAM calculation was restricted to 450 –  
253 670 nm from most  $R^{FM}$  spectra of Figs. 2 – 4.

254 Table 1 shows the SAM results for three types of macroalgae (*Sargassum*, *Ulva*, kelp), three types of microalgae  
255 (*Trichodesmium*, *Microcystis*, red *Nocticula scintillas* or *RNS*), and one type of organic matter (brine shrimp cysts or  
256 *BSC*). [Here, unless noted, \*Sargassum\* refers to \*Sargassum fluitans/natans\* \(dominant pelagic type in the Atlantic  
257 ocean\) and \*Ulva\* refers to \*Ulva prolifera\* \(dominant pelagic type in the Yellow Sea\).](#) For the same floating matter,  
258 if field-based  $R^{FM}$  is available, then it is used as the reference, otherwise the mean HICO-derived  $R^{FM}$  is used as the  
259 reference. For SAM between different floating matters, all HICO-derived  $R^{FM}$  from both types are used (e.g., 4  
260 *Sargassum*  $R^{FM}$  of Fig. 2a and 3 *Ulva*  $R^{FM}$  of Fig. 2b are used to calculate 12 SAM values), with their mean and  
261 standard deviations listed in Table 1.

268 Table 1. Spectral Angle Mapper values (degrees) between different floating matters for the spectral range of 450 – 670 nm,  
269 derived from the HICO-derived and field-measured spectra shown in Figs. 2-4. An SAM of 0° indicates identical spectral  
270 shape, while an SAM of 90° indicates completely different spectral shape. *Sarg*: *Sargassum fluitans/natans*; *Ulva*: *Ulva*  
271 *prolifera*; *Tricho*: *Trichodesmium*; *Micro*: *Microcystis*; *RNS*: red *Noctiluca scintillans*; *BSC*: brine shrimp cysts. Because all  
272 floating algae show similar red-edge reflectance with a reflectance trough around 670 nm, the exclusion of wavelengths of >  
273 670 nm is to reduce the similarity among different types of floating algae.

275 For each type of floating matter, HICO-derived  $R^{FM}$  is very similar to either field-measured  $R^{FM}$  or to their mean  $R^{FM}$ ,  
276 with SAM < 4.6°. In contrast, SAM between different floating matters is always > 9.9°. These results suggest that, if  
277 these floating matters represent all that can be found in natural waters, they can be differentiated through spectroscopy  
278 analysis without any other ancillary information (e.g., knowledge of local oceanography or dominant floating algae  
279 type). This is despite the possible uncertainties in their reflectance magnitude, as discussed above. In the natural  
280 environments, however, there may be other types of floating algae whose spectral shapes may be similar to *Sargassum*  
281 *fluitans/natans* (e.g., *Sargassum honeria* in the East China Sea or other brown algae) or *Ulva prolifera* (e.g., other  
282 green algae). Therefore, some form of ancillary information in addition to spectroscopy is still required in order to  
283 differentiate floating algae type.

Deleted: all these floating matters

284 The results from the SAM table can also be explained through visual inspection and interpretation of the spectral  
285 shapes, as discussed below.

Deleted: Such an observation

286 From Fig. 2, it is clear that although the three types of macroalgae all share the same red-edge reflectance in the NIR,  
287 they have different spectral shapes in the visible wavelengths. Unlike the *Ulva* reflectance with a local peak around  
288 560 nm, the spectral shapes of *Sargassum* reflectance resemble those of typical brown algae where the local reflectance  
289 trough around 625 nm is induced by chlorophyll-*c* absorption and the low reflectance below ~520 nm is due to  
290 carotenoid pigment absorption. These characteristics make it easy to distinguish *Sargassum* from *Ulva* (SAM > 27°,  
291 Table 1). On the other hand, it appears more difficult to spectrally discriminate *Sargassum* from kelp because they

Deleted:

Deleted:

Deleted: , as their reflectance peaks occur in different wavelengths in the visible

Deleted: For the same reason

Deleted:

304 both have reference peaks around 600 – 645 nm, and because they also share a common reflectance trough around  
305 625 nm. However, considering *Sargassum* is moving in the ocean while kelp is fixed in location, they can be separated  
306 using sequential images. Even from a single image, when most visible wavelengths are used, *Sargassum* and kelp can  
307 still be spectrally discriminated (SAM > 13°, Table 1). Within the group of *Sargassum* spectra (Fig. 2a), there is some  
308 variability in the magnitude between 560 – 700 nm. It is unclear what caused such variability, although it could be  
309 due to changes in carbon to chlorophyll ratio in *Sargassum* of different environment, as observed from kelp (Bell et  
310 al., 2015). Such a variability, however, would not impact the spectral discrimination of *Sargassum* against other  
311 floating matters, as SAM between *Sargassum* spectra is < 5°, much lower than between *Sargassum* and any other  
312 floating matters (Table 1).

313 Similar to the macroalgae, the microalgae scums also show elevated NIR reflectance (Fig. 3), and their spectral shapes  
314 in the visible make them straightforward to distinguish from each other (SAM > 17°), and also straightforward to  
315 distinguish from macroalgae (SAM > 9.9°). One exception may be the cyanobacterial scums (blue-green algae blooms)  
316 (Fig. 3b) as they show reflectance peak around 550 nm, similar to *Ulva* (Fig. 2b). However, reflectance around 550  
317 nm is nearly symmetric for cyanobacterial scums, but asymmetric for *Ulva*. There is also a local reflectance trough  
318 around 625 nm for cyanobacterial scums due to absorption of phycocyanin, but such a trough is lacking in the *Ulva*  
319 spectra. Such characteristic makes it possible to differentiate between the two even without *a priori* knowledge of the  
320 ocean or lake environment, as the SAM between the two groups is ~16.8° (Table 1). What's interesting is that within  
321 each class, either *Trichodesmium* or *Microcystis*, although the spectral shape is nearly identical from different spectra  
322 (SAM < 5°), there is substantial variability in the magnitude in the visible wavelengths, which might be due to changes  
323 in their carbon to chlorophyll ratios (Behrenfeld et al., 2005). Furthermore, the spectral wiggling features between 450  
324 and 660 nm in Fig. 3a are due to *Trichodesmium*-specific pigments [such as phycourobilin, phycoerythrobilin, and](#)  
325 [phyocyanin that absorb light strongly at 495, 550, and 625 nm, respectively \(Navarro Rodriguez, 1998\)](#). These  
326 features are unique to *Trichodesmium* scums, which make it straightforward to develop classification algorithms once  
327 certain spectral bands are available to capture these features [\(e.g., Hu et al., 2010\)](#).

328 Of all microalgae scums of Fig. 3, the spectral shapes of red *Noctiluca* (Fig. 3c) appear different from all others, but  
329 they show the same characteristics as reported from the limited field measurements (Van Mol et al., 2007): a sharp,  
330 featureless increase from ~520 nm to ~600 nm. This unique spectral shape makes *RNS* different from all other floating  
331 matters (SAM > 9.9°, Table 1). The difference within this group is that the spectra from Sagami Bay off Japan show  
332 reflectance troughs around 670 nm. Because red *Noctiluca* is known to feed on other algae, it is speculated that the  
333 670-nm trough is due to chlorophyll pigments of the consumed algae. Once more hyperspectral data are available in  
334 the future to test this hypothesis using field data, this characteristic may be used to study how red *Noctiluca* interacts  
335 with other algae. [On the other hand, once more hyperspectral data are available in the future, it is also possible to test](#)  
336 [whether other algae \(e.g., \*Mesodinium rubrum\*, Dierssen et al., 2015\), once forming surface scums, have similar](#)  
337 [spectral shapes as those of red \*Noctiluca\*.](#)

338 The non-algae floating matters in Fig. 4 show spectral characteristics different from both macroalgae and microalgae,  
339 for example they lack the typical red-edge reflectance of vegetation, and lack of typical spectral variations in the

Formatted: Font: Italic

340 visible wavelengths due to pigment absorption. Within this group, the organic matters of BSC (Fig. 4a) and emulsified  
341 oil (Fig. 4b) show some degrees of similarity as they also have monotonic reflectance increases from a wavelength  
342 between 500 – 560 nm to at least 740 nm. The difference between them is that BSC reflectance starts to increase  
343 always at ~560 nm with an inflection wavelength ~640 nm, while reflectance of oil emulsions start to increase at  
344 variable wavelengths without any inflection between 560 – 740 nm. Indeed, the inflection at ~640 nm appears to be a  
345 common feature between BSC slicks and coral spawn slicks (Yamano et al., 2020). In contrast, depending on the oil  
346 emulsion state, oil emulsion may have different spectral characteristics (Lu et al., 2019), suggesting that there is no  
347 fixed “endmember” spectra for oil spills.

348 The inorganic “particles” (i.e., water bubbles, ice) also have distinctive spectral shapes. The examples in Fig. 4c  
349 indicate that submersed bubbles from shipwakes are similar in spectral shapes, but all others are nearly identical in  
350 their lack of any spectral features. Rather, foams, whitecaps, and ice all show flat reflectance spectral shapes between  
351 400 – 800 nm that are consistent with *in situ* measurements of foams (Dierssen, 2019). The lack of spectral features  
352 is similar to marine debris (Garaba and Dierssen, 2020). Such a similarity will make detection of marine debris very  
353 difficult, especially around ocean fronts because these are where surface materials tend to aggregate and foams also  
354 tend to form.

355 In addition to the spectra of Figs. 2-4 that can be well recognized, HICO also showed reflectance spectra that are  
356 difficult to discriminate from spectroscopy alone, as shown in Fig. 5. Without a known reflectance library, one can  
357 only speculate what algae type could be responsible for the algae scum spectra from some ancillary information in the  
358 literature. For example, the often-reported blooms of *Lingulodinium polyedrum* and *Akashiwo sanguinea* in coastal  
359 waters off southern California and in Monterey Bay, respectively, may show spectral shapes of Fig. 5a when they are  
360 heavily concentrated in surface waters. Inference may also be made for other cases once similar ancillary information  
361 is available. Even when such information is absent, one can still rule out some possibilities simply based on the spectral  
362 shapes. For example, the reflectance spectrum in Fig. 5b from Lake Victoria cannot be from cyanobacteria that has  
363 been often reported in this lake (Fig. 3b), but it is most likely from a dinoflagellate bloom, as blooms of other algae  
364 types have also been reported in this lake (Haande et al., 2011). Likewise, the different spectra from the same Taganrog  
365 Bay in Figs. 5c & 5d suggest different algae type. Clearly, although cyanobacterial blooms have been reported in  
366 many lakes, without spectral diagnosis one cannot simply jump to the conclusion that a freshwater bloom is caused  
367 by a certain type of cyanobacterium.

### 368 4.3. Implications for current and future satellite missions

369 Because HICO is a pathfinder sensor that collected only a limited number of scenes, not all reported floating matters  
370 have been captured. For example, no HICO scene appears to have captured pumice rafts, *Sargassum horneri*, sea snots,  
371 or marine debris. Therefore, the spectral reflectance dataset presented here is incomplete. The use of data from other  
372 similar pathfinders, for example the DLR Earth Sensing Imaging Spectrometer (DESI) on the ISS (235 bands from  
373 400 – 1000 nm, 30-m resolution, 2018 – present) and the PRecursorre IperSpettrale della Missione Applicativa  
374 (PRISMA, 237 bands from 400 – 2505 nm, 30-m resolution, 2019 – present), may complement the spectral data using

Deleted: pure

Deleted:

Deleted: 0

378 the same approach (e.g., sea snot reflectance spectra, Hu et al., 2022). Even at its present form, given the large variety  
379 of floating matters presented here, the spectral data may lead to several implications for current and future satellite  
380 missions.

381 First, although all current multi-band sensors can detect floating matters through their elevated NIR reflectance (Qi et  
382 al., 2020), the Sentinel-3 Ocean and Land Colour Imager (OLCI) appears to be the best to differentiate spectral shapes  
383 in the visible wavelengths because of its 21 spectral bands between 400 and 1,020 nm, especially because of its 620-  
384 nm that can be used to differentiate whether an algae scum appears greenish or brownish, thus providing extra  
385 information to discriminate algae type in the absence of hyperspectral data.

386 Second, for the same reason, although only 4 bands (blue, green, red, NIR) are available on the PlanetScope (DOVE)  
387 constellation, the recent SuperDOVE constellation is equipped with 4 additional bands with one centered at 610 nm,  
388 thus may significantly enhance the capacity of the current high-resolution sensors (~ 3-4 m or 30 m), in differentiating  
389 greenish and brownish algae types.

390 Finally, the Ocean Color Instrument (OCI) on NASA's PACE mission, to be launched in 2023, will be the first of its  
391 kind to map global oceans with hyperspectral capacity (5 nm resolution between 340 – 890 nm, plus 7 discrete bands  
392 from 940 to 2260 nm) with a nominal resolution of 1 km. Unlike HICO, OCI will cover global oceans and lakes every  
393 1-2 days, thus providing unprecedented opportunities to detect, differentiate, and quantify various types of floating  
394 matters. The spectral reflectance data, derived from one sensor (HICO) with a stable calibration, may serve as a  
395 consistent dataset to help select the optimal bands towards future applications once PACE data becomes available, for  
396 example, through the use of SAM matrix as demonstrated in Table 1. Likewise, the SBG mission currently being  
397 planned by NASA is expected to have hyperspectral capacity between 380 and 2500 nm with a nominal resolution of  
398 30 m (Cawse-Nicholson et al., 2021); such a mission will provide unprecedented opportunity to map various floating  
399 matters on a global scale where the hyperspectral dataset developed here can help develop algorithms before its launch.

## 400 5. Conclusion

401 Through customized atmospheric correction and spectral unmixing, hyperspectral reflectance in the visible and NIR  
402 wavelengths of various floating matters have been derived from HICO measurements over global oceans and lakes.  
403 The reflectance dataset shows distinguishable spectral shapes between floating algae (macroalgae and microalgae)  
404 and non-algae floating matters (*Sargassum fluitans/natans*, *Ulva prolifera*, kelp, *Microcystis*, *Trichodesmium*, red  
405 *Noctiluca scintillas*, brine shrimp cysts), and also distinguishable spectral shapes in the visible wavelengths between  
406 different floating algae types. While the approach may be extended to other pathfinder missions to complement the  
407 findings here, the spectral reflectance dataset is expected to help select optimal bands for future hyperspectral satellite  
408 missions to differentiate and quantify the various floating matters in global oceans and lakes.
