- 14 **Abstract.** China's forests rank fifth in the world by area and cover a broad climatic
- 15 gradient from cold-temperate to tropical zones, and play a key role in the global carbon
- 16 cycle. Studies on forest soil respiration (Rs) are increasing rapidly in China over the last
- 17 two decades, but the resulting Rs data need to be summarized. Here, we compile a
- 18 comprehensive dataset database of Rs in China's undisturbed forest ecosystems from
- 19 literatures published up to December 31, 2018, including monthly Rs and the concurrently
- 20 measured soil temperature (N=8317), mean monthly Rs (N=5003), and annual Rs
- 21 (N=634). Detailed plot information was also recorded, such as geographical location,
- 22 climate factors, stand characteristics, and measurement description. We examine some
- 23 aspects of the <u>dataset</u>database Rs equations fitted with soil temperature, temperature
- sensitivity (Q_{I0}) , monthly variations and annual effluxes in cold-temperate, temperate,

subtropical and tropical zones. We hope the dataset database will be used by the science community to provide a better understanding of carbon cycle in China's forest ecosystems and reduce uncertainty in evaluating of carbon budget at the large scale. The datasetdatabase is publicly available at https://doi.pangaea.de/10.1594/PANGAEA.943617https://www.pangaea.de/tok/788910d8 d3ae0a415c7bad2e7025a3f16f042a1b (Sun et al. 2021). Keywords: Soil carbon flux, Carbon cycle, Temperature sensitivity, Forest, China

1 Introduction

Soil respiration (*Rs*) refers to the total amount of CO₂ released by undisturbed soil, including autotrophic respiration and heterotrophic respiration, the former from plant roots and their microbial symbionts, and the latter from microorganisms decomposing litter and soil organic matter. As the second-largest terrestrial carbon flux, the recent estimations of global annual *Rs* (80–98 Pg C year⁻¹) are above ten percent of the atmospheric carbon pool (750 Pg C) (Bond-Lamberty and Thomson, 2010b; Hashimoto et al., 2015; Raich et al., 2002; Warner et al., 2019), thus accelerating soil respiration rates with climate warming have a strong potential to influence atmospheric CO₂ levels. It is thus important to understand better soil respiration dynamics and response to climate changes.

Forest area in China ranks fifth in the world (FAO, 2020) and covers a broad climatic gradient, including cold-temperate, temperate, subtropical and tropical zones. In China, most *Rs* measurements began only after 2001 (Chen et al., 2010), but have rapidly increased during the last 20 years (Jian et al., 2020). Several studies have summarized

annual Rs in China's forest ecosystems, but with the small samples (e.g., N=50 in

49 Zheng et al., 2010; N=62 in Chen et al., 2008; N=120 in Zhan et al., 2012; N=139 in Song et al., 2014). Yu et al. (2010) established a geostatistical model with a total of 390 50 monthly Rs data from different ecosystems in China. With 1782 monthly Rs in forest 51 ecosystems across China, Jian et al. (2020) analyzed the spatial patterns and temporal 52 trends from 1961 to 2014. However, amounts of Rs data are still unexploited, because 53 54 they were only displayed in the forms of monthly dynamics in the original papers' figures. Rs data at a subannual timescales are important for upscaling global Rs (Jian et al., 55 2018), which may derive different conclusions and deserve further exploration (Huang 56 et al., 2020). 57 The lack of the large-scale and observation-driven Rs data is a main constraining factor 58 59 in quantifying regional- to global-scale carbon budgetbugedt (Bond-Lamberty and Thomson, 2010a; Rayner et al., 2005). Rs data and concurrently measured temperature 60 thus provide not only a solid base to understand the critical factors influencing Rs, but 61 62 the opportunity to better simulate Rs at the large scale. We attempted to compile a complete forest Rs datasetdatabase at different temporal scales in China, and analyze 63 temperature sensitivity (O_{10}) , monthly and annual Rs in cold-temperate, temperate, 64 subtropical and tropical zones. 65

2 Data and methods

2.1 Data sources

66

67

69

71

72

68 The terms of "soil respiration", "soil carbon (or CO₂) efflux", or "soil carbon (or CO₂)

emission" were searched from publications before 2018 in the China Knowledge

70 Resource Integrated Database (http://www.cnki.net/), China Science and Technology

Journal Database (http://www.sciencedirect. ScienceDirect (http://www.sciencedirect.

com/), ISI Web of Science (http://isiknowledge.com/), and Springer Link

73 (http://link.springer.com/). Means, minimums and maximums of soil respiration during

the observation periods were usually given in these published studies, and monthly patterns of soil respiration rates and the corresponding temperature were frequently shown with figures. WEBPLOTDIGITIZER, a graphic digitizing software, was used to take data from figures when values were not reported in the text (Burda et al., 2017).

The following criteria were used to ensure data consistency and accuracy: i) Rs was measured in the field without obvious disturbances or manipulation experiments, e.g. fire, cutting, nitrogen addition treatments, etc. ii) Forested swamps and commercial plantations (e.g. orchard, rubber, etc.) were not examined. iii) Rs was measured either by static chamber/gas chromatography (GC) or by dynamic chamber/infrared gas analyzers (IRGA, model Li-6400, Li-8100, Li-8150 (LI-COR Inc., Lincoln, Nebraska, USA)), which are the most popular methods and provide methodological consistency (Sun et al., 2020; Wang et al., 2011; Yang et al., 2018; Zheng et al., 2010). Moreover, the data has been carefully cross checked by the authors and from different sources. Based on these criteria, a total of 10288 monthly soil respiration data and 634 annual soil respiration data were assembled from 568 publications. The dataset covers 28 provinces in China (18.61 52.86° N, 84.91 129.08° E) (Fig. 1). Meanwhile, the related information was recorded, including geographical location (province, study site, latitude, longitude and elevation), climate (mean annual temperature and mean annual precipitation), stand description (forest type, origin, age, density, mean tree height and diameter at breast height), measurement regime (method, time, frequency, collar area, height and numbers) (Table 1). There were 155 study sites from 28 provinces in China (18.61-52.86° N, 84.91-129.08° E, 7-4200 m) (Fig. 1). This forest region encompasses a large gradient of climate regimes, mean annual temperature ranging from -5.4 to 23.8 °C and mean annual precipitation ranging from 105 to 3000 mm. The observation years were

from 2000 until 2018.

2.3 Data verification

Soil temperature as a main influencing factor, was usually concurrently measured with Rs. Monthly dynamics of Rs and soil temperature at 5 cm depth (T_s) and/or 10 cm depth (T_{10}) were shown with figures in many literatures. In this study, most of the Rs data (~82%) and the concurrent soil temperature at 5 cm depth (T_s) -and/or 10 cm depth (T_{10}) -were extracted with WEBPLOTDIGITIZER, others (e.g., minimum, maximum) were usually directly given in the original papers. To verify the accuracy of the digital software, the means (Rs, T_s, T_{10}) averaged from the extracted data were compared with the corresponding means directly given in the original papers (Fig. S1). The Root Mean Square Errors (RMSE) of Rs, T_s and T_{10} were 0.09 μ mol m⁻² s⁻¹, 0.35 °C and 0.44 °C, respectively, and the coefficients of determination (R^2) were all larger than 0.99, indicating that the accuracy of WEBPLOTDIGITIZER is excellent. Moreover, the data from the same authors and different sources (e.g. master or Ph. D. dissertation and journal article) has been carefully cross-checked and supplemented.

2.4 Monthly and annual soil respiration calculation

Long-term continuous *Rs* could be monitored with <u>infrared gas analyzers (e.g., Li-8100, Li-8150)Li-8100 or Li-8150</u>, but there are few published studies of such continuous data (Bond-Lamberty et al., 2020; Tu et al., 2015; Wu et al., 2014; Yu et al., 2011). The <u>typical days were usually selected to calculate mean monthly *Rs* and the observation frequency was 1–12 days per month—high during the growing season, but low in winter. *Rs* was measured throughout the day (16%) or at representative time, e.g., 9:00 a.m.–11:00 a.m. (45%), 9:00 a.m.–12:00 a.m. (22%), etc., which had been validated to be close to the diurnal mean value (Xu and Qi, 2001; Yan et al., 2006; Yang et al., 2018; Yao et al., 2011;</u>

123	You et al., 2013, Zheng et al., 2010). Annual son carbon emux was integrated with son
124	respiration model (i.e. integration method) or interpolated the average soil respiration rate
125	between sampling dates (i.e. interpolation method) (Shi et al., 2014). Finally, monthly Rs
126	and annual soil carbon efflux were converted to the common unit of $\mu mol~CO_2~m^{-2}~s^{-1}$
127	and g C m ⁻² year ⁻¹ , respectively (Bond-Lamberty and Thomson, 2010a).
128	2.5 Statistical analysis
129	Monthly and annual Rs were averaged arithmetically in cold-temperate, temperate,
130	subtropical and tropical zones. Independent-Samples T Tests (2 groups) and One-Way
131	ANOVA (\geq 3 groups) at the $P=0.05$ significance level were used to test the differences
132	among different forest types in the same climate zone and among the same forest type
133	in different climate zones. Temperature sensitivity (Q10) is defined as the factor by
134	which Rs is multiplied when temperature increases by 10 °C (Davidson and Janssens,
135	2006; Lloyd and Taylor, 1994), which is usually calculated with the van't Hoff equation
136	(Rs=ae $^{\beta T}$ & $Q_{1\theta}$ =e $^{10\beta}$), where Rs is soil respiration rate (µmol m $^{-2}$ s $^{-1}$), T is temperature
137	(°C). All statistical analyses were performed with SPSS Statistics 21 (SPSS Inc.,

139 3 Results

Chicago, USA).

3.1 Relationship between soil respiration rate and soil temperature

Temperature is often the main factor determining soil respiration rates. There were 6341 and 2878 The samples of the paired $Rs \& T_5$ and $Rs \& T_{10}$ were 6341 (69%) and 2878 (31%) in the dataset database, respectively. There were significantly exponential relationships of Rs with T_5 and T_{10} in forest ecosystems across China, which could explain about 48% and 52% of the Rs variations, respectively (Fig. S2). The exponential correlations were all significant in four climatic zones, and the coefficients of determination for tropical ecosystems (R^2 =0.225-0.291) were smaller than those in

148 other three zones (R²=0.51623-0.934) (Fig. 2). RMSEs in cold-temperate and 149 temperate zones (1.52-1.67 µmol m⁻² s⁻¹) were larger than those in subtropical and tropical zones (1.04–1.32 μ mol m⁻² s⁻¹), except the smallest RMSE from T_{10} in cold-150 151 temperate zone (0.42 μmol m⁻² s⁻¹). 152 Temperature sensitivity (Q10) is defined as the factor by which Rs is multiplied when temperature increases by 10 °C (Davidson and Janssons, 2006; Lloyd and Taylor, 1994). 153 154 Q_{10} could be calculated with the exponential equations between Rs and soil temperature. 155 At the national scale, the Q_{10} values in China's forest ecosystems from T_5 (-16.51– 156 33.58 °C) and T_{10} (-16.40–33.46 °C) were 2.05 and 2.17, respectively. The Q_{10} was the 157 largest in cold-temperate zone (T_5 : 3.74 & T_{10} : 3.32), secondary in temperate zone (T_5 : 2.69 & T_{10} : 3.00), and the smallest in subtropical zone (T_5 : 2.15 & T_{10} : 2.20) and 158 159 tropical zone (*T*₅: 2.28 & *T*₁₀: 1.63). 160 3.2 Monthly dynamics of soil respiration 161 Monthly Rs appeared as a single-peak curve (Fig. 3), which derived from the similar 162 years in cold-temperate (2003–2016), temperate (2002–2018), subtropical (2000–2017) and tropical zones (2003-2015). The largest values occurred in August (4.18-4.36 163 μmol m⁻² s⁻¹) in cold-temperate and temperate zones, larger than the largest values in 164 165 July (3.58–3.83 μmol m⁻² s⁻¹) in subtropical and tropical zones. The lowest values occurred in January in cold-temperate (0.20 μmol m⁻² s⁻¹), temperate (0.49 μmol m⁻² 166 s⁻¹), subtropical (1.10 μmol m⁻² s⁻¹) and tropical zones (1.62 μmol m⁻² s⁻¹). Monthly 167

Annual mean Rs in January–December from low to high was cold-temperate (1.63 μ mol m⁻² s⁻¹), temperate (1.93 μ mol m⁻² s⁻¹), subtropical (2.47 μ mol m⁻² s⁻¹) and

variations were largest in cold-temperate and temperate zones, secondary in subtropical

168

169

170

171

zone, and smallest in tropical zone.

tropical zones (2.57 μmol m⁻² s⁻¹). Meanwhile, annual soil carbon emissions were calculated with the annual mean *Rs*: 621.91 g C m⁻² yr⁻¹ in cold-temperate zone, 733.31 g C m⁻² yr⁻¹ in temperate zone, 937.15 g C m⁻² yr⁻¹ in subtropical zone, and 973.35 g C m⁻² yr⁻¹ in tropical zone. Soil carbon emissions in growing season (May–October) and winter (November–April) accounted for 85% and 15% in cold-temperate zone, 80% and 20% in temperate zone, 69% and 31% in subtropical zone, 61% and 39% in tropical zone. Subtropical and tropical zones still keep high soil respiration rates in November–April winter, which is the main source of their larger annual soil carbon emissions.

3.3 Annual soil carbon effluxes

There were 634 annual soil carbon effluxes, and most of the observations were conducted in subtropical zone (61%) and temperate zone (32%) (Fig. 4). The spanning years were 2003–2014 in cold-temperate zone, 2000–2018 in temperate zone, 2002–2017 in subtropical zone and 2003–2017 in tropical zone. Mean The annual soil carbon effluxesemission ranged from 260.10 g C m⁻² yr⁻¹ to 2058.00 g C m⁻² yr⁻¹ was 851.88 g C m⁻² yr⁻¹ in China's forest ecosystems, and the mean was 851.88±12.75 g C m⁻² yr⁻¹ ranging from 260.10 g C m⁻² yr⁻¹ to 2058.00 g C m⁻² yr⁻¹. The annual soil carbon effluxes increased with the increasing of mean annual temperature and precipitation at the national scale (Fig. S3). Mean annual soil carbon emissions in tropical, subtropical, temperate and cold-temperate zones were 1042.01±68.55, 928.91±16.68, 697.85±16.39 and 684.29±61.81 g C m⁻² yr⁻¹, respectively. The former two was significantly higher than the latter two, but the differences were not significant between tropical and subtropical zones, and between temperate and cold-temperate zones. The differences were not significant for evergreen broadleaf forest (EBF), evergreen

```
195
         needleleaf forest (ENF) and deciduous needleleaf forest (DNF) among different
196
         climate zones. Deciduous broadleaf forest (DBF) in temperate (748.59±25.18 g C m<sup>-2</sup>
         yr<sup>-1</sup>) and subtropical zones (755.41±58.26 g C m<sup>-2</sup> yr<sup>-1</sup>) was similar <del>(-750.00 g C m<sup>-2</sup></del>
197
198
         both of which were larger than that in cold-temperate zone (284.20±21.36 g C m<sup>-1</sup>), both of which were larger than that in cold-temperate zone (284.20±21.36 g C m<sup>-1</sup>)
         <sup>2</sup> yr<sup>1</sup>). Broadleaf and needleleaf mixed forestMF in subtropical zone (977.35±43.56 g
199
200
         C m<sup>-2</sup> yr<sup>-1</sup>) had significantly higher emissions than that in temperate zone
201
         (733.44±45.29 g C m<sup>-2</sup> yr<sup>-1</sup>).
202
            Evergreen forests were usually larger than deciduous ones in the same climatic zone,
203
         for example, ENF (866.98±63.74 g C m<sup>-2</sup> yr<sup>-1</sup>) and DNF (734.56±83.67 g C m<sup>-2</sup> yr<sup>-1</sup>)
         in cold-temperate zone, ENF (699.96±32.77 g C m<sup>-2</sup> yr<sup>-1</sup>) and DNF (555.15±24.19 g C
204
205
         m^{-2} yr^{-1}) in temperate zone, EBF (1073.50\pm26.44 g C m^{-2} yr^{-1}) and DBF (755.41\pm58.26
         g C m<sup>-2</sup> yr<sup>-1</sup>) in subtropical zone. Broad-leaved forests showed significantly larger
206
207
         annual fluxes than coniferous forests in temperate zone (DBF: 748.59±25.18 g C m<sup>-2</sup>
         yr<sup>-1</sup> vs. DNF: 555.15\pm24.19 g C m<sup>-2</sup> yr<sup>-1</sup>) and subtropical zone one (EBF:
208
         1073.50<u>±26.44</u> g C m<sup>-2</sup> yr<sup>-1</sup> vs. ENF: 717.50<u>±17.61</u> g C m<sup>-2</sup> yr<sup>-1</sup>). However, DNF
209
210
         (734.56±83.67 g C m<sup>-2</sup> yr<sup>-1</sup>) was larger than DBF (284.20±21.36 g C m<sup>-2</sup> yr<sup>-1</sup>) in cold-
211
         temperate zone, which was from high-latitude Great Xing'an Mountains (~51° N) and
212
         high-altitude Gongga Mountain (2800-2950 m), respectively. Additionally, bamboo
213
         is a special type in subtropical areas, exhibiting the highest soil carbon emissions
214
         (1133.55 \pm 42.74 \text{ g C m}^{-2} \text{ yr}^{-1}).
215

4 Discussion

216

4.1 Temperature sensitivity ($Q_{1\theta}$) of soil respiration

217	Q_{10} is a key parameter in modelling the effects of climate warming on soil carbon
218	release. The Q_{10} calculated with the exponential equations of T_5 and T_{10} were 2.05 and
219	2.17 at the national scale (Fig. S2), which were lower than the averaged Q_{10} from
220	different studies in the syntheses of China's forest ecosystems (T_5 : 2.28–2.51 and T_{10} :
221	2.74–3.00, Peng et al., 2009; Song et al., 2014; Xu et al., 2015; Zheng et al., 2009) and
222	global forest ecosystems (T_5 : 2.55–2.70 and T_{10} : 3.01–3.31, Wang et al., 2010 a; b).
223	Our results were close to the Q_{10} of 2 commonly used in many biogeochemical models
224	(e.g., Cox et al., 2000; Sampson et al., 2007) and the mean Q_{10} of 2.11 estimated with
225	inverse modeling in forest soils across China (Zhou et al., 2009).
226	Temperature was the most important limiting factor for soil microbial activity and
227	root growth in cold regions, thus, Rs was more sensitive to temperature changes (Lloyd
228	and Taylor, 1994; Peng et al., 2009; Zheng et al., 2009; Zheng et al., 2020). The Q_{10}
229	increased from tropical zone to cold-temperate zone in this study, and varied from 1.63
230	to 3.74. The correlations between Rs and sSoil temperature at the depth of 5 cm and 10
231	cm were lowest could only explain 29% and 23% of the Rs variations and RMSEs were
232	1.09 μmol m ⁻² s ⁻¹ and 1.13 μmol m ⁻² s ⁻¹ in tropical zone, respectively (R^2 =0.225 0.291,
233	Fig. 2d). The difference of the mean Rs between tropical moist forests (1260 g C m ⁻²
234	yr^{-1}) and tropical dry forests (673 g C m^{-2} yr^{-1}) was about 2-fold (Raich and Schlesinger,
235	1992), indicating that soil moisture might play more important roles.
236	4.2 Comparisons of monthly and annual soil carbon effluxes
237	The lowest monthly Rs occurred in January, and the largest values occurred in August
238	in cold-temperate and temperate zones and in July in subtropical and tropical zones
239	(Fig. 3). Similarly, monthly Rs of global terrestrial ecosystems reached their minima in

February and peaked in July and August (Hashimoto et al., 2015; Raich et al., 2002).

240

242 fewer in the cold-temperate and temperate zones. The Rs in winter (November–April) was usually assumed to account for 20% of the total annual Rs (Geng et al., 2017; Yang 243 244 and Wang, 2005), which was in agreement with the proportion in temperate zone, but 245 greater than 15% in cold-temperate zone. 246 Annual soil carbon emission had been synthesized in forest ecosystems across China, and the mean was 745.34 g C m⁻² yr⁻¹ (Zheng et al., 2010), 764.11 g C m⁻² yr⁻¹ (Zhan 247 et al., 2012), 917.73 g C m⁻² yr⁻¹ (Song et al., 2014) and 975.50 g C m⁻² yr⁻¹ (Chen et 248 al., 2008), and the mean of 851.88 g C m⁻² yr⁻¹ in the present study was in the mid-249 range. The mean annual Rs in China's forest ecosystems was slightly lower than the 250 mean Rs of 990.00 g C m⁻² yr⁻¹ in global forest ecosystems (Chen et al., 2010). Warner 251 252 et al. (2019) modelled global Rs and found that the smallest and greatest annual soil carbon emissions were in deciduous needleleaf forestDNF (Mean=344.10 g C m-2 yr 253 254 1) and evergreen broadleaf forestEBF (Mean=1310.47 g C m⁻² yr⁻¹), respectively. 255 Compared with the predicted annual Rs, deciduous needleleaf forest DNF in coldtemperate (Mean=734.56 g C m⁻² yr⁻¹) and temperate zones (Mean= 555.15 g C m⁻² yr 256 1) had larger values, but those of evergreen broadleaf forestEBF in subtropical 257 (Mean=1073.50 g C m⁻² yr⁻¹) and tropical zones (Mean=1065.09 g C m⁻² yr⁻¹) were 258 lower (Fig. 4). 259 260 Mean annual soil carbon emissions from 634 annual Rs and 5003 mean monthly Rs were 684.29 and 621.91 g C m⁻² yr⁻¹ in cold-temperate zone, 697.85 and 733.31 g C m⁻ 261 ² yr¹ in temperate zone, 928.91 and 937.15 g C m⁻² yr⁻¹ in subtropical zone, and 262 1042.01 and 973.35 g C m⁻² yr⁻¹ in tropical zone (Fig. 4 and Fig. 3). The differences 263 between the directly averaged annual Rs and the accumulative mean monthly Rs were 264 smallest in tropical zone (-8.24 g C m⁻² yr⁻¹), secondary in temperate zone (-35.46 g C 265 m⁻² yr⁻¹), and largest in cold-temperate and tropical zones (62.38–68.66 g C m⁻² yr⁻¹)in 266

267 four climatic zones, ranging from -8.24 g C m² yr⁴ to 68.66 g C m² yr⁴. Form Fig. 4 we could also found that the standard errors in tropical and temperate zones (~16 g C 268 269 m⁻² yr⁻¹) were smaller those in cold-temperate and tropical zones (~65 g C m⁻² yr⁻¹). 270 Mean annual soil carbon emissions in temperate, subtropical and tropical ecosystems were 745 g C m⁻² yr⁻¹, 776 g C m⁻² yr⁻¹ and 1286 g C m⁻² yr⁻¹ at the global scale, 271 272 respectively (Bond-Lamberty and Thomson, 2010a), which were comparable with our 273 results. 274 4.3 Improvements of the dataset database 275 Rs measurements were mainly from Li-8100 (47%) and Li-6400 (33%), secondary from gas chromatography (18%), and Li-8150 only accounted for 2%. The differences 276 277 of the four common measurement methods were selected, including Li-6400, Li-8100, 278 Li-8150 and gas chromatography, which had been proved to be consistent small (~10%) 279 (Wang et al., 2011; Yang et al., 2018; Zheng et al., 2010). The sample sizes of annual 280 Rs were 50–139 (Chen et al., 2008; Song et al., 2014; Zhan et al., 2012; Zheng et al, 281 2010) and 634 in the current study, and increased above 4-fold. The global soil respiration database (SRDB-V5) collected 523 undisturbed annual Rs in China's forest 282 283 ecosystems (Jian et al., 2021), but all methods were included, e.g. alkali absorption, gas chromatography and various infrared gas analyzers. Alkali absorption method 284

Jian, 2018). Additionally, we extended the <u>datasetdatabase</u> with the digital software (WEBPLOTDIGITIZER) from the monthly dynamics figures of the original papers,

could underestimate Rs (Chen et al., 2008; Jian et al., 2020). The total samples of mean

monthly Rs were 5003, which was much larger than the other datasetdatabase's

monthly samples of 1782 in China's forest ecosystems (Jian et al., 2020; Steele and

285

286

287

288

289

290

291

(WEBPLOTDIGITIZER) from the monthly dynamics figures of the original papers,

including the paired Rs & T_5 (N=6341) and Rs & T_{10} (N=2878). Predicting soil

respiration from soil temperature has gained extensive acceptance (Shi et al., 2014; Song

et al., 2014; Sun et al., 2020). These data could be used to establish the large-scale soil respiration equation and acquire the key parameters of carbon cycle. Compared with the above-mentioned monthly or annual databases, this study collected all available *Rs* data at different time scales. Fig. S4 showed the length of the individual time series from the different sites, the high frequencies were 12 months (38%), 6–7 months (20%) and 13–24 months (15%). Bamboo forests were seldom considered in the previous databases (Chen et al., 2008; Steele and Jian, 2018; Zhan et al., 2012; Zheng et al, 2010), which exhibited the highest soil carbon emissions (Mean=1133.55 g C m⁻² yr⁻¹, Fig. 4). With the area increasing at a high rate of 3.1% per year (Song et al., 2017), bamboo forests would play an important role in regional and even national carbon cycle. It's worth noting that the *Rs* studies were fewer in the regions of latitude larger than 48° (~2%) or elevation higher than 3000 m (~4%). The potentially under-represented forest types might affect the evaluation of temperature sensitivity of soil respiration and annual soil carbon emission at the regional and national scale.

5 Data availability

The soil respiration <u>datasetdatabase</u> in China's forest ecosystems used to produce the results in this study is free to the public for scientific purposes and can be downloaded at https://www.pangaea.de/tok/788910d8d3ae0a415c7bad2e7025a3f16f042a1b (Sun et al. 2021).

6 Conclusions

In this study, we <u>reviewed the Rs-related literatures and collected in situ Rs</u> measurements with common infrared gas analyzers (i.e. Li-6400, Li-8100, Li-8150) or gas chromatography to assemble a comprehensive and uniform <u>datasetdatabase</u> of China's forest ecosystems at different time scales. Besides the Rs data directly given in

the original papers, the monthly patterns of *Rs* and the concurrently measured soil temperature at 5 cm and/or 10 cm depth in the figures were digitized. Meanwhile, we have made a preliminary analysis of the data. The results showed that soil temperature could explain 22.5%–93.4% of the *Rs* variations. Temperature sensitivity (*Q10*) was about 2.05–2.17 at the national scale, increasing from 1.63 in tropical zone to 3.74 in cold-temperate zone. Monthly *Rs* showed a single-peak curve, and the largest values occurred in August (4.18–4.36 μmol m⁻² s⁻¹) in cold-temperate and temperate zones, larger than the largest values in July (3.58–3.83 μmol m⁻² s⁻¹) in subtropical and tropical zones. Mean annual soil carbon emissions decreased from tropical (1042.01 g C m⁻² yr⁻¹), subtropical (928.91 g C m⁻² yr⁻¹), temperate (697.85 g C m⁻² yr⁻¹) to cold-temperate zones (684.29 g C m⁻² yr⁻¹). This study provides basic data and scientific basis for quantitative evaluation of soil carbon emissions from forest ecosystems in China.

Author contributions. BJ designed the soil respiration <u>dataset</u>database and searched the papers until 2018. HS and BJ collected and digitized soil respiration data and compiled the associated information. HS and BJ prepared the manuscript. ZX provided many useful suggestions and reviewed the paper.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. We are grateful to the scientists who contributed their work to our-the dataset database. We thank Ben Bond-Lamberty and four anonymous reviewers for their constructive comments and improvements to this manuscript. This work was supported by the National Natural Science Foundation of China (32071592) and the National Key Research and Development Program of China (2017YFC0503906).

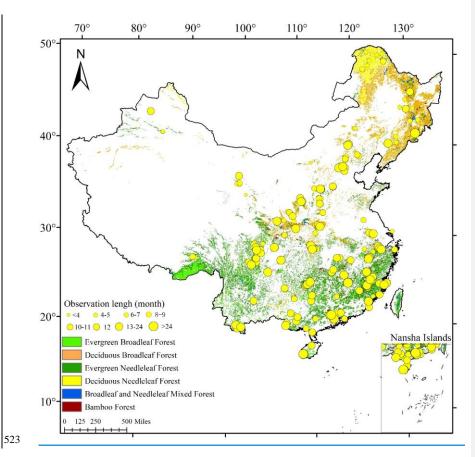

Figure 1. Distribution of study sites used to develop the forest soil respiration

datasetdatabase in China.

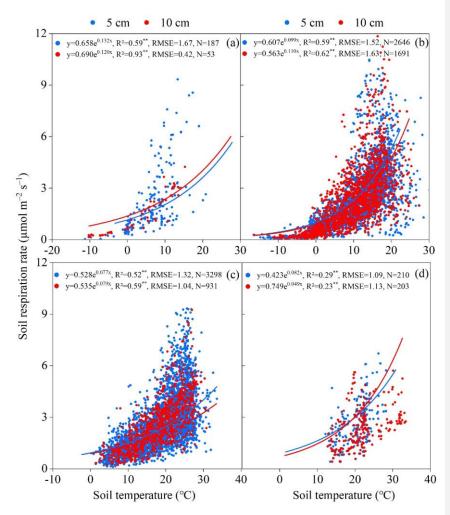

Figure 2. Exponential relationships of forest soil respiration rates with soil temperature at 5 cm depth and 10 cm depth in cold-temperate (a), temperate (b), subtropical (c) and tropical zones (d). P value below 0.01 was described by **. RMSE: Root Mean Square Error.

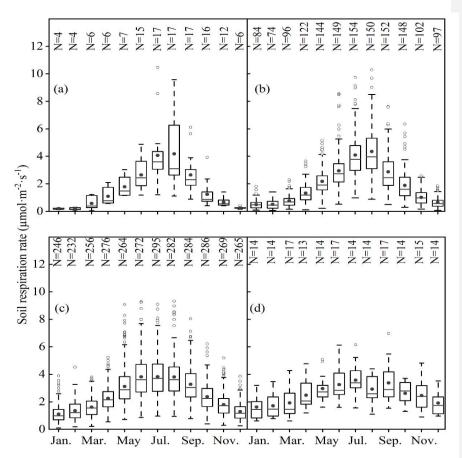

Figure 3. Monthly patterns of forest soil respiration rates in cold-temperate (a), temperate (b), subtropical (c) and tropical zones (d). Solid circle: mean value; Solid horizontal line: median; Box: 25th to 75th percentiles; Whisker: 1.5 times interquartile range; Open circle: data points beyond the whiskers. The samples per month were listed in the upper part of the figure.

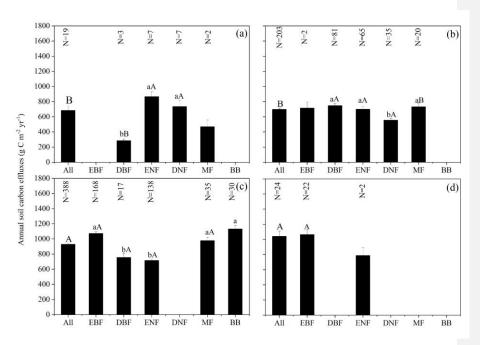

Figure 4. Comparisons of annual soil carbon effluxes (mean ±standard error) among different forest types across China in cold-temperate (a), temperate (b), subtropical (c) and tropical zones (d). Lowercase letters are the comparisons of different forest types in each climatic zone, while capital letters are the comparisons of the same forest type in different climatic zones. The samples were listed in the upper part of the figure, and the samples larger than 3 were compared. EBF: evergreen broadleaf forest, DBF: deciduous broadleaf forest, ENF: evergreen needleleaf forest, DNF: deciduous needleleaf forest, MF: broadleaf and needleleaf mixed forest and BB: Bamboo forest.
