16 **Abstract**

17 Fine particulate matter ($PM_{2.5}$) has altered radiation balance on earth and raised environmental and
18 health risks for decades, but only been monitored widely since 2013 in China. Historical long-term
19 $PM_{2.5}$ records with high temporal resolution are essential but lacking for both research and
20 environmental management. Here, we reconstruct a site-based $PM_{2.5}$ dataset at 6-hour intervals from
21 1960 to 2020 that combines long-term visibility, conventional meteorological observations,
22 emissions, and elevation. The $PM_{2.5}$ concentration at each site is estimated based on an advanced
23 machine learning model, LightGBM, that takes advantage of spatial features from 20 surrounding
24 meteorological stations. Our model's performance is comparable or even better than those of
25 previous studies in by-year cross validation (CV) ($R^2=0.7$) and spatial CV ($R^2=0.76$), and more
26 advantageous in long-term records and high temporal resolution. This model also reconstructs a
27 $0.25^\circ \times 0.25^\circ$, 6-hourly, gridded $PM_{2.5}$ dataset by incorporating spatial features. The results show
28 $PM_{2.5}$ pollution worsens gradually or maintains before 2010 from an interdecadal scale but mitigates
29 in the following decade. Although the turning points vary in different regions, $PM_{2.5}$ mass
30 concentrations in key regions decreased significantly after 2013 due to clean air actions. In particular,
31 the annual average value of $PM_{2.5}$ in 2020 is nearly at the lowest value in history since 1960. These
32 two $PM_{2.5}$ datasets (publicly available at <https://doi.org/10.5281/zenodo.6372847>) provide
33 spatiotemporal variations at high resolution, which lay the foundation of research studies associated
34 with air pollution, climate change, and atmospheric chemical reanalysis.

35

36 1 Introduction

37 In the past decades, anthropogenic emissions of reactive gases and aerosols have been emitted
38 increasingly in the atmosphere and thus led to a substantial increase in fine particulate matter (PM_{2.5}).
39 Increased PM_{2.5} has strongly interacted with solar radiation through absorption and scattering,
40 thereby reducing visibility and influencing the earth's radiance balance. Inhalable PM_{2.5} has
41 increased human morbidity and mortality through penetrating the respiratory system (Pope et al.,
42 2002; Beelen et al., 2007; Chen et al., 2016b). To evaluate the impacts of PM_{2.5} pollution on
43 environment, climate, and health, the primary concern is to understand the spatiotemporal variations
44 of PM_{2.5} concentrations. Namely, extended PM_{2.5} records with high temporal resolution lay the
45 foundation of research studies associated with air pollution, climate change, and environmental
46 health. Nevertheless, it was not until 2013 that the Ministry of Ecology and Environment (MEE)
47 established a nationwide PM_{2.5} monitoring network. Long-term, accurate historical PM_{2.5} datasets
48 are lacking for both research and environmental management.

49 Chemical transport models (CTMs) are expected to simulate the spatial and temporal variations
50 of PM_{2.5} with reasonable emission inventories inputted. However, significant uncertainties still exist
51 in historical emission inventories and physicochemical mechanisms, which resulted in inevitable
52 biases in the simulated absolute values of PM_{2.5}. Satellite-based aerosol optical depth (AOD), which
53 measures the aerosol extinction of the solar beam, is an indicator of ground-level aerosols. AOD
54 data products from Moderate Resolution Imaging Spectroradiometer (MODIS) have broad spatial
55 coverage and relatively long observation periods (~ 20 years). Therefore, assimilating satellite-
56 retrieved AOD to construct atmospheric chemical reanalysis is a practical approach to reduce PM_{2.5}
57 biases. In recent years, several international aerosol reanalysis datasets have been developed
58 preliminarily, including the reanalysis data produced by the Copernicus Atmosphere Monitoring
59 Service (CAMS) from the European Centre for Medium-Range Weather Forecasts (ECMWF)
60 (Inness et al., 2019), the Modern-Era Retrospective analysis for Research and Applications, Version
61 2 (MERRA-2) from the National Aeronautics and Space Administration (NASA) (Gelaro et al.,
62 2017; Randles et al., 2017), aerosol reanalysis from the Navy Aerosol Analysis and Prediction
63 System (NAAPS) (Lynch et al., 2016) and the Japanese Reanalysis for Aerosol (JRAero) from the
64 Japanese Meteorological Agency (Yumimoto et al., 2017). In particular, CAMS produced gridded
65 PM₁, PM_{2.5}, and PM₁₀ data at 80 km resolution since 2003 by assimilating satellite retrievals of total
66 AOD, total tropospheric NO₂ column, total O₃ column, CO column, and vertical profiles (Inness et
67 al., 2019). MERRA-2 reanalysis includes PM_{2.5} and PM₁₀ at 50 km resolution since 1980 by
68 assimilating ground-based and satellite-retrieval (Gelaro et al., 2017; Randles et al., 2017). NAAPS
69 generates gridded AOD data at ~100 km resolution from 2003 to 2013 by assimilating satellite-
70 based AOD products (Lynch et al., 2016). JRAero provides PM_{2.5} and PM₁₀ at ~100 km resolution
71 from 2011 to 2015 by assimilating satellite AOD data (Yumimoto et al., 2017). These reanalysis
72 data have contributed significantly to research in aerosol-related fields. However, there are still some
73 weaknesses in accuracy, spatial resolution, time span, and types of assimilated data. In China, the
74 highest horizontal resolution of the four reanalysis is only 50 km, and this coarse grid setting may
75 not be sufficient to capture the spatial differences in atmospheric pollutants at regional scales. In
76 terms of the type of aerosol data assimilation, these reanalysis data mainly assimilate satellite-based
77 and ground-based AOD, and do not take into account ground PM_{2.5} observations.

78 To overcome the reanalysis's weaknesses in low spatial resolution and high biases, numerical

79 researchers focus on constructing relatively long-term $PM_{2.5}$ datasets based on machine learning
80 techniques that fuse multisource data, including satellite-retrieved AOD, CTM simulations, and
81 even atmospheric chemical reanalysis. For example, Ma et al. (2016) estimated daily $PM_{2.5}$ records
82 at 0.1° resolution between 2004-2013 with MODIS AOD. Liang et al. (2020) rebuilt monthly $PM_{2.5}$
83 concentrations at 1 km resolution during 2000-2016 based on the multiangle implementation of
84 atmospheric correction (MAIAC) from MODIS and reanalysis AOD and $PM_{2.5}$ data from MERRA-
85 2. Geng et al. (2021) reconstructed daily, 10 km $PM_{2.5}$ data between 2000-2020 with MODIS AOD
86 and CTM simulations. Wei et al. (2021) regenerated monthly, 1 km $PM_{2.5}$ records between 2000-
87 2018 based on MAIAC AOD. Huang et al. (2021) estimated $1\text{ km} \times 1\text{ km}$ $PM_{2.5}$ concentrations daily
88 between 2013-2019 based on MAIAC AOD and CTM outputs. However, some inherent limitations
89 in satellited-based AOD are challenging to overcome. Due to the low sampling frequency of
90 satellite-retrieved AOD, AOD-based $PM_{2.5}$ datasets are limited to a maximum temporal resolution
91 of one day. With AOD over land unavailable before 2000, these $PM_{2.5}$ datasets can only be back-
92 calculated to 2000 at the earliest.

93 Compared with satellite data, ground-based meteorological observations have the advantages
94 of long sequence time, high temporal resolution, and good data integrity. In China, the national
95 meteorological observation network of the China Meteorological Administration (CMA) was
96 established in the 1950s and is capable of continuously observing 6-hourly meteorological data on
97 visibility and conventional meteorological variables, including temperature, pressure, wind, and
98 humidity. The number of national stations exceeded 2,000 in 1960 and has stabilized at around 2,450
99 afterward. Therefore, better results may be achieved if these ground-based meteorological data can
100 be used to estimate historical $PM_{2.5}$ data in China. Liu et al. (2017) first estimated monthly visibility-
101 based $PM_{2.5}$ concentrations between 1957-1964 and 1973-2014 based on 674 publicly available
102 meteorological stations. Gui et al. (2020) constructed a virtual daily $PM_{2.5}$ network at 1180
103 meteorological sites between 2017-2018. Our previous research also shows that the visibility-based
104 machine learning model that takes advantage of spatial features has great potential in reconstructing
105 historical $PM_{2.5}$ datasets with long-term records and high temporal resolution (Zhong et al., 2021).
106 In this study, we reconstruct a site-based $PM_{2.5}$ dataset at 6-hour intervals from 1960 to 2020 based
107 on long-term visibility and conventional meteorological observations from ~2450 national stations,
108 together with emissions and elevation. The $PM_{2.5}$ concentration at each site is estimated based on a
109 Light Gradient Boosting Machine (LightGBM) model that takes advantage of spatial features from
110 20 surrounding meteorological stations. By incorporating spatial features, this model also
111 reconstructs a $0.25^\circ \times 0.25^\circ$, 6-hourly, gridded $PM_{2.5}$ dataset. These two $PM_{2.5}$ datasets provide
112 spatiotemporal variations at high resolution, which constitute the basis for research studies
113 associated with air pollution, climate change, and atmospheric chemical reanalysis.

114

115 2 Data and Methods

116 2.1 Multisource input data

117 *Observational PM_{2.5} data.* The MEE began laying out a PM_{2.5} monitoring network in January
118 2013, expanding the scope from key regions including the North China Plain (NCP), the Yangtze
119 River Delta (YRD), the Pearl River Delta (PRD), and the Sichuan Basin (SB) as well as
120 municipalities directly under the Central Government and provincial capitals, to 113 key and model
121 cities for environmental protection, and eventually to all cities above prefecture level, with the
122 number of observation sites expanded from the initial 520 to over 1,600. Since then, PM_{2.5} mass
123 concentrations have been recorded continuously using the β -absorption methods or a micro-
124 oscillating balance following a standard protocol (Huang et al., 2021). Hourly PM_{2.5} data of all sites
125 between 2013–2020 are collected from the China National Environmental Monitoring Center
126 (CNEMC, <http://www.cnemc.cn>). To produce high-quality PM_{2.5} data, a series of quality controls
127 were conducted, including integrity checking, duplicate rejection, and outlier handling. All sites
128 with the proportion of valid PM_{2.5} records exceeding 60% were considered. For each site, identical
129 data for 3 consecutive hours were excluded first, and PM_{2.5} values over three standard deviations
130 from 24-hour and 3-day moving average were regarded as outliers and discarded then. Eventually,
131 PM_{2.5} data from 1485 sites remained for model development and application. In addition, pre-2013
132 PM_{2.5} measurements in US embassies in Beijing and Shanghai are used for independent validation
133 evaluations (<http://www.stateair.net/web/historical>).

134 *Visibility and conventional meteorological data.* The CMA established a national
135 meteorological observation network in the 1950s, with the station number exceeding 2000 at the
136 beginning and stabilizing at ~2,450 afterward. The observation network can continuously record
137 meteorological data on visibility and conventional meteorological variables, including temperature,
138 pressure, wind, and humidity. In recent years, meteorological observations, including 6-hourly
139 records between 1960–2020 and hourly records, have been collected from the National
140 Meteorological Information Center (NMIC). Due to the inconsistency of visibility data in terms of
141 observation methods, we conducted a series of data conversions to ensure continuous and consistent
142 data. Visibility data recorded on a scale ranging from 0 to 9 between 1960–1979 were converted to
143 numerical data based on probability density distributions. Specifically, the probability density
144 distribution of visibility for each of the ten years before and after 1980 was calculated at first. The
145 numerical visibility from 1980 to 1989 was graded into classes, with the median value of each class
146 being the corresponding value for each station, and finally, the class observations were converted
147 into numerical observations. From September 2013 to 2016, visibility measurements gradually
148 shifted from 6-hourly manual observations to 1-hourly automatic observations site-by-site. In
149 keeping with manual measurements, the automatic records, which are slighter lower than manual
150 measurements, were calibrated by dividing 0.75 following the guideline from the CMA (Cma, 2014).

151 *Emission inventories and elevation.* Historical anthropogenic emissions from 1960–2012 are
152 taken from Peking global emission inventories, developed using a bottom-up approach with spatial
153 resolution at 0.1°×0.1° and temporal resolution at 1-month intervals (<http://inventory.pku.edu.cn>)
154 (Chen et al., 2016a; Huang et al., 2014; Huang et al., 2015; Wang et al., 2014). Current
155 anthropogenic emissions during 2013–2020 are from the multiresolution Emission Inventory in

156 China (MEIC, <http://meicmodel.org>) (Zhang et al., 2009; Zheng et al., 2018; Zheng et al., 2021).
157 Six emission variables from these two inventories are used as inputs for model development,
158 including PM_{2.5}, NO_x, SO₂, NH₃, BC, OC, and CO. Thirty-meter elevation data are collected from
159 the Global Digital Elevation Model (GDEM) version 2 (<https://earthexplorer.usgs.gov>). Both
160 emission and elevation data are interpolated from grids to sites to match existing PM_{2.5} sites.

161 *Auxiliary data.* Monthly Normalized Difference Vegetation Index (NDVI) products are
162 downloaded from Level-1 and Atmosphere Archive & Distribution System Distributed Active
163 Archive Center (LADDS DAAC, <https://ladsweb.modaps.eosdis.nasa.gov>). Land cover
164 classification data are taken from National Geographic Information Resources Catalogue Service
165 System (<https://www.webmap.cn/mapDataAction.do?method=globalLandCover>). Population data
166 are taken from the Gridded Population of the World version 4 (GPWv4,
167 <https://sedac.ciesin.columbia.edu/data/collection/gpw-v4>) and are calibrated based on the total
168 population in China City Yearbooks. NDVI, Land cover, and population data are also interpolated
169 according to PM_{2.5} sites and trained as inputs for model development. However, during the model
170 training process, we found that these data had little or no improvement in the hindcast capability of
171 the model, and the time span of these data is insufficient for long-term historical retrieval. Hence,
172 these auxiliary data are not used in model building.

173 2.2 Spatiotemporal feature extraction

174 For each PM_{2.5} site, we extract five variables as temporal inputs, including year, month, day,
175 hour, and day of year. The longitude and latitude variables are taken out as location inputs (Fig. 1b).
176 Visibility, RH, and temperature from the nearest meteorological station of each PM_{2.5} are used as
177 basic meteorological inputs. The distance between these two sites was also added as a feature. In
178 addition to the influence of the nearest meteorological station, PM_{2.5} concentrations at a site are also
179 affected by surrounding conditions. For example, transport of pollution due to air movement is the
180 main cause for the early stage of heavy pollution episodes (Zhong et al., 2017; Zhong et al., 2018).
181 Hence, we need to consider spatial effects from surrounding meteorological stations. Our previous
182 study developed a novel feature engineering approach, which incorporated surrounding impact by
183 extracting spatial features (Zhong et al., 2021). Specifically, the remaining 19 nearest stations were
184 matched for each PM_{2.5} site, except the nearest meteorological station. Five variables, including
185 longitude, latitude, temperature, visibility, and RH, were selected from the 19 stations. Then, we
186 calculated the maximum, the minimum, the average value, the skewness value, and the standard
187 deviation for each of the five variables. These produced features, which take advantage of
188 surrounding conditions, are also considered as inputs. After spatiotemporal feature extraction, a total
189 of 71 features were used as inputs for model training. To reduce computation and training time with
190 guaranteed accuracy, the top 35 features in order of importance during small-sample-testing
191 processes are used for the following model training and hindcasting. These features included
192 visibility, temporal features, spatial features, emission features, and elevation.

193 2.3 Gridded input construction

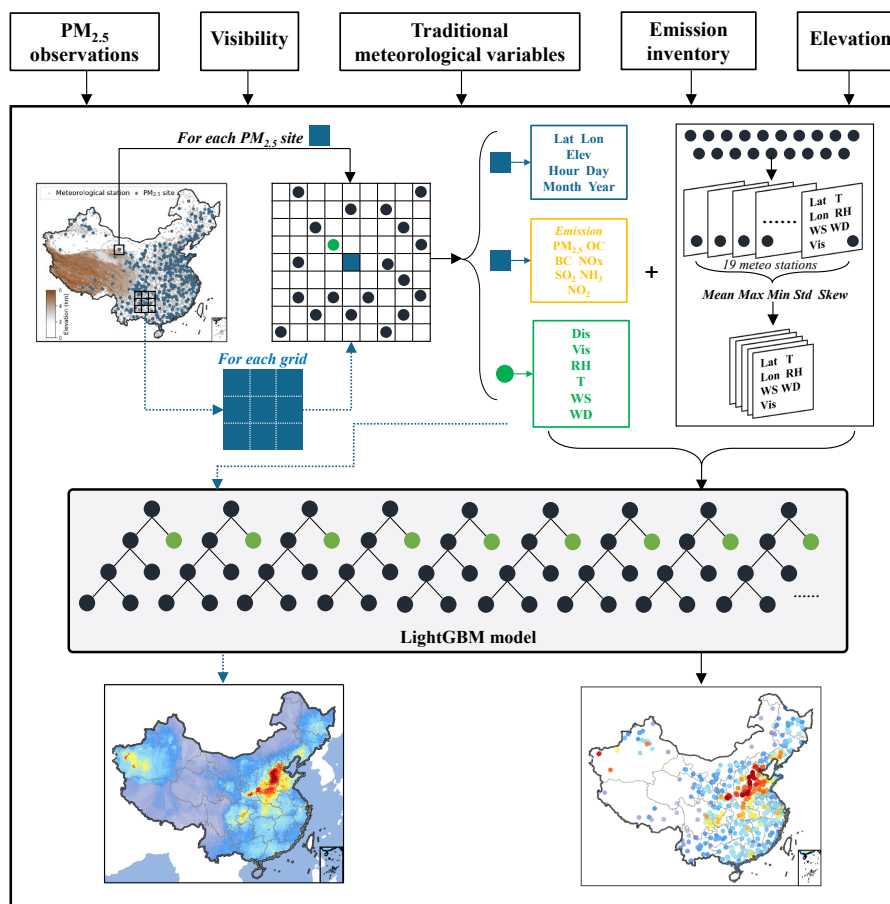

194 In the previous construction of input features for PM_{2.5} sites, we used location information,
195 time information, meteorological information from 20 surrounding meteorological stations,

196 emission information, and elevation. If we assume that each cell in grid cells is a virtual $PM_{2.5}$ site,
197 then it is possible to generate input features for each grid point. After the model is trained based on
198 input features and $PM_{2.5}$ concentrations at real $PM_{2.5}$ sites, we can feed the gridded input data into
199 the model in turn and consequently construct a gridded $PM_{2.5}$ network. Therefore, we define a grid
200 area at $0.25^\circ \times 0.25^\circ$ with longitude from $70^\circ E$ to $150^\circ E$ and latitude from $10^\circ N$ to $60^\circ N$ and select
201 the grid points covering mainland China. For each grid point, we performed spatiotemporal feature
202 extraction and generated the same 71 input features as those of real $PM_{2.5}$ sites.

203 **2.4 Model description**

204 LightGBM is one of the state-of-the-art gradient boosting frameworks with better accuracy,
205 lower memory usage, faster training speed, and capability of handling large-scale data (Ke et al.,
206 2017). Our previous research used this machine learning model to predict $PM_{2.5}$ mass concentrations,
207 which shows an unprecedented predictive capacity on hourly, daily, monthly, and annual
208 timescales (Zhong et al., 2021). This study will continue to use this algorithm and previously tuned
209 hyperparameters for model development (Zhong et al., 2021). For hindcasting historical $PM_{2.5}$
210 datasets prior to 2013, a LightGBM model is trained and validated based on $PM_{2.5}$ observations and
211 feature inputs from 2013 to 2020. The hindcast capability is validated using cross-validation
212 methods, which are standard methods for parameter tuning and model validation in machine
213 learning. The training dataset is divided into several parts, one of them is used as test data, and the
214 remaining are used as training data in turn. Each result yields a corresponding evaluation value,
215 which is then averaged to provide an estimate of the model's accuracy. This estimation is quantified
216 by two metrics, including the coefficient of determination (R^2) and root-mean-square error (RMSE).
217 The hindcast capability is also validated using $PM_{2.5}$ observations from the US embassies in Beijing
218 and Shanghai, which have been observing $PM_{2.5}$ data since as early as 2008. After model training
219 and validation, historical 6-hourly input data are inputted into this model to reconstruct a site-based
220 $PM_{2.5}$ dataset at 6-hour intervals from 1960 to 2020; and gridded input data are inputted into the
221 model to reconstruct a $0.25^\circ \times 0.25^\circ$, 6-hourly, gridded $PM_{2.5}$ dataset. The daily, monthly, yearly, and
222 decadal average $PM_{2.5}$ concentrations for each site and each grid are also calculated based on the
223 two datasets. Monthly-average values were obtained with daily values no less than 20 days;
224 otherwise, they will be missing. Year-average values were calculated with 12 valid month values,
225 and decadal-average values were calculated with 10 valid year-average values. The flowchart of
226 reconstructing $PM_{2.5}$ datasets is shown in Fig. 1.

228 **Fig. 1** A conceptual scheme for constructing long-term historical site-based and gridded $PM_{2.5}$
229 records based on long-term visibility, conventional meteorological observations, emissions, and
230 elevation.
231

232 3 Results and Discussion

233 3.1 Evaluation of model hindcast performance

234 The hindcast performance of our model is evaluated using two CV methods, including 10-fold
 235 CV and by-year CV. The 10-fold CV partitions the original training datasets into 10 subsamples,
 236 one of which is retained as the validation data in turn for testing the model, and the remaining 9
 237 subsamples are used as training data. This method is the most common CV that can be compared
 238 with results in other studies. However, 10-fold CV often overestimates the model's ability to
 239 hindcast continuous historical data. Therefore, we also use by-year CV, during which one year of
 240 data is selected sequentially for testing, and the remaining data are used for model training. This
 241 method is specifically designed to evaluate the hindcast capability of the model.

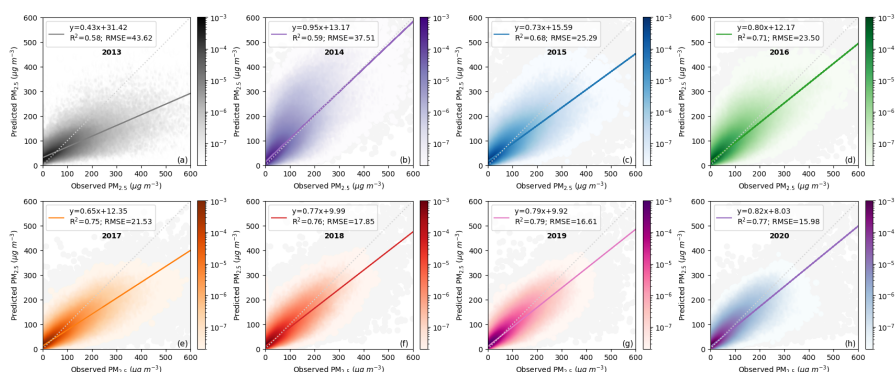

242 **Tab. 1** Model performance in primary predictors, temporal resolution, and hindcast capability
 243 compared with other national PM_{2.5} datasets in China.

Related studies	Primary predictors	Temporal resolution	CV type	CV resolution	CV R ²	CV RMSE
Ma et al., 2016	AOD	daily (2004-2013)	10-fold CV by-year CV	daily	0.79 0.41	27.40

Bai et al., 2022	AOD	daily (2000-2020)	10-fold CV	daily	0.79	20.04
Our study	Visibility	6-hourly (1960-2020)	10-fold CV	hourly/6-hourly 6-hourly daily monthly	0.79 0.78 0.85 0.92	20.07 21.14 16.11 7.90
			by-year CV	hourly/6-hourly 6-hourly daily monthly	0.70 0.71 0.78 0.83	26.36 25.63 20.90 13.37

245 Table 1 compares our dataset and the available datasets in primary predictors, temporal
 246 resolution, and CV results (Ma et al., 2016; Fang et al., 2016; Liu et al., 2017; Xiao et al., 2018; Xue
 247 et al., 2019; Liang et al., 2020; Huang et al., 2021; Wei et al., 2021; Van Donkelaar et al., 2021;
 248 Geng et al., 2021; Bai et al., 2022). AOD-based datasets are only available from around 2000 at the
 249 earliest, with temporal resolutions ranging from daily scale to monthly scale. In contrast, our
 250 visibility-based dataset spans 61 years from 1960 to 2020 at 6-hourly intervals, showing a clear
 251 advantage in terms of time span and resolution. The R² and RMSE values of our 10-fold CV results
 252 are 0.78 and 21.14 μg m⁻³ for 6-hourly estimations, respectively, which indicates our model is quite
 253 robust in estimating PM_{2.5}. Due to a reduction in data amount, the R² and RMSE values further
 254 improved to 0.85 and 16.11 μg m⁻³ for daily estimations and 0.92 and 7.90 μg m⁻³ for monthly
 255 estimations. This result is comparable or even better than those of other available datasets whose
 256 10-fold CV R² ranges from 0.61 to 0.80 for daily scale and from 0.71 to 0.93 for monthly scale. Our
 257 by-year CV's R² and RMSE values are 0.71 and 25.63 μg m⁻³ for 6-hourly estimations, which
 258 indicates our model is still robust in hindcast performance. The by-year CV R² values for daily and
 259 monthly estimations (0.78 and 0.83) are higher than those in other available datasets (0.41-0.62 and

260 0.80), which might be partly attributed to spatial feature extraction and the large volume of our
261 training dataset. Zhong et al. (2021) has shown that extracting spatial features can result in a better
262 hindcast performance by fully representing dimensional heterogeneity. Compared to hundreds of
263 thousands to millions of training samples in AOD-based models, the training samples for the
264 visibility-based model are over 100 million. An increase in the order of magnitude for training
265 datasets will yield better results in machine learning.

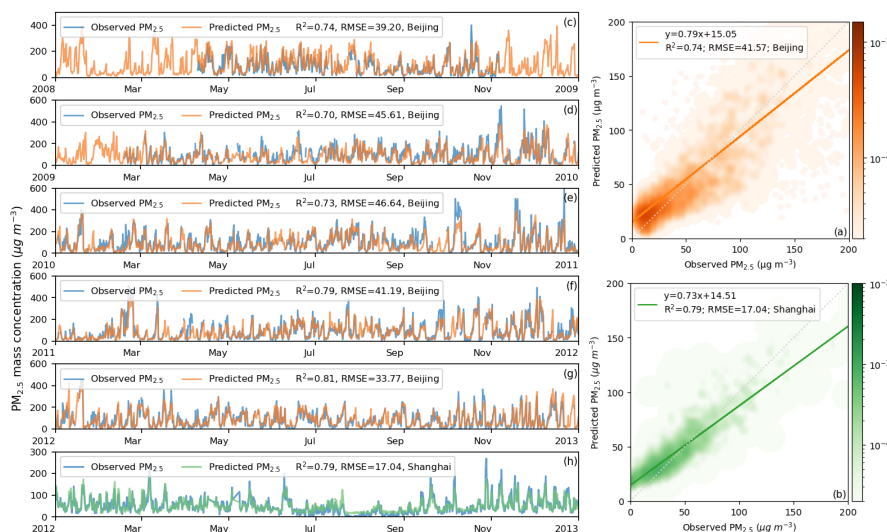

267 **Fig. 2** Density scatterplots of observed $\text{PM}_{2.5}$ and estimated $\text{PM}_{2.5}$ across China for by-year CV
268 from 2013 to 2020 (Colors are probability distribution densities).
269

270 The refined by-year CV results for each year between 2013-2020 are shown in Fig. 2. The
271 by-year CV R^2 lies between 0.58 and 0.79, with better hindcast performance after 2014. The
272 potential reasons why the R^2 value in 2013 is slightly lower than those in other years are as follows.
273 First, the $\text{PM}_{2.5}$ observation network was just established in 2013, during which dehumidification
274 systems, processing procedures, and data quality control methods are incomplete, and therefore the
275 overall data quality cannot be guaranteed. With the improvement of the observation network after
276 2014, both the quality and quantity of observations increase significantly. This situation where data
277 quality is relatively low initially but increased over time is also found in O_3 observations. Second,
278 the CMA began to convert some of the manual visibility observations to automatic observations in
279 2013, during which there were also some irregular procedures in instrument equipment, observation
280 steps, and data quality control. Lastly, although we have corrected the biases between manual and
281 automated observations, some biases may still exist. However, the biases are further reduced as we
282 integrate all manual visibility observations in 2013 into our training dataset.

283 The model's hindcast capability is further evaluated independently using pre-2013 $\text{PM}_{2.5}$
284 observations. For the $\text{PM}_{2.5}$ data currently available, only the US embassies in Beijing and Shanghai
285 have at least one year's $\text{PM}_{2.5}$ observations. Therefore, $\text{PM}_{2.5}$ data from these two sites are applied
286 as an independent evaluation dataset. Figure 3 shows our estimated $\text{PM}_{2.5}$ are in close agreement
287 with in-situ measurements in Beijing and Shanghai, where the overall R^2 between observations and
288 estimations is 0.74 and 0.79, respectively. For each year between 2008-2012 in Beijing, the R^2
289 values fluctuated between 0.70 and 0.81, reflecting a stable and accurate by-year hindcast capability.
290 As shown in Fig. 3 (c-h), the low values, high values, and temporal variations in $\text{PM}_{2.5}$
291 measurements are all well estimated. In particular, $\text{PM}_{2.5}$ measurements are lacking at the US
292 Embassy in Beijing in early 2008 and around 2009, but our model can provide reasonable and

293 continuous estimations to fill in the gaps. This ability can also be used to fill in missing $PM_{2.5}$
294 observations of MEE from 2013 onwards, building a complete $PM_{2.5}$ dataset. Overall, the
295 independent validation results show that historical $PM_{2.5}$ data can be well reconstructed by our
296 model.

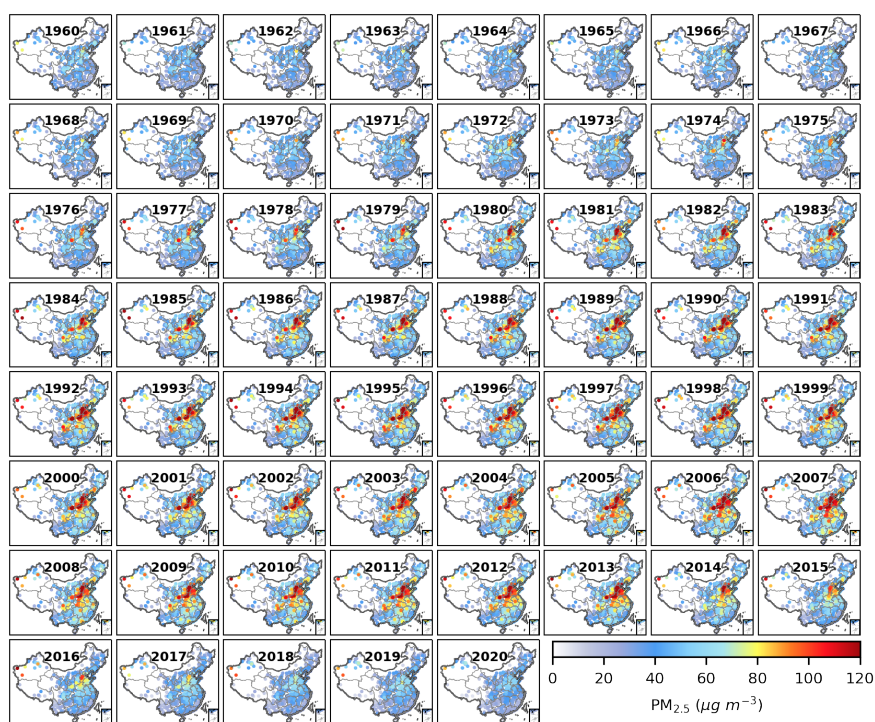

298 **Fig. 3** (a) Density scatterplots of observed $PM_{2.5}$ and estimated $PM_{2.5}$ between 2008-2012 at the
299 US Embassy in Beijing; (b) Density scatterplots of observed $PM_{2.5}$ and estimated $PM_{2.5}$ in 2012 at
300 the US Embassy in Shanghai; (c-g) Timeseries of observed $PM_{2.5}$ and estimated $PM_{2.5}$ for each
301 year between 2008-2012 at the US Embassy in Beijing; and (h) Timeseries of observed $PM_{2.5}$ and
302 estimated $PM_{2.5}$ for each year in 2012 at the US Embassy in Shanghai.

303 3.2 Spatiotemporal variations in the site-based $PM_{2.5}$ dataset during 1960-2020

304 Figure 4 shows the spatiotemporal variations in annual average site-based $PM_{2.5}$ between 1960-
305 2020. The trend of $PM_{2.5}$ in China experiences three major stages, corresponding to a slow increase
306 under low concentrations between 1960-1978, a continuous accumulation with high concentrations
307 reached between 1979-2013, and a rapid decrease between 2014-2020. During the first stage, though
308 $PM_{2.5}$ pollution occurred in parts of the NCP and the Guanzhong Plain (GZP), $PM_{2.5}$ concentrations
309 remain low in the vast majority of areas. This is mainly because anthropogenic emissions of $PM_{2.5}$
310 precursors and primary $PM_{2.5}$ grow slowly at a low base, resulting in relatively low total emissions
311 in different regions. However, $PM_{2.5}$ pollution still occurring in the NCP and GZP, even with
312 relatively low emissions, indicates the low environmental capacity of these two regions. During the
313 second stage, $PM_{2.5}$ reached an unprecedentedly high concentration after a continuous increase in
314 nearly all regions in China. The heaviest $PM_{2.5}$ pollution occurred in the NCP and the GZP. The SB
315 and the Northeast China Plain (NeCP) are the polluted regions with the next highest $PM_{2.5}$ pollution.
316 Even the YRD and the PRD also experienced $PM_{2.5}$ pollution during this stage. This worsening of
317 $PM_{2.5}$ pollution is closely associated with massive anthropogenic emissions from rapidly increasing
318 living and industrial activities after reform and opening-up policies. From 1979 to 2013, primary
319 $PM_{2.5}$, NO_x , SO_2 , NH_3 , BC, OC, and CO from the Peking emission inventory increased by 98%,

320 457%, 159%, 117%, 45%, -22%, and 243%, respectively. Despite a slow reduction in SO₂ after
321 2006, the total anthropogenic emissions each year still increase and thereby cause high-level PM_{2.5}
322 pollution after 2006. The results indicate that air pollutants cannot be emitted without restraint, even
323 in regions with high atmospheric capacity. Otherwise, PM_{2.5} pollution will inevitably occur. In
324 addition to anthropogenic emissions, sand and dust storms, resulting in high PM_{2.5} concentrations
325 in western Xinjiang, worsened PM_{2.5} pollution by trans-regional transport from the desert regions.
326 During the last stage, PM_{2.5} decreased nationwide with the mass concentrations in nearly all stations
327 approximately or below 35 $\mu\text{g m}^{-3}$ in 2020, even in the NCP and the GZP with limited environmental
328 capacity. The substantial declines in PM_{2.5} illustrate the effectiveness of implementing the toughest-
329 ever clean air policy in China. The spatiotemporal variations of PM_{2.5} between 1960-2020 clearly
330 show the long-term impact of economic development and energy consumption on our air quality
331 and the effectiveness of recent years' unprecedented emission control policies.

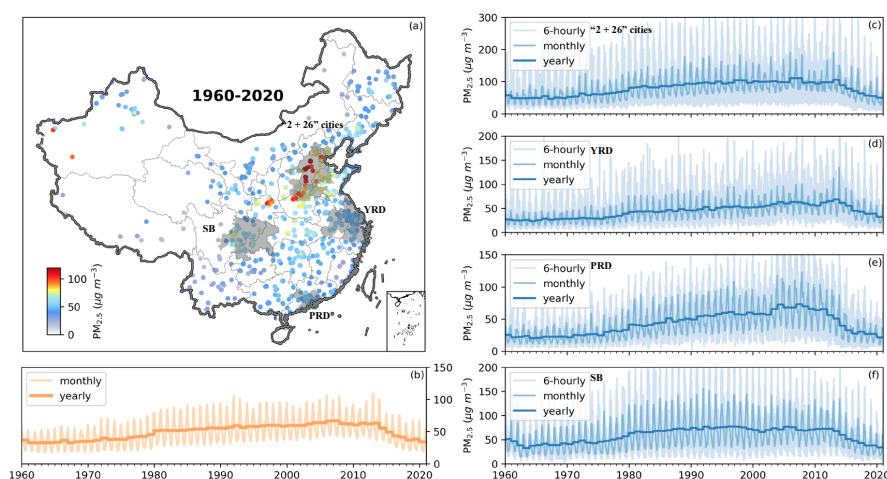

333 **Fig. 4** Spatial distribution of annual average PM_{2.5} mass concentration at 1485 stations from 1960
334 to 2020
335

336 The specific turning points in annual PM_{2.5} concentrations for different regions were
337 investigated additionally. Figure 5 shows the temporal variations in national-average monthly and
338 yearly PM_{2.5} mass concentrations and regional average 6-hourly, monthly, and yearly PM_{2.5} mass
339 concentrations in "2+26" cities of the NCP, the YRD, the PRD, and the SB. The national-average
340 yearly PM_{2.5} reached a peak of 67 $\mu\text{g m}^{-3}$ in 2007, declined in 2008, and then remained steady until
341 2013. A sharp fall followed after 2014 with PM_{2.5} concentrations decreasing from 63 $\mu\text{g m}^{-3}$ in 2013

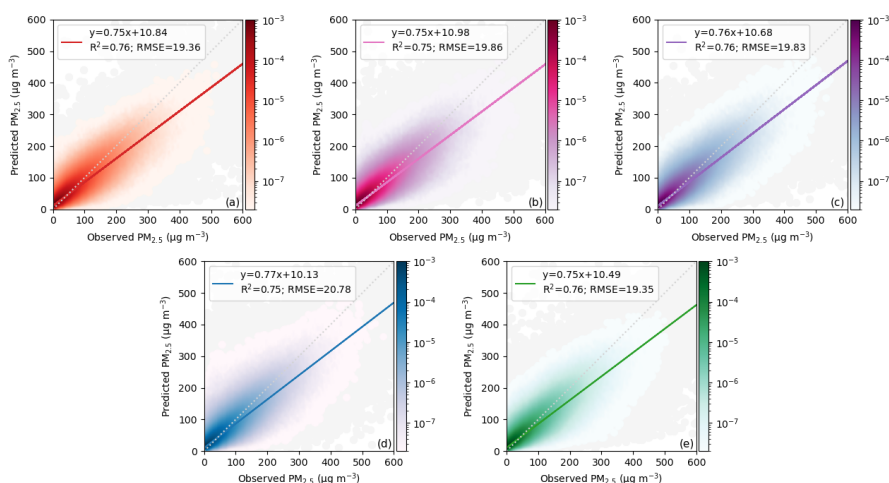

342 to $34 \mu\text{g m}^{-3}$ in 2020. The annual $\text{PM}_{2.5}$ concentrations in the "2+26" cities also experienced similar
343 changes with a peak at 2007 and a reduction in 2008, which might be related to emission reduction
344 for the Beijing Olympics in 2008. For the YRD, the maximum value of $\text{PM}_{2.5}$ mass concentration
345 occurred in 2013 without a striking peak in 2007. For the PRD, the annual $\text{PM}_{2.5}$ concentrations
346 increased steadily between 1960-1978, then rose more and more steeply in the following years with
347 a steep increase in 2003 and 2004 and peaked in 2004. A steady decrease with slight fluctuation
348 occurred in 2005-2013, and then a sharp fall followed after 2014. This trend is different from that
349 in the "2+26" cities and the YRD. For the SB, the turning point occurred in 2013, before which the
350 annual $\text{PM}_{2.5}$ concentrations increased steadily and remained steady.

352 **Fig. 5** (a) Spatial distribution of average $\text{PM}_{2.5}$ mass concentrations between 1960-2020; (b-f)
353 Timeseries of average $\text{PM}_{2.5}$ mass concentrations for all sites in China (b), "2+26" cities (c),
354 Yangtze River Delta (d), Pearl River Delta (e) and Sichuan Basin (f), respectively.

355 3.3 Detailed spatial distributions from gridded $\text{PM}_{2.5}$ datasets

356 The model's ability to make $\text{PM}_{2.5}$ predictions at locations outside the scope of the training
357 stations is evaluated by spatial CV. For spatial CV, all the monitoring stations are randomly divided
358 into five subsets, and the model is trained using data from four subsets and tested on the data from
359 the remaining subset each time. As shown in Fig. 6, the R^2 for spatial cross-validation in different
360 groups is between 0.75 and 0.79, reflecting robust predictive power for $\text{PM}_{2.5}$ concentrations at sites
361 outside the training sites. Our previous study also examined this predictive ability using $\text{PM}_{2.5}$ data
362 from 23 untouched regional $\text{PM}_{2.5}$ stations (Zhong et al., 2021).

364 **Fig. 6** Density scatterplots of observed $\text{PM}_{2.5}$ and estimated $\text{PM}_{2.5}$ for each group of spatial CV
365 results
366

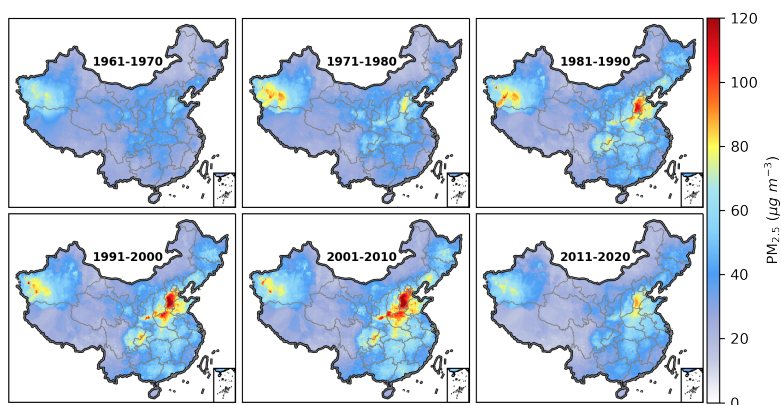

367 Figure 7 shows the annual spatial variations in $0.25^\circ \times 0.25^\circ$ gridded $\text{PM}_{2.5}$ between 1960-2020.
368 Compared to site-based distributions, gridded $\text{PM}_{2.5}$ can portray the spatiotemporal variations in a
369 clearer and more detailed way. For example, the most widespread and heaviest $\text{PM}_{2.5}$ pollution in
370 western Xinjiang occurred in 1979. This abnormal pollution corresponds to the historical
371 construction of northern severe dust storms, which recorded the event with the largest affected areas
372 in April 1979 (Zhou and Zhang, 2003). As exposed to nearly the most frequent air stagnation in
373 winter due to terrain and meteorological conditions (Wang et al., 2018), the NCP is the region with
374 $\text{PM}_{2.5}$ pollution first to appear and last to disappear except areas affected by dust storms (Fig. 7).
375 For year-to-year comparisons, it can be clearly seen that $\text{PM}_{2.5}$ concentrations in the NCP decreased
376 slightly from 2007 to 2008 and from 2012 to 2013, respectively, and decreased significantly in 2014
377 relative to 2013. The $\text{PM}_{2.5}$ reduction is insignificant from 2015 to 2016 but striking from 2016 to
378 2017. In 2020, the nationwide $\text{PM}_{2.5}$ concentrations are comparable to those in 1960s and close to
379 the lowest level ever recorded in almost 61 years.

381 **Fig. 7** Gridded distribution of annual average $PM_{2.5}$ mass concentration from 1960 to 2020

382

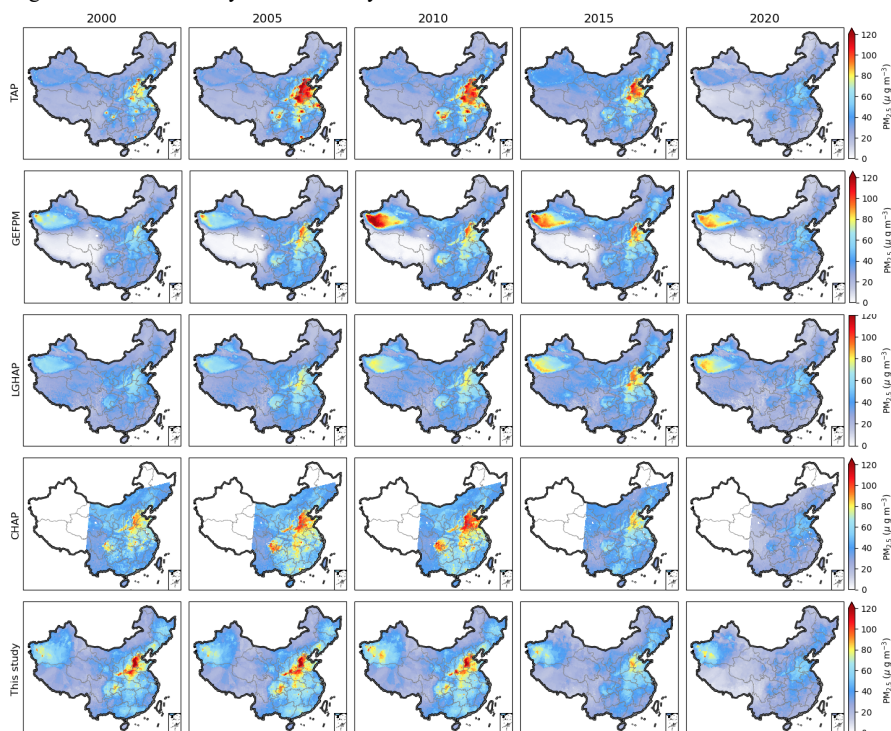

383 Figure 8 shows inter-decadal spatial variations in gridded $PM_{2.5}$ between 1961–2020. $PM_{2.5}$
384 concentrations maintained at low levels in most areas over the first decade and increased to a certain
385 extent in the NCP and western Xinjiang over the second decade. In the following decades, $PM_{2.5}$
386 pollution has worsened significantly in several key regions, including the NCP, the GZP, and the SB.
387 This worsening is maintained until the last decade, during which $PM_{2.5}$ pollution mitigates
388 significantly in nearly all populous and polluted regions in eastern China.

390 **Fig. 8** Gridded distribution of decadal average $PM_{2.5}$ mass concentration from 1960 to 2020

391 The multi-year trend of our gridded $PM_{2.5}$ dataset is also compared with those of publicly
392 available datasets, including the TAP data (Geng et al., 2021), the GEFPM data (Van Donkelaar et
393 al., 2021), the LGHAP data (Bai et al., 2022), and the CHAP data (Wei et al., 2021), which have
394 been interpolated to the same grid resolution. Figure 9 shows the spatial distributions of $PM_{2.5}$ from
395 those datasets at 5-year intervals between 2000-2020. One consistent trend across all datasets was
396 that nationwide $PM_{2.5}$ mass concentrations experienced an increase following a decrease from 2000
397 to 2020. However, the turning points are different for different datasets. From 2010 to 2015, $PM_{2.5}$
398 pollution alleviated for TAP, CHAP, and our data but worsened for GEFPM and LGHAP. For the
399 time (2015 and 2020) with ground observations available, all $PM_{2.5}$ data show similar spatial
400 distributions with the most severe pollution in the NCP in 2015 and significant improvement in
401 nationwide air pollution in 2020. For the years (2000, 2005, and 2010) when ground observations
402 were unavailable, significant disparities in pollution levels and regional distribution emerged from
403 different datasets. Specifically, the LGHAP data are significantly lower than other data, while the
404 TAP data are higher than others in nearly all regions except western Xinjiang. In western Xinjiang,
405 $PM_{2.5}$ concentrations from the GEFPM data are the highest among all the datasets. Due to a lack of
406 ground $PM_{2.5}$ observations before 2000, it's challenging to determine which dataset has the least
407 bias and more reasonable distributions. In the future, applying ensemble average to multi-datasets
408 might be an effective way to eliminate systematic bias.

410 **Fig. 9** Distribution of reconstructed $PM_{2.5}$ by different $PM_{2.5}$ datasets in 2000, 2005, 2010, 2015,
411 and 2020. From top to down are TAP, GEFPM, LGHAP, CHAP, and our dataset.
412

413 **4 Data availability**

414 The 6-hourly $PM_{2.5}$ datasets from 1960 to 2020, including site-based and gridded data, are publicly
415 accessible. Daily, monthly, and yearly sited-based and gridded $PM_{2.5}$ datasets are also provided. The
416 sited-based $PM_{2.5}$ dataset are in the CSV format, and the gridded dataset $PM_{2.5}$ are in the NETCDF
417 format. All of them are available at <https://doi.org/10.5281/zenodo.6372847> (Zhong et al., 2022).

418 **5 Conclusion**

419 This study is among the first to generate long-term site-based and gridded $PM_{2.5}$ datasets
420 between 1960-2020 with 6-hourly resolution, based on long-term visibility, conventional
421 meteorological observations, emissions, and elevation. A new feature engineering method that takes
422 advantage of spatial features from 20 surrounding meteorological stations is employed in our
423 LightGBM model to incorporate spatial effects of meteorological conditions. For by-year CV, The
424 R^2 values of our model are 0.71, 0.78, and 0.83 for 6-hourly, daily, and monthly estimations,
425 respectively, which are higher than those in other available datasets (0.41-0.62). This hindcast
426 capability is further evaluated independently using pre-2013 $PM_{2.5}$ data of 6 years from US
427 embassies in Beijing and Shanghai. The low values, high values, and temporal variations in US-
428 embassy $PM_{2.5}$ measurements are all well estimated with the overall R^2 being 0.74 and 0.79 in
429 Beijing and Shanghai, respectively. Both by-year CV and independent validation show that our
430 model has a stable by-year hindcast capability and can reconstruct historical $PM_{2.5}$ data in a
431 relatively accurate way. Our datasets show that $PM_{2.5}$ variations in China experience a slow increase
432 under low concentrations between 1960-1978, a continuous accumulation with high concentrations
433 reached between 1979-2013, and a rapid decrease between 2014-2020. The worsening of $PM_{2.5}$
434 pollution is closely associated with massive anthropogenic emissions after reform and opening-up
435 policies, while the substantial declines in $PM_{2.5}$ are mainly due to the implementation of the
436 toughest-ever clean air policy in China. In 2020, the nationwide $PM_{2.5}$ concentrations were close to
437 the lowest recorded level in almost 61 years. These two reconstructed $PM_{2.5}$ datasets provide
438 spatiotemporal variations at high resolution, which lay the foundation of research studies associated
439 with air pollution, climate change, and atmospheric chemical reanalysis. It is worth noting that our
440 datasets still have some weaknesses, with the main weakness being a lack of detailed bias
441 estimations for each value in our datasets due to limited historical observations. In the future, we
442 will collect as many $PM_{2.5}$ observations as possible to validate the accuracy of our datasets and
443 provide evaluations of uncertainty for our datasets.
444

445 **Acknowledgements**

446 The authors are grateful to all the organization and groups that provided indispensable datasets that
447 we used in this study. We would like to acknowledge to CMA for providing the long-term visibility
448 and MEE for the observational PM_{2.5} data. Also, we acknowledge the MEIC team and Peking for
449 providing the emission inventories and GDEM data provider.
450

451 **Financial support**

452
453 This research was supported by the Major Project from Natural Science Foundation of China
454 (42090030).

455 **Author Contributions**

456 XZ designed the research and led the overall scientific questions. JZ, KG, and LG carried out data
457 processing and analysis based on suggestions from ZZ, DW, YW, and HC. LL calibrated PM_{2.5} data
458 and meteorological observations. YF performed visibility conversions from class values to numeric
459 values before 1980. LJ and LJ provided calibrated visibility from 2013 to 2016 and suggestions
460 about manuscript structures. JZ wrote the first draft of the manuscript, and XZ revised the
461 manuscript. All authors read and approved the final version.

462 **Competing financial interests**

463 The authors declare no competing financial interests.
