19

20 **Abstract.** Arctic soils store large amounts of organic carbon and other elements such as amorphous silica, silicon,
21 calcium, iron, aluminium, and phosphorous. Global warming is projected to be most pronounced in the Arctic leading
22 to thawing permafrost, which in turn is changing the soil element availability. To project how biogeochemical cycling
23 in Arctic ecosystems will be affected by climate change, there is a need for data on element availability. Here, we
24 analysed amorphous silica (ASi), silicon (Si), calcium (Ca), iron (Fe), phosphorus (P), and aluminium (Al) availability
25 from 574 soil samples from the circumpolar Arctic region. We show large differences in ASi, Si, Ca, Fe, P, and Al
26 availability among different lithologies and Arctic regions. We summarized these data in pan-Arctic maps of ASi, Si,
27 Ca, Fe, P, and Al concentrations focussing on the top 100 cm of Arctic soil. Furthermore, we provide values for
28 element availability for the organic and the mineral layer of the seasonally thawing active layer as well as for the
29 uppermost permafrost layer. Our spatially explicit data on differences in the availability of elements between the
30 different lithological classes and regions now and in the future will improve Arctic Earth system models for estimating
31 current and future carbon and nutrient feedbacks under climate change.

32

33 1 Introduction

34 Temperatures in northern high latitude region have risen more than twice as fast as the global average within the last
35 decades (IPCC, 2021). This warming leads to thawing of perennially frozen ground known as permafrost (Brown and
36 Romanovsky, 2008; Romanovsky et al., 2010). Frozen conditions prevent organic matter (OM) from microbial
37 degradation and also limits fluvial export of soil-bound nutrients to the sea by runoff (Mann et al., 2022). Thawing of
38 frozen ground (defined as permafrost soils in the following) may in turn accelerate global warming by potentially
39 releasing potent greenhouse gases such as carbon dioxide (CO₂) and methane (CH₄) through soil organic carbon
40 mineralization (Schoor et al., 2015). The frozen ground of the Arctic-boreal regions (hereafter called ‘Arctic’, but also
41 including subarctic regions) are the largest pool of soil organic carbon worldwide. Approximately, 1014 - 1035 ± max.
42 194 Pg of organic carbon is stored within the upper 3 m of permafrost region soils (Hugelius et al., 2014; Mishra et
43 al., 2021). To full depth, ca. 1460 - 1600 Pg carbon is stored in the permafrost region (Strauss et al., 2021a), and
44 approximately one third of this is in ice rich Yedoma deposits, exceeding 3m depth (Fuchs et al., 2018; Strauss et al.,
45 2017). The Yedoma deposits formed in unglaciated areas of the northern hemisphere during the glacial period, when
46 melt water from glacial areas and eolian processes transported fine sediment to the unglaciated lowlands (Schoor et
47 al., 2013; Strauss et al., 2021b; Strauss et al., 2013). Yedoma deposits are characterized by high carbon and water
48 content. The water is mostly bound in massive ice in ice wedges as well as segregated ice and pore ice in sediment
49 columns (Schirmer et al., 2011). Thus, Yedoma soils are highly vulnerable to thawing as the loss of the high ice
50 volume leads to surface subsidence and thermokarst processes, which can accelerate thaw and remobilize deep
51 elemental stocks.

52 The temperature and near-surface water content in the Arctic soils have changed rapidly in the last decades and further
53 changes are expected in future (Box et al., 2019). An important effect of Arctic warming is a deepening of the
54 seasonally-thawed active layer and related thermokarst processes, which may lead to a mobilization of nutrients from
55 permafrost soil layers (Abbott et al., 2015). Additionally, increased temperatures in the Arctic regions may accelerate
56 weathering, potentially enhancing nutrient availability in terrestrial Arctic ecosystems and export to freshwater
57 systems, and finally to the nearshore zone and sea (Holmes et al., 2013).

58 As the Arctic features a mineral composition of the sediments that is different from many other global soils
59 (Monhonval et al., 2021a), the availability (for microbes and plants) of elements in Arctic soils may differ as well.
60 Yedoma deposits, for example, are important pools of OM in the Arctic. Because Yedoma deposits include materials
61 transported from nearby mountains, the mineral compositions of the Yedoma soils depend on the original geology of
62 the mountains (Schirmer et al., 2011). Sediments of marine origin are often rich in calcium (Ca), phosphorus (P)
63 and silicon (Si), while magmatic rocks such as granite or basalt contain large amounts of Si, iron (Fe), aluminum (Al),
64 and P. The availability of these elements in soils is the complex product of soil genesis and nutrient release, which
65 depend on physical and chemical conditions including temperature, water content and pH. In this context, Si, Ca, Fe,
66 Al or P are bound in or on mineral phases and are released via enzymatic activity or weathering. Ongoing Arctic
67 climate warming now threatens to disturb the pools that have equilibrated to conditions characteristic for the past
68 millennia.

69 The availability of elements such as P, Fe, Ca, and Si in soils are known controls for soil OM respiration (Brady and
70 Weil, 2008; Schaller et al., 2019). A release of inorganic nutrients such as P or Si can lead to increased greenhouse
71 gas production and potentially to further export of these elements to the fresh and seawaters. In marine systems, P, Fe,
72 Ca, and Si are well-known to control carbon (C) fixation in terms of algae biomass productivity (Tremblay et al.,
73 2015). In terrestrial systems, P availability is positively related to silicic acid ($\text{Si}(\text{OH})_4$) (Schaller et al., 2019) or its
74 polymers, which mobilize from, e.g., amorphous silica (ASi) (Schaller et al., 2021). The mobilization of P by Si was
75 shown to occur due to competition for binding at Fe-minerals (Schaller et al., 2019), which tend to strongly bind P
76 under condition of low Si availability (Gérard, 2016). Contrary to Si, Ca bind P by calcium phosphate co-precipitation
77 with calcium carbonate, at least under high soil pH conditions (Otsuki and Wetzell, 1972). Like P, OM is also binding
78 to Ca, Fe and Al-phases (Kaiser and Zech, 1997; Wiseman and Püttmann, 2006) but being mobilized from those
79 phases by Si (Hömborg et al., 2020). If the Fe availability in soils is low, the binding of P may be related to Al-minerals
80 (Eriksson et al., 2015).

81 Despite the important role of soil elements in driving soil and ecosystem processes and the potential for rapid changes
82 in the Arctic due to climate change, the spatial distribution of elemental stocks (beyond C, N) is not well understood.
83 An ecologically based classification of soil Ca concentrations was proposed by Walker et al. (2001), differentiating
84 between a Ca rich non-acidic tundra and a Ca poor acidic tundra based on differences in vegetation types for the
85 Alaskan Arctic region. This classification system was further used to estimate pan-Arctic soil OM stocks (Hugelius et
86 al., 2014), which proved to be a useful approach as vegetation is tightly connected to OM stocks (Quideau et al., 2001).
87 Based on the work of Hugelius et al. (2014), Alfredsson et al. (2016) related vegetation cover to amorphous Si (ASi)
88 concentration to scale up Arctic ASi stocks. However, in contrast to OM stocks being clearly related to vegetation
89 (Hugelius et al., 2014), the effect of vegetation on mineral availability in soils is debatable. Therefore, the extrapolation
90 of circum-polar Arctic maps of element availability for P, Fe, Ca, Al, and Si based on vegetation distribution alone
91 may be associated with high uncertainties. A much stronger driver of element availability could be parent material
92 and lithology (Alloway, 2013).

93 In this study, we aim to map pan-Arctic soil element bio-availability (for microbes and plants) by applying a lithology-
94 based extrapolation of plot level sampling data on nutrient availability. We provide maps for ASi, Si, Ca, Fe, P and
95 Al as these elements have direct effects on OM binding and greenhouse gas (GHG) emission from the circumpolar
96 Arctic. In addition, these elements are limiting nutrients for CO_2 binding in terms of primary production in Arctic
97 marine systems or interfere with those. Better understanding of element availability is crucial to reduce uncertainties
98 for reliable modelling of future scenarios on how Arctic system may respond to global warming.

99 **2 Material and Methods**

100 **2.1 General approach**

101 Based on the Geological Map of the Arctic (Harrison et al., 2011), we estimate the bio-availability and potential
102 mobility of ASi, Si, Ca, Fe, Al and P in Arctic soils. We analyzed soil samples from organic, mineral and permafrost
103 layers from pan-Arctic sampling campaigns. We used the biological available element concentrations of certain
104 lithologies to compile pan-Arctic maps covering 7.6×10^6 km² for ASi, mineral Si, Ca, Fe, Al and P.

105

106 **2.2 Sampling and storage**

107 In total, we analyzed 574 Arctic soil samples from 25 locations (Fig. 1). To ensure a pan-Arctic coverage we analyzed
108 samples from Siberia (222 samples from six locations), North America (115 samples from six locations), Greenland
109 (111 samples from nine locations), Northern Europe (13 samples from one location) and Svalbard (103 samples from
110 three locations) (Fig. 1 and S1, Table S1). We analyzed samples from the thawed near-surface organic layer (252 soil
111 samples, mainly 0-20 cm in depth), mineral layer (208 soil samples, mainly 20-50 cm depth) and permafrost layer
112 (104 soil samples, mainly 50-100 cm depth). We split the annually thawed active layer in the upper organic layer and
113 the mineral layer below by C content, except for soils where the organic layer corresponds to the active layer. The
114 organic layer contained mainly organic matter (OM) in different mineralization states. The mineral soil layer has
115 variable OM content depending on which soil processes have affected this layer and reaches to the perennally frozen
116 permafrost layer. We took samples using an auger or a spade and stored them frozen until analysis or as described
117 before (Faucherre et al., 2018; Kuhry et al., 2020). Samples consisted of 5-50 g frozen soil. Before analysis, the
118 samples were oven dried and ground.

119

120 **2.3 Extraction and analysis**

121 Available concentrations of Si, Ca, Fe, Al and P were quantified using the Mehlich III method (Sims, 1989). Briefly,
122 we extracted 0.5 to 5 g of freeze-dried soil using 10 ml g⁻¹ Mehlich III solution (0.015 M NH₄F, 0.001 M EDTA,
123 0.25 M NH₄NO₃, 0.00325 M HNO₃, 0.2 M HAc). The samples were shaken for 5 min at 200 min⁻¹ and centrifuged
124 for 5 min at 10.000 x g. Afterwards, the supernatant was filtered using a 0.2 µm cellulose acetate filter. The analysis
125 was done by inductive coupled plasma with optical emission spectroscopy (ICP-OES) (Vista-PRO radial, Varian
126 Medical Systems, Palo Alto, California). For extraction of available amorphous silica (ASi) an alkaline extraction was
127 used (DeMaster 1981), extracting ASi from 30 mg of freeze-dried soil using 40 ml 0.1 M Na₂CO₃ solution at 85°C
128 for 5 h. After 1 h, 3 h and 5 h the suspension was mixed, and 10 ml of the supernatant was subsampled, filtered by a
129 0.2 µm cellulose acetate filter and analyzed by ICP-OES. The ASi concentration was calculated using a linear
130 regression of ASi concentration in solution over time and the intersection with the Y-axis was used as concentration
131 of available concentration according to DeMaster (1981). To determine the dry weight (DW) of the samples 0.5-2 g
132 of frozen material was freeze dried until weight constancy.

133

134 **2.4 Statistics**

135 **2.4.1 Statistics and graphics**

136 Data were analyzed using the R Studio (R_Core_Team, 2021). We extracted the original data (lithology, location,
137 geometry) given for GIS polygons (shape files from the different regions, Greenland, Can_USA, Ice,
138 N_Europa_Russia) of the Geological Map of the Arctic containing locations. We extracted 14 lithological classes in
139 total. We matched the soil sampling locations for which we obtained data for element availability by extraction (see
140 above) with the GIS polygons (geology) by ARCVIEW_GIS_3.2 extensions “Spatial Analyst” command “analysis:
141 tabulate Areas”. The sum of areas with the same map label was extracted by map label “shape area”. We considered
142 only terrestrial areas. For every location, we calculated the element concentrations for the different samples from
143 organic, mineral and permafrost layer. We calculated quantiles, mean and standard error using “summarise” from the
144 “dplyr” R package. We clustered element concentration data for all locations by lithological class and calculated mean
145 and standard error for organic, mineral and permafrost layer. The number of samples for each lithological class is
146 given in Fig. 1.
147

148 **2.4.2 Element concentration maps**

149 We used the “Geological Map of the Arctic (1:5 000 000 scale, in the Arctic polar region, north of latitude 60°N”) as
150 the basis for our maps. We calculated the weighted numeric mean concentration for each element in the first 100 cm
151 from the soil surface using formula (1). The mean mass fraction (w_m) of an element (X) is the sum of the products of
152 the mass fractions in organic (OL), mineral (ML) and permafrost (PL) layer and the thickness (d) of each layer in cm
153 divided by 100 cm. We colored the represented area based on the element concentration.

154
$$w_m(X) \left[\frac{mg}{g} \right] = \frac{(w_{OL}(X) \left[\frac{mg}{g} \right] * d_{OL} [m] + w_{ML}(X) \left[\frac{mg}{g} \right] * d_{ML} [m] + w_{PL}(X) \left[\frac{mg}{g} \right] * d_{PL} [m])}{100 [cm]} \quad (\text{eq. 1})$$

155 **3 Results**

156 **3.1 Geographical and lithological representation**

157 Our sampling locations represent 13 out of 17 original geographic domains (missing: North Asia and North America,
158 ice, none assigned), defined by the base map (76.5 %) (Table 1, Fig. S1 and Table S2) of the Arctic. The single areas
159 and shares for the maps of Canada/Alaska, Greenland and North Europe/Russia are given in Table S3. Our data
160 represent 17 eras of the Geological Map of the Arctic. The age ranged between 2.6 and 2,500 mya. The number of
161 samples per age code are shown in Fig S2. Our data represent 14 lithological classes of the “Geological Map of the
162 Arctic” (Table S4). These 14 lithological classes represent $7.63 \times 10^{12} \text{ m}^2$ out of $1.57 \times 10^{13} \text{ m}^2$ (48.49 % of the area
163 represented by the Geological Map of the Arctic, including ice sheets). Sediments cover $1.03 \times 10^{13} \text{ m}^2$ of the Arctic.
164 Our data represent sedimentary classes that cover $6.77 \times 10^{12} \text{ m}^2$ (65.9 % of the Arctic sediment cover) (Fig. S3). In
165 total $3.68 \times 10^{11} \text{ m}^2$ of $7.37 \times 10^{11} \text{ m}^2$ (49.9 %) of Yedoma deposits were represented (Fig. S4). The 14 lithological
166 classes can be observed in the igneous type (extrusive: mafic: class 1, n=26), type unclassified (Metamorphic
167 undivided: class 2, n=21) and the sedimentary type (Carbonate: class 3, n=24; class 4, n=58; class 5, n=64; Clastic:
168 shallow marine: class 6, n=13; Clastic: deltaic and nearshore: class 7, n=68; Sedimentary: undivided: class 8, n=38;
169 class 9, n=39; Clastic: shallow marine: class 10, n=91; class 11, n=60; Sedimentary and/or volcanic: undivided: class
170 12, n=21; and Slope and deep water: class 13, n=43; class 14, n=8).

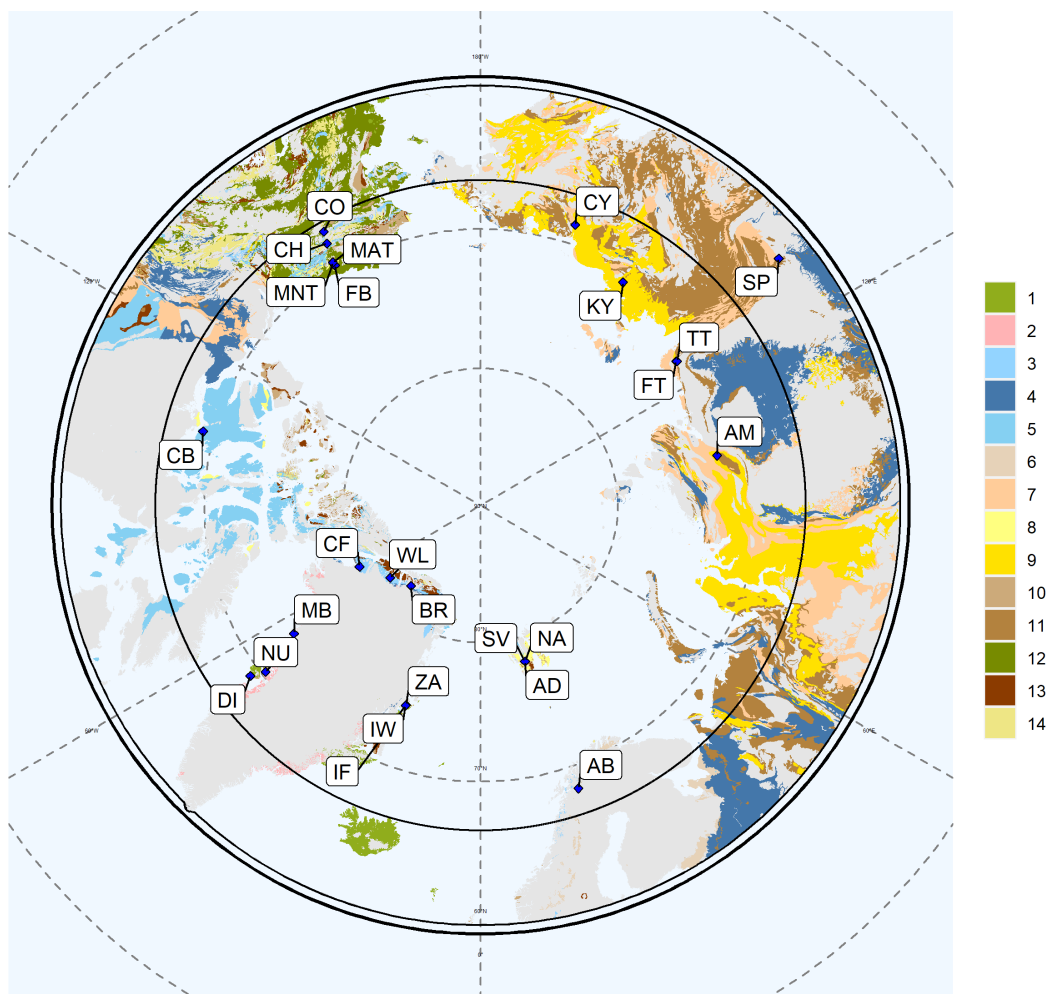

171 **Table 1:** First column lists original parameters given by the Geological Map of the Arctic (Harrison et al., 2011) and
 172 Yedoma deposits (Strauss et al., 2021b). The column “Represented” gives absolute numbers for chronological or
 173 lithological classes and of the area extrapolated by this study. For the area, relative share in comparison to total area
 174 given by original studies is given, too.

Parameter	Represented	Explanation	Example
Geographic domain	13 (76.5%)	“Phanerozoic regions are based on major physiographic features of the Arctic” (Harrison et al., 2011)	Interior western Alaska
Era	17 (2.6 – 2,500 mya)	“Standardization of map-unit attributes has been facilitated by the International Stratigraphic Chart (August 2009 version) published by the International Commission on Stratigraphy (ICS)” (Harrison et al., 2011)	Neogene (23.0 - 2.6 Ma)
Represented area	7.63×10 ¹² m ² (43.03%)	Area of the Geological Map of the Arctic (Harrison et al., 2011) containing own data to element concentrations (Fig. 3-8).	
Lithological class	14	Specification and examples of rock type	Lithological class 2: Gneiss, migmatite; reworked amphibolite and granulite facies rocks
Sediments	6.77×10 ¹² m ² (65.9%)	Areas with lithological classes of the sedimentary type	Lithological class 7: Sandstone, siltstone, shale, coal; plant fossils; metamorphic grade not identified
Yedoma deposition	3.68×10 ¹¹ m ² (49.9%)	Areas that contain Yedoma deposits defined by Strauss et al. (2021b)	

175

176

177

178

179 Fig. 1: Map of extrapolated element concentrations. The Arctic Circle (66.6°N) is included as a black circle. Each
180 color represents a bedrock lithology: 1: Basalt, olivine basalt, tholeiite, alkali basalt, basanite, pillow basalt, flood
181 basalt (n=26); 2: Gneiss, migmatite; reworked amphibolite and granulite facies rocks (n=11); 3: Limestone, dolostone,
182 shale, evaporites, chalk; carbonate reefs or metamorphosed equivalent (n=24); 4: Limestone, dolostone, shale,
183 evaporites, chalk; carbonate reefs; metamorphic grade not identified (n=58); 5: Limestone, dolostone, shale,
184 evaporites, chalk; carbonate reefs (n=64); 6: Quartz sandstone, siltstone, claystone, limestone, dolostone,
185 conglomerate, tillite (n=13); 7: Sandstone, siltstone, shale, coal; plant fossils; metamorphic grade not identified
186 (n=68); 8: Sandstone, siltstone, shale, limestone (n=38); 9: Sandstone, siltstone, shale, limestone; metamorphic grade

187 not identified (n=39); 10: Sandstone, siltstone, shale; marine fossils (n=91); 11: Sandstone, siltstone, shale; marine
188 fossils; metamorphic grade not identified (n=60); 12: Sedimentary and/or volcanic rock: undivided (n=21); 13: Shale,
189 chert, iron-formation, greywacke, turbidite, argillaceous limestone, matrix-supported conglomerate (n=43); 14: Shale,
190 chert, iron-formation, greywacke, turbidite, argillaceous limestone, matrix-supported conglomerate or
191 metamorphosed equivalent (n=8). Grey color means areas of base map that are not represented by our data on element
192 concentrations. Abbreviations for locations: CH: Alaska, Chandalar; CO: Alaska, Coldfoot; FB: Alaska, Franklin
193 Bluff-Dry; MAT: Alaska, Moist acidic tundra; MNT: Alaska, Moist non-acidic tundra; CB: Canada, Cambridge Bay;
194 BR: Greenland, Brønlund; CF: Greenland, Cass Fjord; DI: Greenland, Disko; MB: Greenland, Melville Bay; NU:
195 Greenland, Nussuaq; WL: Greenland, Warming Land; ZA: Greenland, Zackenberg; IW: Greenland, Zackenberg, Ice
196 Wedge; IF: Greenland, Zackenberg, Infilling Fan; AM: Russia, Ary-Mas; CY: Russia, Chersky; KY: Russia, Kytalyk;
197 FT: Russia, Lena delta, first terrace; TT: Russia, Lena Delta, third terrace; SP: Russia, Spasskaya; AB: Sweden,
198 Abisko; AD: Svalbard, Adventalen; NA: Svalbard, Adventalen; SV: Svalbard. This map is based on the Geological
199 Map of the Arctic (Harrison et al., 2011).
200

201 3.2 Element availabilities across lithological classes at 0-1 m depth

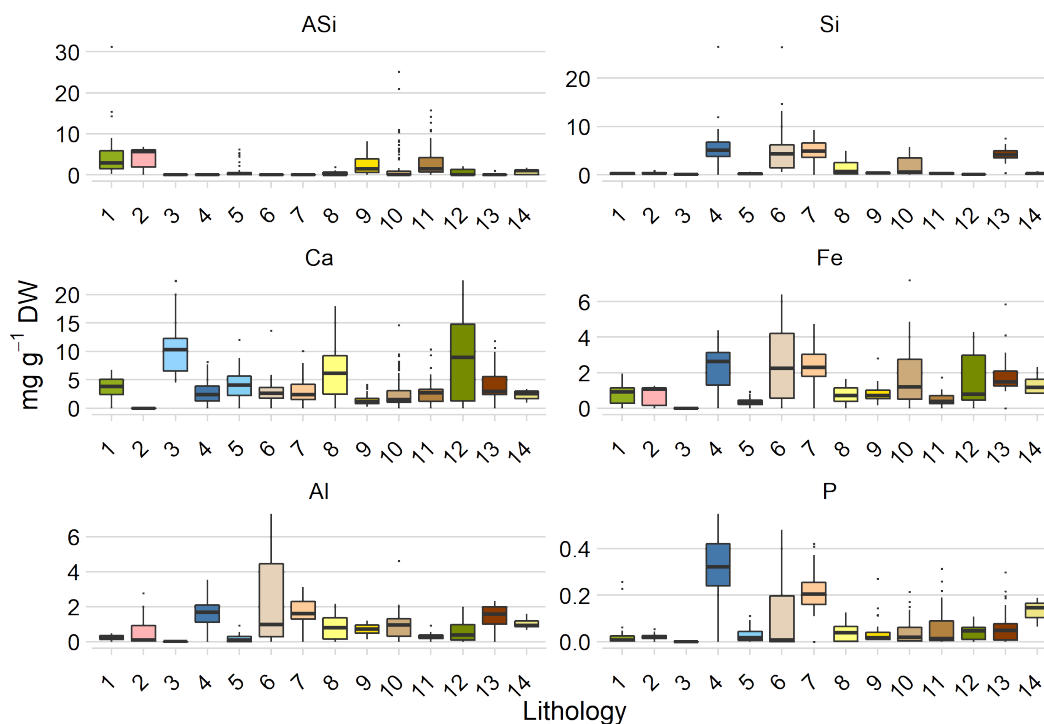

202 The lithological classes differed substantially in their element availabilities (Fig. 2; Fig S5):

- 203 • We found a large range in **ASi concentrations** in the Arctic covering values from 0.03 ± 0 mg g⁻¹ DW ASi to
204 6.68 ± 1.17 mg g⁻¹ DW ASi. The highest concentrations of ASi were found in basalt and associated rock (class 1:
205 6.68 ± 1.17 mg g⁻¹ DW ASi), Gneiss and associated rock (class 2: 4.11 ± 1.24 mg g⁻¹ DW ASi), Sandstone and
206 associated rock (class 9: 2.01 ± 0.24 mg g⁻¹ DW ASi. class 10: 2.06 ± 0.01 mg g⁻¹ DW ASi). ASi concentrations
207 were lowest in Limestone (class 3: 0.03 ± 0 mg g⁻¹ DW ASi) (Fig. 2).
- 208 • **Si concentrations** were highest in Limestone and associated rock including shale (class 4: 5.65 ± 0.78 mg g⁻¹
209 DW Si), Quartz sandstone (class 6: 6.61 ± 1.83 mg g⁻¹ DW Si) and Sandstone (class 7: 5.46 ± 0.66 mg g⁻¹
210 DW Si). Si concentrations were lowest in Limestone and associated rock (class 3: 0.1 ± 0.02 mg g⁻¹ DW Si)
211 (Fig. 2).
- 212 • The highest **Ca concentrations** were observed in Limestone and associated rock (class 3: 10.73 ± 2.15 mg g⁻¹
213 DW Ca), Sedimentary and/or volcanic rock (class 12: 8.77 ± 0.12 mg g⁻¹ DW Ca) and Sandstone and associated
214 rock (class 8: 8.06 ± 0.36 mg g⁻¹ DW Ca). Ca concentrations were lowest in Gneiss (class 2: 0.05 ± 0.02 mg g⁻¹
215 DW Ca) (Fig. 2).
- 216 • **Fe concentrations** were highest in shale and associated rock (class 13: 2.93 ± 0.45 mg g⁻¹ DW Fe), Limestone
217 (class 4: 2.28 ± 0.32 mg g⁻¹ DW Fe) and Quartz sandstone (class 6: 2.49 ± 0.69 mg g⁻¹ DW Fe). The lowest Fe
218 concentrations were observed in lithological Limestone and associated rock (class 3: 0.01 ± 0.001 mg g⁻¹ DW Fe)
219 (Fig. 2).
- 220 • The highest **concentrations of Al** were observed in to quartz sandstone (class 6: 2.52 ± 0.70 mg g⁻¹ DW Al),
221 Sandstone (class 7: 1.63 ± 0.20 mg g⁻¹ DW Al) and shale and associated rock (class 13: 1.5 ± 0.23 mg g⁻¹ DW Al).
222 The lowest Al concentrations were observed in limestone and associated rock (class 3: 0.02 ± 0 mg g⁻¹ DW Al)
223 (Fig. 2).
- 224 • High **P concentrations** were observed in limestone and associated rock (class 4: 0.31 ± 0.04 mg g⁻¹ DW P),
225 Sandstone (class 7: 0.19 ± 0.02 mg g⁻¹ DW P) and Shale and associated rock (class 14: 0.15 ± 0.05 mg g⁻¹ DW P).
226 P concentrations were lowest in Basalt and associated rock (class 1: 0.0116 ± 0.002 mg g⁻¹ DW P) (Fig. 2).

227

228

229

230 Fig. 2: Element concentrations related to lithology. Each color represents a bedrock lithology: 1: Basalt, olivine basalt,
 231 tholeiite, alkali basalt, basanite, pillow basalt, flood basalt (n=26); 2: Gneiss, migmatite; reworked amphibolite and
 232 granulite facies rocks (n=11); 3: Limestone, dolostone, shale, evaporites, chalk; carbonate reefs or metamorphosed
 233 equivalent (n=24); 4: Limestone, dolostone, shale, evaporites, chalk; carbonate reefs; metamorphic grade not
 234 identified (n=58); 5: Limestone, dolostone, shale, evaporites, chalk; carbonate reefs (n=64); 6: Quartz sandstone,
 235 siltstone, claystone, limestone, dolostone, conglomerate, tillite (n=13); 7: Sandstone, siltstone, shale, coal; plant
 236 fossils; metamorphic grade not identified (n=68); 8: Sandstone, siltstone, shale, limestone (n=38); 9: Sandstone,
 237 siltstone, shale, limestone; metamorphic grade not identified (n=39); 10: Sandstone, siltstone, shale; marine fossils
 238 (n=91); 11: Sandstone, siltstone, shale; marine fossils; metamorphic grade not identified (n=60); 12: Sedimentary
 239 and/or volcanic rock: undivided (n=21); 13: Shale, chert, iron-formation, greywacke, turbidite, argillaceous limestone,
 240 matrix-supported conglomerate (n=43); 14: Shale, chert, iron-formation, greywacke, turbidite, argillaceous limestone,
 241 matrix-supported conglomerate or metamorphosed equivalent (n=8). All values are given in mean and standard error.
 242 The distribution of the lithological classes is shown in Fig. 1, the assignment to the geographic domain is given in
 243 Table S5.

244

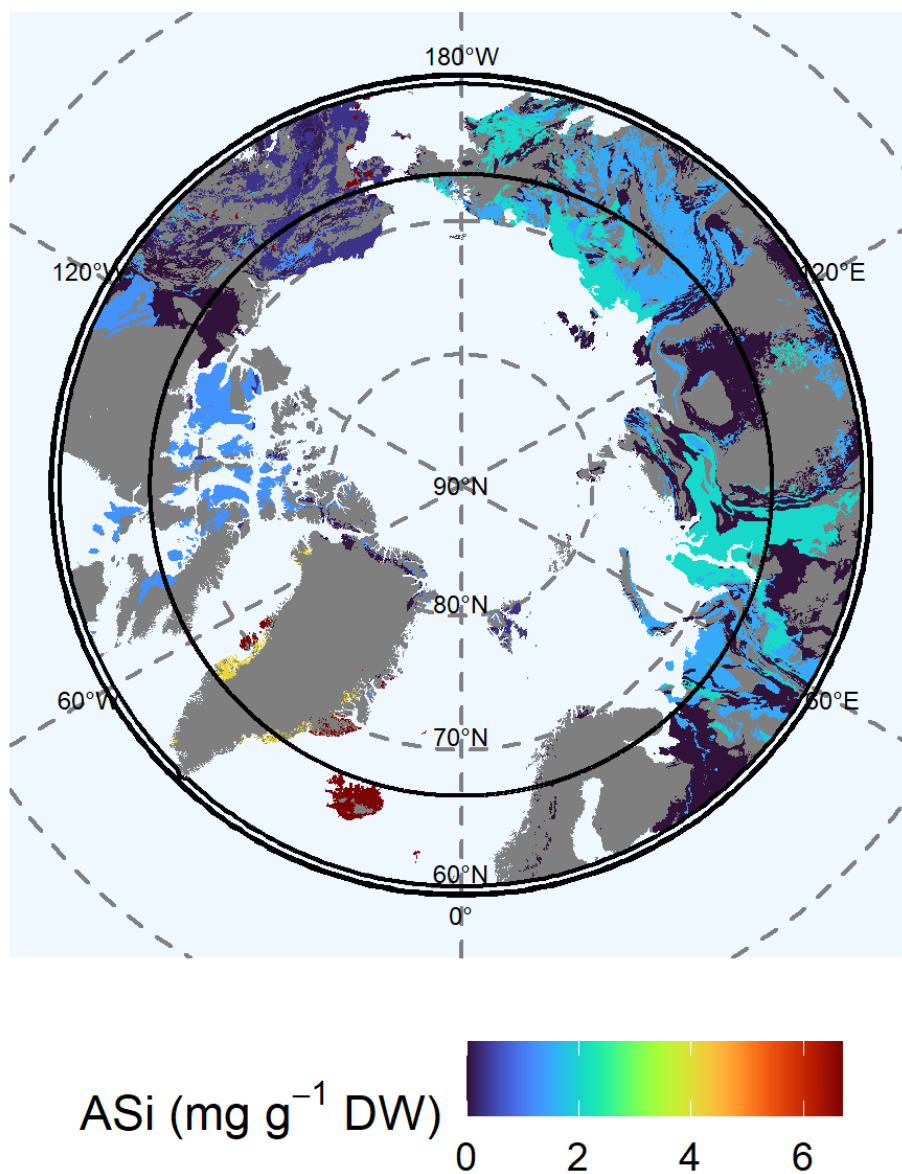

245 **3.3 Maps of element concentration in 1 m depth**

246 **3.3.1 Amorphous silica in top 1 m**

247 We found the highest concentrations of ASi located in the Arctic-North Atlantic region (Fig. 3). Here, mafic basalt
248 and metamorphic Gneiss are dominant (lithological class 1 and 2) and contained concentrations of 4.11 ± 1.24 to
249 6.68 ± 1.17 mg ASi g-1DW. Other high concentrations of ASi were found for the Brooks Range (Alaska), Chukotka,
250 Arctic Shelf (eastern Siberia) and the West Siberian Basin. Those soil contained 2.01 ± 0.24 mg ASi g-1 DW
251 (lithological class 9). The Verkhoyansk-Kolyma region showed a lower concentration of 1.48 ± 0.16 mg ASi g-1DW
252 (lithological class 11). We found similar concentrations (1.24 ± 0.14 mg ASi g-1DW; lithological class 5) were found
253 for the Canadian Shield. We found low concentrations of 0.31 ± 0.01 mg ASi g-1 DW (lithological class 12) in interior
254 western Alaska and western parts of Brooks Range, Alaska, Chukotka and Arctic Shelf. Increasing active layer depth
255 will potentially release higher ASi concentrations from permafrost soils (Fig. S6) in the Canadian Shield as the
256 concentration in the permafrost layer is 2.80 ± 2.50 mg ASi g-1DW (lithological class 5) compared to the
257 1.24 ± 0.14 mg ASi g-1DW in the current active layer (Table S4). A further increase in ASi concentration can be
258 expected for the Arctic, North-Atlantic region by permafrost thaw as the concentration is 8.68 ± 2.51 mg ASi g-1DW
259 in the permafrost layer compared to the 4.11 ± 1.24 ASi g-1DW of the current active layer (lithological class 1)
260 (Fig. S6 Table S4). However, the permafrost layer in Siberia contains lower concentrations of ASi
261 (0.77 ± 0.23 mg ASi g-1DW, lithological class 9 and 1.38 ± 0.28 mg ASi g-1DW, lithological class 11) compared to the
262 current active layer with 2.01 ± 0.24 mg ASi g-1DW (lithological class 9) and 1.48 ± 0.16 mg ASi g-1DW (lithological
263 class 11) probably leading to lower overall ASi concentrations with proceeding thaw.

264

265

266 Fig. 3: Map of mean concentration of amorphous silica (ASi) in the top 100 cm of soils. For each lithological class
267 the mean concentration is shown. Grey shaded areas are not represented by our data.

268 **3.3.2 Silicon in 0-1 m depth**

269 Available Si (Fig. 4) showed a different distribution than ASi (Fig. 3). High Si concentrations were generally
270 associated with sediments. We found high concentrations (5.65 ± 0.78 mg Si g⁻¹ DW) for lithological class 4, the
271 West Siberian basin and the Siberian plain. Other regions with high Si concentrations were the East European plain,
272 the Ural Mountains and the Canadian Shield. Another lithological class with high Si concentrations ($4.51 \pm$
273 0.69 mg Si g⁻¹ DW) is class 13, located in the Innuitian Region, North Greenland and in Alaska. In Alaska lithological
274 class 10 with moderate high concentrations of Si (2.06 ± 0.03 mg Si g⁻¹ DW) is also abundant. We found low
275 concentration of Si (0.36 ± 0.05 mg Si g⁻¹ DW, lithological class 9) for Brooks Range, Chukotka, Arctic shelf, the
276 West Siberia Basin and the Siberian Plain. In addition, the Verkhoyansk-Kolyma-Region and the East-European Plain
277 and the Ural Mountains were poor in Si (0.39 ± 0.04 mg Si g⁻¹ DW, lithological class 11). Lowest concentrations
278 (0.15 ± 0.01 mg Si g⁻¹ DW, lithological class 12) were observed in Interior Western Alaska. Increasing thawing depth
279 may potentially increase Si concentrations in the western Verkhoyansk-Kolyma-Region to the east European Platform
280 as the concentration in the permafrost layer is 6.26 ± 1.52 mg Si g⁻¹ DW (lithological class 4) compared to the lower Si
281 concentration of the current active layer with 5.56 ± 0.78 mg Si g⁻¹ DW (lithological class 4) (Figure S6, Table S4).

282

283

Si (mg g^{-1} DW)

284

286 class the mean concentration is shown. Blue colors represent low concentrations of Si; red colors represent high
287 concentrations. Grey shaded areas are not represented by our data.

288 3.3.3 Calcium in 0-1m depth

289 The highest Ca concentrations in soils was in limestone and associated rock (class 3: 10.73 ± 2.15 mg Ca g⁻¹ DW) in
290 North Greenland, Alaska and the Canadian Shield (3.79 ± 0.45 mg Ca g⁻¹ DW, lithological class 5) (Fig. 5). In
291 addition, supracrustal rocks in Alaska contained very high concentrations of Ca (8.77 ± 0.12 mg Ca g⁻¹ DW,
292 lithological class 12). Mafic rocks in the Arctic North Atlantic region (3.65 ± 0.70 mg Ca g⁻¹ DW, lithological class
293 1) contained moderate Ca concentrations. We found moderate to low Ca concentrations (2.88 ± 0.32 mg Ca g⁻¹ DW,
294 lithological class 11) for the soils of the Verkhoyansk-Kolyma-Region, the East European Plain and the Ural
295 Mountains. Large regions of eastern and western Siberia and the Siberian Plain were poor in Ca (1.51 ± 0.14 mg Ca g⁻¹
296 DW, lithological class 9; 2.56 ± 0.34 mg Ca g⁻¹ DW, lithological class 4). The Ca concentrations of the permafrost
297 layer for Alaska (10.42 ± 2.08 mg Ca g⁻¹ DW, lithological class 12) is higher than in the active layer
298 (2.93 ± 0.45 mg Ca g⁻¹ DW) (Fig. S6). In the largest part of Siberia and the Canadian Shield the Ca concentrations are
299 slightly lower in the permafrost layer with 2.15 ± 0.96 mg Ca g⁻¹ DW (lithological class 4) and 1.59 ± 0.32 mg Ca g⁻¹
300 DW, lithological class 7) than in the active layer with 2.56 ± 0.34 mg Ca g⁻¹ DW (lithological class 4) and $1.51 \pm$
301 0.14 mg Ca g⁻¹ DW, lithological class 7) (Figure S6, Table S4).

Ca (mg g^{-1} DW)

302

303 Fig. 5: Map of mean concentration of mineral calcium (Ca) for the uppermost 100 cm of soils. For each lithological
304 class the mean concentration is shown. Blue colors represent low concentrations of Ca, red colors represent high
305 concentrations. Grey shaded areas are not represented by our data.

306

307 **3.3.4 Iron (Fe) in 0-1 m depth**

308 Fe concentrations were higher in the eastern Arctic, than in the western Arctic (Fig. 6). We found highest
309 concentrations in northern Greenland (lithological class 13 contained 2.93 ± 0.45 mg Fe g⁻¹ DW). The soils of the
310 lithological class 4 in the western Siberian Basin, Siberian and Canadian plain contained 2.28 ± 0.32 mg Fe g⁻¹ DW.
311 The Verkhoyansk-Kolyma region showed similar Fe concentrations (2.21 ± 0.27 mg Fe g⁻¹ DW, lithological class 7).
312 Moderate to high Fe concentration we found for igneous mafic rocks in Iceland and Greenland (0.94 ± 0.18 mg Fe g-
313 1 DW, lithological class 1) and for supracrustal rocks in Alaska (1.24 ± 0.14 mg Fe g⁻¹ DW, lithological class 12).
314 The Chukotka region and western Siberia were relatively poor in Fe (0.83 ± 0.13 mg Fe g⁻¹ DW, lithological class 9).
315 Eastern Siberia and North Europe contained even lower Fe concentrations (0.49 ± 0.04 mg Fe g⁻¹ DW, lithological
316 class 11). Fe concentrations in the Canadian Shield were similarly low (0.41 ± 0.06 mg Fe g⁻¹ DW, lithological class
317 12). We expect increasing Fe concentrations at the Canada and Greenland shield due to predicted future thaw of the
318 permafrost layer as the concentration in the permafrost layer (0.61 ± 0.15 mg Fe g⁻¹ DW, lithological class 5) and in
319 parts of Alaska (1.97 ± 0.3 mg Fe g⁻¹ DW, lithological class 14) is higher compared to the current active layer with
320 (0.41 ± 0.05 mg Fe g⁻¹ DW, lithological class 5) and in parts of Alaska (1.08 ± 0.38 mg Fe g⁻¹ DW, lithological class
321 14) (Fig. S7, Table S4).

322

323 Fig. 6: Map of mean concentration of mineral iron (Fe) for the uppermost 100 cm of soils. For each lithological class
324 the mean concentration is shown. Blue colors represent low concentrations of Fe, red colors represent high
325 concentrations. Grey shaded areas are not represented by our data.

326 3.3.5 Aluminum in 0-1 m depth

327 Northern Europe contained highest concentrations of available Al (2.52 ± 0.07 mg Al g⁻¹ DW, lithological class 6)
328 (Fig. 7). Relative high concentrations of Al were distributed over Siberia and the Canadian Shield ($1.63 \pm$
329 0.02 mg Al g⁻¹ DW, lithological class 7; 1.57 ± 0.22 mg Al g⁻¹ DW lithological class 4). Parts of Alaska contained
330 moderate Al concentrations (0.94 ± 0.06 mg Al g⁻¹ DW, lithological class 10; 1.5 ± 0.23 mg Al g⁻¹ DW, lithological
331 class 13), while areas represented by supracrustal rocks were poor in Al (0.47 ± 0.06 mg Al g⁻¹ DW, lithological class
332 12). We found relative low concentrations (0.73 ± 0.01 mg g⁻¹ DW) of Al for Chukotka, eastern and western Siberia
333 observed in lithological class 9. The Verkhoyansk-Kolyma Region and the East European plain showed the lowest Al
334 concentrations (0.26 ± 0.02 mg Al g⁻¹ DW, lithological class 11), together with the Canada plain (0.21 ± 0.03 mg g-
335 1 DW Al, lithological class 5). Increasing thawing depth may increase the Al concentration by the predicted thaw of
336 the permafrost layer in North Europe as the concentration in the permafrost layer is 4.88 ± 1.02 mg Al g⁻¹ DW
337 (lithological class 6) and across the Greenland and Canadian shield it is 0.3 ± 0.07 mg Al g⁻¹ DW (lithological class
338 5) compared to the current active layer with 2.52 ± 0.7 mg Al g⁻¹ DW (lithological class 6) and across the Greenland
339 and Canadian shield it is 0.21 ± 0.03 mg Al g⁻¹ DW (lithological class 5) (Fig. S7, Table S4).

Al (mg g^{-1} DW)

0.5 1.0 1.5 2.0 2.5

340

341 Fig. 7: Map of mean concentration of mineral aluminum (Al) for the uppermost 100 cm of soils. For each lithological
342 class the mean concentration is shown. Blue colors represent low concentrations of Al, red colors represent high
343 concentrations. Grey shaded areas are not represented by our data .

344 3.3.6 Phosphorous in 0-1 m depth

345 We found the highest P concentrations we found for the West Siberian Basin, the Canadian Shield and the Siberian
346 and East European Plain (0.306 ± 0.042 mg P g⁻¹ DW, lithological class 4) (Fig. 8). In the Chukotka region the P
347 concentrations were 0.189 ± 0.023 mg P g⁻¹ DW (lithological class 7. We found moderate P concentration for
348 Northern Europe (0.123 ± 0.034 mg P g⁻¹ DW, lithological class 6) and in Alaska (0.153 ± 0.054 mg P g⁻¹ DW,
349 lithological class 14). Wide areas of supracrustal rocks in Alaska were poor in P (0.024 ± 0.004 mg P g⁻¹ DW,
350 lithological class 12). The Canadian shield (0.037 ± 0.005 mg P g⁻¹ DW, lithological class 5), the Verkhoyansk-
351 Kolyma region, the east European Plain (0.017 ± 0.002 mg P g⁻¹ DW, lithological class 11) and the Chukotka region
352 (0.030 ± 0.003 mg P g⁻¹ DW, lithological class 9) were poor in P. Due to permafrost thaw we expect increasing P
353 concentrations the Canadian shield as the P concentrations in the permafrost layer is 0.06 ± 0.01 mg P g⁻¹ DW
354 (lithological class 5) compared to the current active layer with 0.04 ± 0.005 mg P g⁻¹ DW (lithological class 5) (Fig. 7,
355 Table S4).

356

357 Fig. 8: Map of mean concentration of mineral phosphorous (P) for the uppermost 100 cm of soils. For each
358 lithological class the mean concentration is shown. Blue colors represent low concentrations of P, red colors
359 represent high concentrations. Grey shaded areas are not represented by our data .

360 **4 Discussion**

361 **4.1 Element availability in relation to lithology and geography**

362 We found large differences in the availability of all analysed elements between the different lithology classes of the
363 Arctic. The igneous lithological type for example is dominated by alkaline and Ca-rich basaltic rocks from Alaska.
364 Rocks built up by sedimentation are often more complex or variable in their chemical composition than igneous rocks.
365 Sedimentary rocks cover a wide range of pH, as the parent material is more diverse. Limestone sediments for example
366 differ in their content of Fe and P, depending if their origin is biological (lithological class 4), physical or chemical.
367 Sandstone can contain high Fe concentrations, too, but it contains Si as the main element (lithological class 7-8)
368 (Yurchenko et al., 2019). Previously, there was no map existing for availability of Si, Ca, Fe, P, and Al in Arctic soils,
369 and only a map on ASi stocks but not concentrations. Our maps show element concentration available for plants and
370 microbes together. We further show what changes in element availability will occur during permafrost thaw and we
371 discuss these changes in element availability in regard to occurring nutrient limitations and Arctic C-fluxes.
372

373 **4.2 Relevance of element availability in a dynamic Arctic**

374 Low temperatures in the Arctic systems slow down biological and chemical processes and preserve OM for millennia
375 (Sher et al., 2005). Due to Arctic warming these processes are accelerated by an increased nutrient and OM
376 mobilization from the permafrost (Salmon et al., 2016). Consequently, OM may become vulnerable to respiration
377 (Hugelius et al., 2020; Strauss et al., 2017). However, OM is not the single driving force regarding the acceleration of
378 Arctic soil respiration. Elements like Si, Ca, Fe, P and Al may also interfere this process (Monhonval et al., 2021a;
379 Monhonval et al., 2021b).
380 Nutrient cycles and limitations were identified as important for improving of high latitude ecosystems estimations
381 vegetation functional parameter like gross primary production (GPP) (Chadburn et al., 2017). The dataset presented
382 in our study could therefore serve as a basis for providing soil nutrient concentrations for biogeochemical models that
383 are capable of considering nutrient limitations in permafrost ecosystems. Our maps cover nearly the half of the Arctic
384 area. The distribution of ASi in Arctic regions was first estimated by Alfredsson et al. (2016). Alfredsson et al. (2016)
385 showed maps of ASi stocks (not concentrations) related to vegetation cover, covering 30 soil profiles. The effect of
386 current vegetation on mineral availability in soils is low and associated with high uncertainties as the vegetation
387 involved in forming the soil ASi pool may be different. A more appropriate measure of element availability may be
388 parent material and lithology (Alloway, 2013). It was shown, that geochemical element concentration in Arctic
389 permafrost soil allow to distinguish geologies (Reimann and Melezchik, 2001). Consequently, our lithology-based
390 extrapolation of nutrient availability will help to reduce the so far uncertainties in pan-Arctic soil element availability.
391 Due to deepening of the active layer, as for example observed at the Canadian shield and in the North-Atlantic region,
392 our data suggest higher ASi concentrations, as the concentration in the permafrost layer is higher compared to
393 shallower soil layers (Fig. S6). This may increase P and OM availability (Reithmaier et al., 2017; Schaller et al., 2019)
394 by competing for binding sites on the surface of minerals subsequently mobilizing both P and OM, potentially
395 increasing the leaching of both to the sea. It was also shown that Si leads to a release of P from minerals of Arctic

396 soils and increases OM decomposition, increasing soil greenhouse gas release (Schaller et al., 2019). Ca can
397 immobilize OM by cation bridging and by this preserve OM from microbial decomposition (Sowers et al., 2020). Ca
398 reduces the osmotic stress for microbes (Läuchli and Grattan, 2007) by decreasing the freezing point of water and
399 increasing the availability of liquid pore water (Jessen et al., 2014). Ca is relevant for the mineral formation because
400 it can bind CO₂ as Ca(HCO₃)₂ in soil with pH higher than 7 (Dessert et al., 2003; Köhler et al., 2010). The
401 concentration of soluble Ca in Yedoma soils is mainly driven by thermokarst processes. In deeper soil layers, Ca
402 concentrations are usually lower than in upper layers. Consequently, a future increase in temperatures may lead to a
403 widespread decrease in Ca concentrations, especially in the Yedoma regions. Fe is also of high importance for
404 ecosystems as it is a key element in microbial activity (Colombo et al., 2014) and nitrogen fixation (Jasniewski et al.,
405 2019). Fe minerals are important electron acceptors under anaerobic conditions and Fe is essential for microbial
406 methane production (Colombo et al., 2018). After being released from rocks by weathering, Al forms amorphous
407 aluminosilicates that mineralizes slowly (Schaller et al., 2021). Al is relevant for the OM respiration due to its high
408 cytotoxicity to organisms (Rengel, 2004). Thawing permafrost may be a source for Al, especially across Canada, the
409 Greenland shield and Northern Europe. Increasing P availability, as predicted for Greenland and the Canadian shield
410 (Fig. 7) may for example increase CO₂ release to the atmosphere by increasing the mineralization rates of OM (Street
411 et al., 2018; Yang et al., 2021).
412

413 **4.3 Importance of element interactions for nutrient availability**

414 In permafrost layers, the mineralization of OM by microbial activity is negligible due to frozen conditions. Like in
415 temperate soils, binding of OM on mineral phases can prevent OM from mineralization (Dutta et al., 2006; Mueller et
416 al., 2015). Mineral phases may bind parts of soil OM reducing the amount of OM for microbial respiration. A large
417 share of OM may be associated with iron and aluminium oxides/hydroxides. In particular iron minerals may strongly
418 bind OM, whereby a high stability of stored carbon is likely (Herndon et al., 2017). Thereby the binding between OM
419 and the minerals is determined by the quantity of minerals that can bind OM (Wiseman and Püttmann, 2006). This
420 would imply that a higher concentration of Fe, Al and Ca in Arctic soils due to permafrost thaw may lead to a lower
421 GHG emission from Arctic soils due to complexation of OM with those elements. Such increase in element availability
422 binding OM and with this resulting in potentially lower GHG emissions may happen for Alaska (higher Ca and Fe
423 concentration in permafrost layer compared to current active layer), Canadian Shield and Greenland (higher Fe and
424 Al concentration in permafrost layer compared to current active layer), and North Europe (higher Al concentration in
425 permafrost layer compared to current active layer) (see results part). However, lower Ca concentrations can be
426 expected in large parts of Siberia and the Canadian Shield, as the concentrations in the permafrost layer are lower
427 compared to the current active layer. Si however, can potentially mobilize OM from those phases, by binding
428 competition of silicic acid with some functional groups of organic material (Hömberg et al., 2020), potentially
429 increasing GHG emissions. An increase in Si availability upon permafrost thaw can be expected in the western
430 Verkhoyansk-Kolyma-Region to the east European Platform as the concentration in the permafrost layer is higher
431 compared to the current active layer (see results part). P competes with OM for binding on soil minerals (Schneider

432 et al., 2010). Such increasing P concentration due to permafrost thaw can be expected for the Canadian Shield (results
433 part). Based on the differences in element (Si, Fe, Al, Ca and P) concentration, the stability of OM differs in Arctic
434 regions, depending on the dominating mineral composition, lithology and element availability. Also the availability
435 of nutrients (P in this case) is modified by mineral composition. For example, P is often strongly bound to Fe mineral
436 phases, reducing P availability (Gérard, 2016). Si however, is able to mobilize P from strong binding to Fe mineral by
437 competing for binding sites (Schaller et al., 2019). Unlike Si, Ca binds P by calcium phosphate precipitation at alkaline
438 conditions (Cao and Harris, 2008) or as calcium carbonate/phosphate co-precipitation (Otsuki and Wetzels, 1972).
439 Under conditions of low Fe availability in soils, the binding of P may be related to Al-minerals (Eriksson et al., 2015).
440 A lack of available P leads also to a reduction of the physiological activity of microbes (Walker et al., 2001), thus
441 potentially reducing microbial respiration of OM. Free Si seems limit the availability of ions like Fe, Al, or Ca by
442 precipitating those elements in amorphous or crystalline phases (Schaller et al., 2021). Hence, the mobilization of
443 elements like Si, Ca, Fe and Al strongly interfere with both P and OM availability and thus potentially with GHG
444 emissions. To unravel the dominant processes upon permafrost thaw, or which element mobilization is dominant in
445 terms of OM binding or mobilization and with this affecting GHG emission, future studies are urgently needed.
446

447 **4.4 Transport of elements to the Arctic Ocean**

448 With the ongoing deepening of the active layer in Arctic soils, an increased leaching of elements and nutrients may
449 occur (Mann et al., 2022; Sanders et al., 2022), which may substantially impact marine biodiversity and ecosystem
450 function. We have shown for several regions of the Arctic that there will be regional differences in element
451 mobilization upon permafrost thaw. For example, increased export of Fe and P, which are the main limiting nutrients
452 for marine net primary production (NPP; Zabel and Schulz (2006)), has already contributed to a 30% increase in NPP
453 in the Arctic Ocean between 1998 and 2009 (Arrigo and van Dijken, 2011). Increased Fe concentration upon
454 permafrost thaw can be expected for the Canadian Shield, Greenland and Alaska, whereas increased P mobilization
455 may occur only in the Canadian Shield. Si and Ca also have a crucial role in marine primary production. Both elements
456 are components of the inorganic spheres of diatoms (Si) and coccolithophores (Ca), which fix CO₂ in the Arctic
457 Ocean, an important global carbon sink (Krause et al., 2018). At the Arctic Canadian coast, Si inputs led to an increase
458 of diatoms from 2 % to 37 % (Terhaar et al., 2021). Diatoms and coccolithophores are the basis of the marine food
459 chain, and therefore, shifts in their populations may have widespread implications for the marine ecosystem (Daniels
460 et al., 2018). Permafrost thaw is likely to accelerate inputs of Si and Ca to Arctic waters. Increased Si concentration
461 can be expected in the western Verkhoyansk-Kolyma-Region to the east European Platform as the concentration in
462 the permafrost layer is higher compared to the current active layer, (see Results section). Ca mobilization may increase
463 or decrease depending on the Arctic region. Increase Ca mobilization can be expected for Alaska, whereas a slight
464 decrease in Ca mobilization may occur in large parts of Siberia and the Canadian Shield (see Results section). Yedoma
465 deposits readily leach soluble ions, including Si and Ca, as a result of thaw degradation (Strauss et al., 2017). Alaskan
466 soils store huge amounts of Ca in the mineral layer (see above) that could be transported to the Beringia Sea with
467 increasing soil degradation, promoting the growth of coccolithophores. In Siberia, the Lena River could transport large

468 amounts of Si to the Laptev Sea increasing the growth of diatoms. The same could happen at the East European plain.
469 In the same way P concentrations in these regions of the Arctic Sea could rise, too, as P concentrations in the
470 permafrost layer of the Canadian Shield are higher compared with the current active layer (see results part). In
471 summary, in the many areas of the Arctic with high Si, Ca and P storage, there could be increased inputs to Arctic
472 waters with permafrost thaw potentially increasing CO₂ fixation by marine primary production.
473

474 **5 Data availability**

475 The data for element availability from all single locations, soil profiles, transects, lithology's, as well as bootstrap data
476 for location and lithology can be can be downloaded via the open-access MPG repository EDMONT under
477 <https://doi.org/10.17617/3.8KGQUN> (Schaller and Göckede, 2022). During review process, the data is available
478 under: <https://edmond.mpdl.mpg.de/privateurl.xhtml?token=8cbb0bd8-790f-4719-8cd1-a3df4ff99477> (Schaller and
479 Göckede, 2022) to allow corrections based on reviewer comments. The repository contains a readme file ("Read
480 me.docx"). In this file, all necessary information can be found, including all columns descriptions need to use the data.
481 The element availability from all single locations, soil profiles, transects, lithology's labelled (loction_samples.txt)
482 with following parameters: geological map of the Arctic, individual ID of the polygon, official name of the sampling
483 site, study internal name of the soil sample, soil horizon, coordinates of sampling sites, concentration of alkaline
484 extractable silicon, Mehlich-3 extractable Si, Ca, Fe Al and P, thickness of the layer, original depth where soil was
485 taken, size of the polygon that contains the sampling site, age code, scientific name of the age, where bedrock was
486 formed, scientific name of the eon, where bedrock was formed, scientific name of the era, where bedrock was formed,
487 scientific name of the period, where bedrock was formed, maximal and minimal age of bedrock, information if
488 lithogenesis was of the supracrustal, sedimentary or igneous type, most common rock types in the cluster group of the
489 setting, code of metamorphic type, code of domain region, name of tectonic and geographic domain, as well as name
490 of region within geographic domain.
491 In the location_bootstrap.txt file the bootstrapped means of concentration of alkaline extractable silicon, Mehlich-3
492 extractable Si, Ca, Fe Al and P for the organic, mineral active and permafrost layer of the single locations are given
493 in mg/g DW.
494 In the file "lithology_bootstrap.txt" element concentration for the first 1 m, including organic, mineral and permafrost
495 layer are given as bootstrapped mean with standard deviation for alkaline extractable silicon as well as Mehlich-3
496 extractable Si, Ca, Fe Al and P.
497

498 **6 Conclusion**

499 Here, we identified large differences in Si, Ca, Fe, P, and Al availability between different Arctic regions. With the
500 future projected warming of the Arctic and the associated thaw of permafrost, the availabilities of the elements will
501 change. Depending on dominance or limitation of certain elements, biogeochemical processes such as OM
502 mineralization may increase or decrease. Moreover, not only microbial processes like OM respiration may be affected

503 by changes in Si, Ca, Fe, P, and Al availability, but also processes such as primary production (CO₂ fixation by plants)
504 in terrestrial systems. This could be stabilizing soil OM, but may also trigger elevated biomass production of plants
505 due to increased nutrient supply. In addition, marine systems will receive higher loads of leached elements, which
506 could increase algae biomass production due to larger nutrient transport to the sea. Our spatially data product including
507 the differences in elements availability between the different lithological classes and regions will help improving
508 models of Arctic biogeochemical cycles for estimating future carbon feedback under the predicted climate change.
