Abstract. This study focuses on the determination and validation of a new global mean sea surface (MSS) model, named SDUST2020 (Shandong University of Science and Technology 2020), with a grid size of 1'×1'. This new model was established with a 19-year moving average method and fused multi-satellite altimetry data over a 27-year period (from January 1993 to December 2019). The data of HaiYang-2A, Jason-3, and Sentinel-3A were first ingested in the SDUST2020 MSS but not in any other global MSS model, such as the CLS15 and DTU18 MSS models. Validations, including comparisons with the CLS15 and DTU18 MSS models, GPS-levelled tide gauges, and altimeter data, were performed to

15 evaluate the quality of the SDUST2020 MSS model, all of which showed that the SDUST2020 MSS model is accurate and reliable. The SDUST2020 MSS dataset is freely available at the site (data DOI: https://doi.org/10.5281/zenodo.6555990, Yuan et al., 2022).

1 Introduction

The mean sea surface (MSS) is a relative steady-state sea level within a finite period with important applications in geodesy,

- 20 oceanography, and other disciplines (Andersen and Knudsen, 2009; Schaeffer et al., 2012; Andersen et al., 2018; Pujol et al., 2018; Guo et al., 2022). It is obtained by time averaging the instantaneous sea surface height (SSH) observed by an altimeter over a finite period (Andersen and Knudsen, 2009). However, the sea level contains information about ocean variation at multiple time scales, such as seasonal and interannual variation. To completely separate the mean and time-varying parts of sea level, it is necessary to continuously collect SSH data in time and space. As a result, establishing an MSS model that
- 25 accurately filters time-varying sea-level signals and obtains high-resolution mean SSH data within a finite period is challenging.

Since the 1970s, continuous efforts have been made to establish an optimal MSS model after the success of Geos-3 satellite altimetry data. Every update of the satellite altimetry data is accompanied by the establishment of new MSS models. The

30 precision and grid size of the MSS model has been gradually improved and enhanced with the development of satellite

altimetry techniques. As such, it can be said that the development of an MSS model is the epitome of the development history of satellite altimetry technology.

At present, only two research institutions, the Centre National d'Etudes Spatiales (CNES) and the Space Research Center of
the Technical University of Denmark (DTU), are updating and publishing new MSS models. The series MSS models
CNES_CLS11 (Schaeffer et al., 2012), CNES_CLS15 (Pujol et al., 2018), and CNES_CLS19 (ongoing to compute) were
published by CNES, while the series MSS models DTU10 (Andersen et al., 2010), DTU13 (Andersen et al., 2015), DTU15
(Andersen et al., 2016), and DTU18 (Andersen et al., 2018) were published by DTU. Among them, CNES_CLS15 (CLS15)
and DTU18 are the latest MSS models, which have the same fundamental elements, including the mean profile of
Topex/Poseidon (T/P), Jason-1, and Jason-2 from 1993 to 2012. They also have a grid size of 1'×1'. However, the spatial
coverage and altimetry data used are different. For example, the global coverage of the CLS15 model is 80°S–84°N, while
that of the DTU18 model is 90°S–90°N. The CLS15 model ingests the exact repeat mission (ERM) data (T/P, Jason-1, Jason-2, ERS-2, Envisat, GFO), as well as the geodetic mission (GM) data (ERS-1/GM, Jason-1/GM, Cryosat-2). Compared
with CLS15, DTU18 replaces GFO data with SARAL/ERM data and ERS-1/GM data with SARAL drifting phase (DP) data.

45

50

With the continuous development of satellite altimetry technology, the types and quantity of available SSH data are also increasing. The SSH data can be obtained from both in-orbit and newly launched altimetry satellites. Multi-satellite altimetry data were fused to establish an MSS model over a long-time span. Among the altimeter data, HaiYang-2A (HY-2A), Jason-3, and Sentinel-3A have not been ingested in any global MSS model (e.g., CLS15 and DTU18). In this study, these altimeter data will be used together with other altimeter data (e.g., T/P, Jason-1, Jason-2, ERS-1, ERS-2, Envisat, GFO, Cryosat-2, and SARAL) to establish a new global MSS model.

Ocean tides are one of the main sources of error that affect the quality of altimetry data. However, after tidal error correction, the residual error remains that cannot be ignored in an MSS model (Yuan et al., 2020). Therefore, a new method, the 19-year

55 (corresponding to the 18.61-year cycle signal of ocean tide) moving average method, was used to establish a global MSS model. This new method has been proven to be effective in improving the accuracy of the established MSS model proposed by Yuan et al. (2020).

The focus of the paper is the establishment and validation of a new global MSS model named the SDUST2020 (Shandong University of Science and Technology 2020) model with the grid size of 1'×1' with the 19-year moving average method from multi-satellite altimetry data covering the period 1993 to 2019. Besides the introduction, the paper is composed of the following five sections. Sections 2 and 3 introduce the altimeter data used in this study and the data processing methodology, respectively. Section 4 presents the results and discussions as well as the SDUST2020 model. Section 5 validates the SDUST2020 model and Section 6 is the conclusion.

2.1 Satellite altimetry data

The multi-satellite altimetry data used in this study were selected from the along-track Level-2p (L2P; version_02_00) products released by the Archiving Validation and Interpretation of Satellite Oceanographic Data (AVISO) (CNES, 2020). The L2P products contained multi-satellite altimetry data, including ERS-1, T/P, ERS-2, GFO, Jason-1, Envisat, Jason-2,

- 70 Cryosat-2, HY-2A, SARAL, Jason-3, Sentinel-3A, and Sentinel-3B. They are generated by the 1 Hz mono-mission along-track altimetry data through various error corrections, data editing and quality control, unification of the reference ellipsoids (adjusted to the same reference ellipsoid as T/P), and other data processing (CNES, 2020). The error corrections for each mission are detailed in the along-track L2P products handbook (CNES, 2020), which include instrumental errors, environmental perturbations (wet tropospheric, dry tropospheric and ionospheric effects), ocean sea state bias, tide effects
- 75 (ocean tide, solid earth tide, and pole tide), and atmospheric pressure (combining atmospheric correction: high-frequency fluctuations of the sea surface topography and inverted barometer height correction). The effects of ocean tide for all the altimeter missions are corrected by the ocean tide model of FES2014 (Carrère et al., 2014). The purpose of data editing and quality control is to select valid measurements over the ocean with the data editing criteria. The editing criteria are defined as minimum and maximum thresholds for altimeter, radiometer and geophysical parameters (detailed in the along-track L2P)
- 80 products handbook). After data editing and quality control, data near the coastline with poor quality have been eliminated (CNES, 2020).

Multi-satellite altimetry data spanning from 1 January 1993 to 31 December 2019 selected from L2P products are shown in Table 1. The purpose of selecting full-year ERM data is to remove seasonal and interannual signals in the altimeter data
(Schaeffer et al., 2012; Pujol et al., 2018). The ERS-1/GM, Cryosat-2, Jason-1/GM, HY-2A/GM, and SRL/DP data were used to improve the spatial resolution of the MSS model. All ERM and GM data were jointly used to establish the SDUST2020 model.

Missions	Time span	Cycles	Missions	Time span	Cycles

2.2 Data of GPS-levelled tide gauges around Japan

100

90 The tide gauge data were downloaded from the Permanent Service for Mean Sea Level (PSMSL) website (www.psmsl.org/). The PSMSL is responsible for the collection, publication, analysis, and interpretation of sea-level data from the global network of tide gauges (Holgate et al., 2013). It provides the monthly and annual mean values for each tide gauge, which were reduced to a common datum called Revised Local Reference (RLR) datum. This reduction was performed by the PSMSL using the tide gauge datum history provided by the supplying authority. To avoid negative numbers in the resulting RLR monthly and annual mean values, an offset of 7000 mm was also used.

The GPS station data were obtained from the Système d'Observation duNiveau des Eaux Littorales (SONEL) website (www.sonel.org). SONEL provides the ULR6b GPS daily data calculated by the University of La Rochelle (ULR) with GAMIT/GLOBK software, and the GPS data have been corrected for emergencies, such as earthquakes (Santamaria-Gomez et al., 2017).

The sea level observed by the satellite altimeter was relative to the reference ellipsoid. However, the sea level obtained from tide gauges is relative to a certain benchmark (e.g. RLR). Therefore, there were differences between the two surfaces. Fortunately, the ellipsoidal height of the RLR can be obtained by GPS (equipped on the tide gauges) observations, which can

105 be used to unify the sea level obtained by the tide gauges to the reference ellipsoid. Figure 1 shows the relationship between the sea level observed from the satellite altimeter relative to the reference ellipsoid, the sea level obtained from the tide gauges relative to the RLR, and the height of the RLR derived from GPS relative to the reference ellipsoid.

Figure 1. Relationship between the sea surface height (SSH) observed from altimetry satellite, the relative SSH obtained from tide 110 gauges above the Revised Local Reference (RLR), and the height of RLR derived from the joint GPS stations above the reference ellipsoid.

There are approximately 34 tide gauges around Japan listed on the PSMSL website, which have continuous annual data spanning from 1993 to 2019 and joint GPS data. The information on the 34 tide gauge stations and joint GPS stations around

115 Japan is provided in the Appendix of this study. The data from GPS-levelled tide gauges around Japan were selected to validate the SDUST2020 MSS model.

3 Methodology

Figure 2 shows the data processing procedure used to establish the SDUST2020 model. First, the multi-satellite altimetry data (Table 1), spanning from 1 January 1993 to 31 December 2019 selected from L2P products, were grouped into 19-year-120 long moving windows shifted by one year starting in January 1993, and nine groups of multi-satellite altimetry data were obtained. Second, the multi-satellite altimetry data of each group were independently processed to establish a global MSS model, including the collinear adjustment of ERM data, ocean variability correction of GM data (addressed by objective analysis and polynomial fitting interpolation), multi-satellite joint crossover adjustment, and the least-squares collocation (LSC) technique for gridding. Third, MSS models with a grid size of 1'×1' were established, resulting in nine MSS models 125 with the same grid size. Finally, the SDUST2020 model was obtained by weighting the weighted average value of the nine

models according to the reciprocal square of the estimated SSH error (derived from the LSC technique for gridding) at the same grid point. The calculation method is shown in Equations (1) and (2):

$$mssh_{i,SDUST2020} = \frac{\sum_{j=1}^{9} (mssh_{i,j}/(err_{i,j})^2)}{\sum_{j=1}^{9} 1/(err_{i,j})^2}$$
(1),

$$err_{i,\text{SDUST2020}} = \frac{1}{\sqrt{\sum_{j=1}^{9} 1/(err_{i,j})^2}}$$
 (2).

130 where mssh_i SDUST2020 and err_i SDUST2020 are the SSH and the error of the SSH at the grid point *i* in the SDUST2020 model, respectively; and $mssh_{i,SDUST2020}$ ($j = 1, \dots, 9$) and $err_{i,j}$ ($j = 1, \dots, 9$) are the SSH and the error of the SSH at the grid point *i* in each of the nine MSS models, respectively.

Figure 2. Data processing of L2P products to establish the SDSUT2020 model.

135 **3.1 Ocean variability correction**

The correction of altimeter data for ocean variability is a major challenge when attempting to establish an MSS model (Schaeffer et al., 2012; Pujol et al., 2018). Because the ground tracks of altimetry satellites with ERM coincide with each other, the ocean variability correction of ERM data can be solved using the collinear adjustment method. This method makes it possible to remove ocean variability (seasonal and interannual), but also to obtain the mean along-track SSH. The collinear

140 adjustment method used in this study is the same as that described by Yuan et al. (2021).

Because GM data do not have the characteristics of repeated periods, such as ERM data, the ocean variability correction of GM data cannot be addressed by collinear adjustment. Fortunately, the ocean variability of GM data was obtained simultaneously using ERM data. For example, ERS-1/GM data contain the same ocean variability as the T/P data for the same period (1994–1995). Currently, the main methods for the correction of GM data for ocean variability are objective analysis or the use of polynomial functions (e.g. polynomial fitting interpolation, PFI). The objective analysis method is considered to be the best method to correct the ocean variability of GM data (Schaeffer et al., 2012; Pujol et al., 2018) and has been applied successfully to the establishment of MSS models, such as CLS11 and CLS15. It can be used to interpolate the ocean variability of one or more missions considered as a reference at the spatial and temporal positions of the satellite 150 that would be corrected for ocean variability (Schaeffer et al., 2012). The objective analysis method used in this study is described by Yuan et al. (2021), and further details are provided by Le Traon et al. (1998; 2001; 2003) and Ducet et al. (2000).

T/P series (refer to T/P, Jason-1, Jason-2, and Jason-3) satellite altimetry data are widely known to have the highest measurement accuracy. Therefore, the mean along-track SSH of the continuous T/P series during 1993–2019 is used as the basis for calculating the ocean variability of the ERM data. The orbit inclination of T/P series satellites is approximately 66°, whereas that of GM satellites is usually greater than 66°. For example, the orbital inclinations of ERS-1/168, HY-2A/GM, SARAL/DP, and Cryosat-2 were 98.52°, 99.3°, 98.55°, and 92°, respectively. Therefore, the objective analysis method can only correct the ocean variability of GM data within the latitude range of 66°S to 66°N, whereas that beyond 66°S or 66°N

160 cannot be corrected. In this study, when correcting GM data (such as ERS-1/168, HY-2A/GM, SARAL/DP, and Cryosat-2) for ocean variability, an objective analysis method was adopted for GM data between 66°S and 66°N, whereas the PFI method was adopted for GM data beyond 66°S or 66°N.

The basic principle of the PFI method can be expressed as follows: first, a fitting polynomial is used to fit the grid sea level 165 variation time series to extract the ocean variability, and the least squares solution is used to solve the fitting parameters; second, the ocean variability of GM data (above 66°S or 66°N) is interpolated with time as the independent variable, to complete the ocean variability correction of GM data. The grid sea level variation time series is the monthly averaged grid sea level variation time series between 1993 and 2019 provided by AVISO, with a grid of $15' \times 15'$. The fitting polynomial was as follows (Andersen et al., 2006; Andersen and Knudsen, 2009; Jin et al., 2016):

170 $y = k + B \cdot t + C \cdot \cos(2 \cdot \pi \cdot t) + D \cdot \sin(2 \cdot \pi \cdot t) + E \cdot \cos(4 \cdot \pi \cdot t) + F \cdot \sin(4 \cdot \pi \cdot t)$ (3),

where y is the sea-level variation time series, t is the time, k is the bias, B is the trend, C and D are the coefficients of the annual signal, and E and F are the coefficients of the semi-annual signal.

3.2 Crossover adjustment

The crossover adjustment is an important method for the data fusion of multi-satellite altimetry (Huang et al., 2008). The 175 crossover adjustment method used in this study was performed in two steps: (i) condition adjustment at crossover adjustment; and (ii) filtering and predicting the observational corrections along each track. This crossover adjustment method has been described in detail by Huang et al. (2008) and Yuan et al. (2020). In the crossover adjustment, an error model is established to reflect the combined effect of systematic errors (varied in very complicated ways) on the altimeter data. These errors include the radial orbit error, residual ocean variation, residual geophysical corrections, and so on. The error model can be 180 expressed as follows (Huang et al., 2008; Yuan et al., 2020; 2021):

$$f(t) = a_0 + a_1 \cdot (t - T_0) + \sum_{j=1}^n (b_i \cdot \cos(j \cdot \omega \cdot (t - T_0)) + c_i \cdot \sin(j \cdot \omega \cdot (t - T_0)))$$
(4),

where f(t) is the systematic errors; t is the observation time of the SSH; a_0, a_1, b_i , and $c_i (i = 1, \dots, n)$ are model parameters to be solved; ω represents the angular frequency corresponding to the duration of a surveying track ($\omega = 2\pi/(T_1 - T_0)$), where T_0 and T_1 represent the start and end times of the surveying track, respectively); and n is a positive integer determined

185

by the length of the track. Based on empirical evidence, n is proposed to be 1-2 for a short track, 3-5 for a middle-long track, and 6-8 for a long track (Huang et al., 2008; Yuan et al., 2020).

Because the mean along-track SSH of the continuous T/P series derived from the collinear adjustment is used as the basis of the MSS model, it will remain unchanged and only correct crossover differences for other satellite altimetry data in the 190 process of multi-satellite joint crossover adjustment. The details of the crossover adjustment method used in this study are discussed in Yuan et al. (2020; 2021).

3.3 Gridding

In this study, the LSC technique (Hwang, 1989; Rapp and Bašić, 1992) was used for gridding, which has been previously proven to be the most suitable method for gridding (Jin et al., 2016). In the process of gridding with the LSC, a second-order

195 Markov process is used to describe the two-dimensional isotropic covariance function to obtain prior statistical information about the altimeter data and improve the accuracy of gridding. This process can be expressed as follows (Jordan, 1972; Moritz, 1978):

$$D(d) = D_0 \cdot (1 + d/\alpha) \cdot e^{-d/\alpha}$$
(5),

where *d* is the two-dimensional distance between the observation point and grid point; D_0 is the local variance parameter, 200 which can be expressed as the variance of all observed data participating in gridding within the local range; and α is the correlation length (where a 50% correlation is obtained). Moreover, an accuracy of $1/\sqrt{2}$ times the single-satellite crossover differences after the crossover adjustment was introduced into the LSC as the noise of the corresponding satellite data.

In the gridding process, the number of observation points within the range determined by the given search radius needs to be 205 no less than 20, and the search radius is usually twice the grid spacing (e.g., 1'). When the number of observation points within a given search radius is less than 20, the search radius should be appropriately expanded until the conditions are met. The search method ensures at least five observation data points in each quadrant within the specified search range in the four quadrants centered on the grid point. The purpose of this method is to ensure that the observation data points around the grid point are uniformly distributed, which is conducive to ensuring the accuracy of grid data.

210

215

To improve the computational efficiency of gridding with the LSC, the globe was divided into several blocks, namely, $20^{\circ} \times 20^{\circ}$ blocks in the ranges of 80° S– 60° N and 0° – 360° , and 126 blocks in total. In the ranges of 60° N– 80° N and 0° – 360° , $24^{\circ} \times 20^{\circ}$ blocks were divided into 18 blocks. In this way, the globe was divided into 144 blocks, of which there are only 141 blocks that have SSH observations; two blocks (40° N– 60° N, 60° W– 100° W) in the Asian continent and one block (40° N– 60° N, 240° W– 260° W) in the American continent have no SSH observations. After gridding these 141 blocks, the number of the 141 grids SSH data are merged. When merging, the SSH of grid points on the repeated latitude and longitude lines was the SSH weighted average of grid points in the two adjacent blocks, and the weight was determined by the reciprocal of the square of the SSH error estimate at the grid points to obtain the final gridded global MSS model.

4 Results and Discussion

220 4.1 Processing results and analysis of altimetry data

Ocean variability correction can eliminate or weaken the influence of sea-level long-wave ocean variation signals, partial satellite radial orbit errors, and residual errors after the correction of geophysical and environmental errors. Ocean variability correction was conducted for the altimeter missions in Table 1 in the global ocean, and the SSHs of these missions before and after ocean variability correction were compared with those of the SDUST2020 model. The statistical results of the

225 comparisons are shown in Table 2, which shows the impact of removing the ocean variability. As shown in Table 2, the magnitude of the RMS (between the SSH of each satellite altimetry mission and the SDUST2020 model) was reduced from decimetres before ocean variation correction to centimetres after ocean variation correction. The RMS of the T/P series (T/P+Jason-1+Jason-2+Jason-3) after ocean variation correction was the smallest (0.0119 m).

Figures 3 and 4 show what could be achieved by correcting the ocean variability of Jason-1/GM. Figure 3 shows the differences between the SSHs of the Jason-1/GM and SDUST2020 model, where ocean variability has not been corrected. Before applying this correction, the differences in SSH were dominant in the western boundary currents. However, these differences improved significantly after correction for ocean variability (Figure 4).

235 -14 -12 -10 -8 -6 -4 -2 0 2 4 6 8 10 12 14 Figure 3. Sea surface height differences between Jason-1/GM and the SDUST2020 model before oceanic variability correction.

Figure 4. Sea surface height differences between Jason-1/GM and the SDUST2020 model after oceanic variability correction.

- All of the altimeter missions listed in Table 1 were performed by self-crossover adjustment after completing the correction of ocean variability. Table 3 presents the statistical results of the crossover differences between these missions before and after the self-crossover adjustment. It can be seen from the results in Table 3 that the accuracy of all missions was greatly improved after self-crossover adjustment. The accuracy of the ERM data was improved by approximately 1 cm from 1–2 cm before adjustment to approximately 1 cm after adjustment, while that of the GM data was improved by approximately 2 cm
- from 7–9 cm to 6–7 cm. Moreover, the accuracy of the ERM data (average accuracy of approximately 1 cm) was much higher than that of the GM data (average accuracy of approximately 6 cm), and the accuracy of different missions was also

different. Therefore, the accuracy of each mission is considered in the process of multi-satellite joint crossover adjustment and gridding with LSC.

4.2 Establishment of the SDUST2020 model

According to the procedure of data processing in Figure 2, the SDUST2020 model was established using a 19-year moving average method from multi-satellite altimetry data (shown in Table 1). The SDSUT2020 model is illustrated in Figure 5, with a grid size of 1'×1' and a global coverage range of 80°S–84°N, with a reference time spanning from 1 January 1993 to 31 December 2019. As shown in Figure 5, the global MSS was generally uneven, with the highest SSH of approximately 88 m and the lowest SSH of approximately –106 m, with a difference of 194 m.

Figure 5. Global mean sea surface model SDUST2020.

4.3 Data availability

265

260 The SDUST2020 MSS dataset is available open-access at https://doi.org/10.5281/zenodo.6555990 as .nc file (Yuan et al., 2022). The dataset includes geospatial information (latitude and longitude) and mean sea surface height.

5 Comparison and validation

Several independent methods have been proposed to validate the SDSUT2020 model. First, we inspected the differences with other MSS models, such as CLS15 and DTU18; then, we compared the MSS models with the data of GPS-levelled tide gauges around Japan; and finally, we compared the independent altimeter data including ERM and GM data.

5.1 Comparison with CLS15 and DTU18 models

The CLS15 and DTU18 models are representative MSS models published by different institutions (CLS15 published by CLS and CNES and DTU18 published by DTU). In this study, these two models were used to validate the SDUST2020 model. Table 4 shows the information for the SDUST2020, CLS15, and DTU18 models. The main differences between
SDSUT2020, CLS15, and DTU18 are the reference period and altimeter data ingested. The reference period of SDUST2020 was 1993-2019, while that of CLS15 and DTU18 was 1993-2012. Compared to CLS15 and DTU18, SDSUT2020 ingests more altimeter data. Among the altimeter data, Jason-3, HY-2A, and Sentinel-3A (ingested in the SDUST2020 model) were first used to establish an MSS model.

MSS m	odel	SDUST2020	CLS15	DTU18	
Grid size		1'×1'	1'×1'	1'×1'	
Reference	period	1993-2019	1993-2012	1993-2012

Saterinte	GM	E1, J1, H2A, SA, C2	E1, J1, C2	J1, C2, SA	

Table 4. Mean sea surface models SDUST2020, CLS15, and DTU18.

275 ^aFootnote: T/P for Topex/Poseidon, J1 for Jason-1, J2 for Jason-2, J3 for Jason-3, E1 for ERS-1, E2 for ERS-2, EN for Envisat, H2A for HY-2A, C2 for CryoSat-2, S3A for Sentinel-3A, SA for SARAL.

Table 5 shows the comparative statistical results of the SDUST2020, CLS15, and DTU18 models in terms of SSH. In the comparison, the ocean variability caused by averaging over distinct periods (27 years from 1993 to 2019 for SDUST2020, and 20 years from 1993 to 2012 for CLS15 and DTU18) was removed, which was calculated from the monthly averaged grid sea level variation time series between 1993 and 2019 provided by AVISO, with a grid of 15'×15'. Compared with DTU18, the STD of SDUST2020 was less than that of CLS15; compared with CLS15, the SDT of SDUST2020 was also less than that of DTU18, while compared with SDUST2020, the STD of CLS15 was less than that of DTU18. Therefore, it can be inferred that the accuracy of these three models, from high to low, is SDUST2020, CLS15, and DTU18.

Table 5. Statistical results of comparisons between different mean sea surface models (unit: m).

Model discrepancy	Max	Min	Mean	STD	RMS	Number of points
SDUST2020-CLS15	9.0319	-13.8801	0.0098	0.2083	0.2085	155330402
SDUST2020-DTU18	7.5640	-9.0388	0.0225	0.2775	0.2784	155330402
CLS15-DTU18	13.8590	-7.8108	0.0127	0.2927	0.2930	155330402

285

If the three models of SDUST2020, CLS15, and DTU18 are not correlated with each other, then according to the error propagation law, the STDs of these three models can be expressed as follows:

$$\begin{cases} STD_{S_{c}c}^{2} = STD_{S}^{2} + STD_{c}^{2} \\ STD_{S_{c}D}^{2} = STD_{S}^{2} + STD_{D}^{2} \\ STD_{c_{c}D}^{2} = STD_{c}^{2} + STD_{D}^{2} \end{cases}$$
(6)

where STD_{S_c} , STD_{S_D} and STD_{C_D} are the STD of SDUST2020 compared with CLS15, SDUST2020 compared with DTU18, and CLS15 compared with DTU18, respectively; STD_s , STD_c and STD_D are the STD of SDUST2020, CLS15, and DTU18, respectively. According to the statistical results in Table 5, the SDT of SDUST2020, CLS15, and DTU18 can be calculated using Equation (6), which are approximately 0.1318, 0.1613, and 0.2442 m, respectively. This result confirms that the accuracy of these three models, from high to low, is SDUST2020, CLS15, and DTU18.

295 The results listed in Table 5 are the statistical results of the comparison between the three models in the global ocean. A total of 1 5533 0402 grid points are counted, including grid points in the coastal regions. After outliers in the differences are rejected by three times STD to avoid contamination by the poor observations around coastal regions, the results are shown in Table 6. It can be inferred that the differences between the three models are around 1-2 cm, and the SDUST2020 MSS and CLS15 MSS models have the best consistency.

300 Table 6. Statistical results of comparisons between different mean sea surface models after rejecting outliers in differences by three times STD (unit: m).

Model discrepancy	Max	Min	Mean	STD	RMS	Number of points
SDUST2020-CLS15	0.0413	-0.0396	0.0009	0.0135	0.0135	133495409
SDUST2020-DTU18	0.0554	-0.0405	0.0074	0.0160	0.0176	131613306
CLS15-DTU18	0.0487	-0.0365	0.0060	0.0142	0.0155	129765806

The SSH differences between the SDUST2020, CLS15, and DTU18 models in the long and short wavelengths are shown in Figure 6 (the SSH differences between SDUST2020 and CLS15), Figure 7 (the SSH differences between SDUST2020 and DTU18), and Figure 8 (the SSH differences between CLS15 and DTU18), which were drawn after Gaussian filtering with the tools available in the GMT6.0 (Generic Mapping Tools version 6.0) software (Wessel et al., 2019). Similar to Andersen et al. (2018), a wavelength of 150 km was selected as the dividing line between the long and short wavelengths. As shown in Figures 6, 7, and 8, there were no significant differences between these models in the short wavelength (wavelength less than 150 km), and the average differences were within 2 cm, whereas there were some significant differences in the long

310 wavelength (wavelengths greater than 150 km). The differences between these models at long wavelengths were mainly concentrated in the polar regions and the western boundary current region (including the Kuroshio Current, Mexico Gulf, Agulhas Current, etc.). There are two reasons: on the one hand, it is related to the large sea level change in these regions (Jin et al., 2016); on the other hand, it is also related to the different altimeter data used and data processing methods implemented in the modelling (Andersen and Knudsen, 2009; Schaeffer et al., 2012; Pujol et al., 2018).

315 -12 -10 -8 -6 -4 -2 0 2 4 6 8 10 12 Figure 6. Differences between SDUST2020 and CLS15: (a) wavelength less than 150 km; (b) wavelength greater than 150 km.

Figure 7. Differences between SDUST2020 and DTU18: (a) wavelength less than 150 km; (b) wavelength greater than 150 km.

320 Figure 8. Differences between CLS15 and DTU18: (a) wavelength less than 150 km; (b) wavelength greater than 150 km.

At the optimal interpolation (using the LSC technique for gridding) output, a calibrated formal error was obtained. The formal error is caused by three terms: an instrumental noise, a residual effect of the oceanic variability, and an along-track bias. These three terms are complementary and correspond, respectively, to white noise, a spatially correlated noise (at

325 mesoscale wavelengths), and a long-wavelength error that is assumed to be constant along the tracks. The formal error does not match the precision of the MSS but is nonetheless an excellent indicator of the consistency of the grid (Schaeffer et al., 2012; Pujol et al., 2018).

Figures 9, 10, and 11 highlights the formal errors in SDUST2020, CLS15, and DTU18, respectively, which indicate that SDUST2020 was much more homogenous and accurate than CLS15 and DTU18. This is also confirmed by worldwide

330 statistics. The average and RMS about the formal error of SDSUT2020 were 1.0 cm and 1.5 cm, while those of CLS15 were 1.4 cm and 1.9 cm, and those of DTU18 were 1.9 cm and 2.0 cm.

Figure 10. Formal error of the CLS15 model.

5.2 Comparison with GPS-levelled tide gauges

A comparison between 34 GPS-levelled tide gauges around Japan and the SSH of the SDUST2020, CLS15, and DTU18

- 340 models was used to independently validate the accuracy differences of the models that are close to the coast (Andersen and Knudsen, 2009). Before the comparison, the SSH obtained from the GPS-levelled tide gauges was adjusted to have the same reference ellipsoid as T/P. It is not clear how wide SSH can be represented by a single tide gauge. The SSH of different models at the location of the tide gauge was calculated by the reciprocal weighting of the spherical distance from the tide gauge to the points, which were determined by different search radii (e.g. 10, 20, 30, 40, and 50 km), which were centered on
- 345 the tidal station. The SSH differences of different models compared with 34 GPS-levelled tide gauges around Japan with different search radii are shown in Figure 12, and their STDs are listed in Table 7. As shown in Figure 12 and Table 7, the larger the search radii, the greater the difference between the models and GPS-levelled tide gauges. In Table 7, the STD of SSHs difference between the MSS model and the GPS-levelled tide gauges reaches the decimeter level. The reason is may be closely related to the poor observations of offshore altimeter data. The STD of the SSH differences of SDUST2020 compared with the GPS-level tide gauges is smaller than those of CLS15 and DTU18, indicating that the accuracy of
- SDUST2020 was better than that of CLS15 and DTU18.

 Table 7. STD of SDUST2020, CLS15, and DTU18 models compared with GPS-levelled tide gauges around Japan in different search radii (unit: m)

Search radii	10 km	20 km	30 km	40 km	50 km
SDUST2020	0.1917	0.2102	0.2588	0.3264	0.3911
CLS15	0.2413	0.2296	0.2806	0.3634	0.4385
DTU18	0.2752	0.2777	0.3052	0.3512	0.4003

Figure 12. Sea surface height differences of different models compared with 34 GPS-levelled tide gauges around Japan in different search radii. (a), (b), (c), (d), and (e) correspond to the search radius of 10, 20, 30, 40, and 50 km, respectively.

5.3 Comparison with altimeter data

Comparison with the altimeter data can be used to estimate the accuracy of the MSS models (Andersen and Knudsen, 2009;

- 360 Schaeffer et al., 2012; Jin et al., 2016), which is another effective way to validate MSS models. Several datasets were chosen, including the ERM and GM data. The ERM data were the mean along-track SSH after collinear adjustment, and the GM data were not processed by ocean variability correction. The ERM data included 1-year ERS-1, 2-year HY-2A, 2-year Jason-3, 2.5-year Sentinel-3A, and 1-year Sentinel-3B data, and the GM data included 1.5-year Envisat/GM, 2-month Jason-2/GM, and 1-year HY-2A/GM data. Among these, the data of Sentinel-3B and Envisat/GM were not ingested in the SDUST2020,
- 365 CLS15, and DTU18 models, and the data of HY-2A, Jason-3, and Sentinel-3A were ingested in the SDUST2020 model, while they were not ingested in the CLS15 and DTU18 models.

Table 8 shows the differences in the STD of the SSH for the SDUST2020, CLS15, and DTU18 models compared to the altimeter data. From the results in Table 8, the differences between the STD given by these three models are at the millimetre

370 level, but nearly all STDs given by SDSUT2020 are lower than CLS15 and DTU18, indicative of higher accuracy. The STDs given by these three models were approximately 4–6 cm compared with the ERM data (the first five groups), approximately 10 cm compared with GM data (the last three groups), and almost half of the former. The reason may be that the altimeter data of the first five groups have been corrected for the ocean variability, while those of the last group have not.

 Table 8. STDs of the sea surface height differences of the models SDUST2020, CLS15, and DTU18 compared with satellite

 375
 altimetry data (unit: m).

Satellite (period)	SDUST2020	CLS15	DTU18
ERS-1 (1995.04.01-1996.04.30)	0.0529	0.0509	0.0524
HY-2A (2014.04.12-2016.03.15)	0.0565	0.0610	0.0618
Jason-3 (2017.01.01-2018.12.31)	0.0414	0.0431	0.0480
Sentinel-3A (2016.06.28-2018.12.31)	0.0448	0.0479	0.0548
Sentinel-3B (2019.01.01-2019.12.31)	0.0502	0.0522	0.0576
Envisat/GM (2010.10.27-2012.04.08)	0.0999	0.1007	0.1038
Jason-2/GM (2017.07.13-2017.09.13)	0.0991	0.0999	0.1013
HY-2A/GM (2018.12.26-2019.12.30)	0.1180	0.1187	0.1201

To more accurately assess and quantify the differences in the model errors for SDUST2020, CLS15, and DTU18 at different wavelengths, Sentinel-3B data (1-year, 2019.01.01–2019.12.31) were selected to calculate sea level anomaly (SLA) along track based on these three models and obtain the SLA power spectral density (PSD). Because the Sentinel-3B data were independent of these three models, the difference between the SLA pSDs of Sentinel 2D close track based on

380

independent of these three models, the difference between the SLA PSDs of Sentinel-3B along-track calculated based on these three models reflected the difference in the error of these three models (Pujol et al., 2018; Sun et al., 2021).

Figure 13(a) shows the mean global SLA PSD along Sentinel-3B tracks when different MSS models were used. As shown in Figure 13(a), all PSDs varied with the wavelength; the longer the wavelengths, the greater the PSDs, and there were also

- 385 differences between the PSDs of different MSS models for different wavelengths. Since the SSH and MSS were based on independent data and periods, for long wavelengths (e.g., wavelengths longer than 150 km), the ocean variability signal dominated, for short wavelengths (e.g., wavelengths from ~25 to 150 km), the errors of MSS models dominated, while for shorter wavelengths (e.g., wavelengths shorter than 25 km), the altimeter noise floor dominated (Pujol et al., 2018).
- The PSD of the SDUST2020 model was significantly less than that of CLS15 and DTU18, and the PSD of CLS15 was slightly smaller than that of DTU18 for wavelengths longer than 150 km. The reason for the former was that the reference period of SDUST2020 (1993–2019) was longer than that of CLS15 and DTU18 (1993–2012), and the reason for the latter was that the data pre-processing method for Sentinel-3B is the same as that of the altimeter data ingested in the CLS15 model. This has also been confirmed by worldwide statistics. The average values of the SLA based on SDUST2020, CLS15, and DTU18 were 0.0155, 0.0494, and 0.0596 m, respectively, and the RMS values were 0.0525, 0.07919, and 0.0829 m, respectively.

Figure 13(b) shows the ratio between the PSD curves in Figure 13(a), which can better quantify the differences between the MSS models. Compared with the CLS15 model, the errors of the SDUST2020 model improved in the wavelength range from 25 to 150 km, with a maximal impact of approximately 40 km, which is an improvement of approximately 15%.

400

Figure 13. (a) The SLA PSD along Sentinel-3B tracks using several models. (b) The ratio of SLA PSD from panel (a).

Table 9 lists the STD of the SLA of these three MSS models for wavelengths ranging from 25 to 150 km along different altimeter tracks. As shown in Table 9, the accuracy difference among these three models was very small, all at the submillimetre level; however, the accuracy of SDUST2020 was slightly better than those of CLS15 and DTU18.

Table 9. STD of SLA for short wavelengths along the track of different altimeters, based on different MSS models (passband filtered from 25 to 150 km) (unit: m).

	ERS-1	HY-2A	Jason-3	Sentinel-3A	Sentinel-3B	Envisat/GM	Jason-2/GM	HY-2A/GM
SDUST2020	0.0109	0.0099	0.0073	0.0089	0.0087	0.0201	0.0198	0.0205
CLS15	0.0107	0.0102	0.0067	0.0094	0.0090	0.0201	0.0198	0.0206
DTU18	0.0115	0.0107	0.0076	0.0099	0.0097	0.0202	0.0201	0.0207

6 Conclusions

410 In this study, SDUST2020, a new global MSS model, was established using a 19-year moving average method from multisatellite altimetry data. Its global coverage was from 80°S to 84°N with a grid size of 1'×1' and a reference period from January 1993 to December 2019.

Firstly, in comparison with the CLS15 and DTU18 models, the SDUST2020 model was innovative in the data processing 415 method of model establishment, namely the 19-year moving average method; secondly, the reference period of the SDUST2020 model extended from 1993 to 2019, while CLS15 and DTU18 only ranged from 1993 to 2012; thirdly, the establishment of the SDUST2020 model for the first time integrated the altimeter data of HY-2A, Jason-3, and Sentinel-3A, which have not been used in the establishment of any other global MSS models.

420 Comparing SDUST2020 with the CLS15 and DTU18 models, the results presented in this study show that the accuracy of these three models, from high to low, is SDUST2020, CLS15, and DTU18. Comparing SDUST2020, CLS15, and DTU18 with the data of GPS-levelled tide gauges around Japan and the altimeter data of several satellites, these results show that the accuracy of SDUST2020 is better than that of CLS15 and DTU18.

- Acknowledgements. We are very grateful to AVISO for providing the along-track Level-2+(L2P) products and the delayedtime gridded monthly mean of sea-level anomalies product, which can be obtained by downloading freely from AVISO official website (ftp://ftp-access.aviso.altimetry.fr). We are also thankful to CLS for providing CNES_CLS15 MSS (ftp://ftpaccess.aviso.altimetry.fr) and DTU for providing the DTU18 MSS (https://ftp.space.dtu.dk/pub/). The tide gauge records are available online (https://www.psmsl.org/) and the GPS data are available online (https://www.sonel.org).
- 440 Financial support. This work was partially supported by the National Natural Science Foundation of China (grants 42192535 and 41774001), the Autonomous and Controllable Project for Surveying and Mapping of China (grant 816517), the SDUST Research Fund (grant 2014TDJH101), and the Scientific Research Foundation for High-level Talents of Anhui University of Science and Technology (grant 2022yjrc66).
