Abstract. The Global Runoff Data Centre provides time series of observed discharges that are valuable for calibrating and validating the results of hydrological models. We address a common issue in large-scale hydrology that has not been satisfactorily solved, though investigated several times. To compare simulated and observed discharge, grid-based hydrological models must fit reported station locations to the resolution-dependent gridded river network. We introduce an Intersection over
10 Union ratio approach to selected station locations on a coarser grid-scale, reducing the errors in assigning stations to the correct upstream basin. We update the 10-year-old database of watershed boundaries with additional stations based on a high-resolution (3 arc seconds) river network and provide source codes and high- and low-resolution watershed boundaries. The dataset is stored on Zenodo with the associated DOI [https://doi.org/ 10.5281/zenodo.6906577](https://doi.org/10.5281/zenodo.6906577).

1 Introduction

15 River discharge is one of the most important variables in hydrological modeling because all basin processes are integrated into this variable. Discharge spatially and temporally integrates the range of meteorological variables and basin characteristics. Spatially and temporally distributed properties of river and lake morphology, soil, groundwater, snow, glaciers, climate, land cover, and human interaction influence discharge at the outlet of a basin. Although discharge is a useful indicator, for semi-arid and arid regions, its value declines as evapotranspiration becomes the most significant basin outflow, as it then represents
20 relatively less of the water cycle outflows (e.g., Norwegian basins have a discharge/actual evaporation ratio of 80/20, and African basins can have a ratio of 20/80). Discharge is extremely useful for calibrating and validating hydrological models using different objective functions, such as Nash-Sutcliffe (Nash and Sutcliffe, 1970) and Kling-Gupta (Kling et al., 2012) for calibrating global hydrological models (Müller Schmied et al., 2021; Sutanudjaja et al., 2014; Hanasaki et al., 2008). It is also useful for tasks like estimating flood hazards (Alfieri et al., 2015), inland navigation (Nilson et al., 2013; Christodoulou et al.,
25 2020), energy power production (Hunt et al., 2020; Van Vliet et al., 2016), and water scarcity (Hoekstra et al., 2012; Van Beek et al., 2011).

Since the establishment of the Global Runoff Data Centre (GRDC) database (Vorosmarty et al., 1998; Fekete and Vörösmarty, 1999), the number of stations has increased, and the number of publications using the GRDC dataset is also growing - the

30 GRDC publication database of 2021 (GRDC, 2020) references 118 publications using the discharge time series. The Generic
Statistical Information Model (GSIM) database (Do et al., 2018) provides a good overview of several river discharge databases
worldwide. Although there are several public databases of river discharge at a basin-scale (e.g., Mekong basin, Mekong River
Commission (2020)), the GRDC database offers the richest source of global river discharge data, as follows:

35 “A global hydrological database is essential for research and application-oriented hydrological and
climatological studies at global, regional, and basin scales. The Global Runoff Database is a unique
collection of river discharge data on a global scale. It contains time series of daily and monthly river
discharge data of well over 10,000 stations worldwide. This adds up to around 470,000 station-years with
an average record length of 45 years” (GRDC, 2020).

40 Quality checking of station attributes and spatial redistribution of station locations for different gridded river networks for
hydrological models have been carried out since the beginning of GRDC data collection (Fekete and Vörösmarty, 1999) and
for each model again and again (Sutanudjaja et al., 2018; Zhao et al., 2017; Wang et al., 2018). For example, to test the
Community Water Model (CWatM) (Burek et al., 2020) global model performance on 30 arc minutes ($0.5^\circ \sim 50 \text{ km} \times 50 \text{ km}$,
hereafter, 30'), we used the station data and the global drainage direction map (DDM30) network (Döll and Lehner, 2002) and
45 corrected the locations to fit with the approach of Zhao et al. (2017). Several errors can occur when the discharge station is
used for gridded hydrological modeling, as follows:

- a) The station location is not at the correct location and is too far from the river.
- b) The station location is at the correct location, but because of the river width and/or the grid resolution of a high-
50 resolution river network, the station location is not in the suitable grid cell of the river network or because, even
at 90 meters, the network is not high-resolution enough to capture the station location.
- c) The high-resolution network does not represent reality (e.g., the river does not flow in the deepest part of the
valley because of human interventions.
- d) Upscaling error. When a coarser resolution for hydrological modeling is applied (e.g., 30' for ISIMIP), using the
55 original station location might lead to its position being wrongly assigned because, for instance, the coarser grid
cell river network may include the junction with a tributary. In contrast, the station may indicate the tributary
itself.
- e) Mismatch error. Suppose the station location is selected only by comparing the upstream area of the upscaled
network with the reported upstream area. In that case, a station could be assigned to the wrong basin because
the upstream area fits slightly better.
- 60 f) Global station density is unevenly distributed. We find a high density for North America and Europe and a low
density for Asia and Africa. In North America or Europe, some stations are close downstream to other ones,
even though no significant tributaries are entering.

This paper addresses these possible errors and gives examples of how to correct them. Lehner (2012) has already calculated
65 explicit watershed boundaries for 7,163 basins on a high-resolution network. These watershed boundaries are freely available
on the GRDC webpage (GRDC, 2020). We repeated this exercise, but using a higher-resolution network based on a more up-
to-date dataset, the (3 arcseconds (3''~93m) MERIT hydro-network (Yamazaki et al., 2019) rather than the 15 arcseconds
HydroSHEDS (Lehner et al., 2008). Moreover, we used a greater number of GRDC stations added in the last ten years (10,701
70 stations as opposed to 7,532). In addition to the high-resolution basins, we added a method for upscaling each station
automatically to 5' and 30' using a more advanced method than simply comparing the river network upstream area with the
reported upstream area. Using this method, a selection of stations can be appropriated to the resolution of the hydrological
model. Furthermore, our code is available and open source in Python to change or calculate stations for individual applications.

2 Methods

2.1 Procedure for station allocation on a high-resolution network

75 2.1.1 Automatic procedure

We used the MERIT hydro database of Yamazaki et al. (2019), which comes as an open-source database in chunks of $5^\circ * 5^\circ$
at 3 arc seconds (~100 m) resolution (36 billion grid cells per $5^\circ * 5^\circ$). We used the river network direction maps and applied
80 the D8 flow model convention: either each grid cell can flow into one of the eight neighboring grid cells, or it is a sink. This
approach, which does not allow rivers to be split into two streams or grid cells to contribute to several basins simultaneously,
is used in most Land-Surface Models and grid-based hydrological models. We obtained the upstream area of each high-
resolution grid cell from the upstream area in km^2 from the MERIT dataset. For the evaluation, we used all stations with an
upstream area greater than or equal to 10 km^2 or with no upstream area record.

85 For the automatic station allocation, we mainly follow the protocol of Lehner (2012):

1. A rectangular search radius of 165 arcsec (~5 km) for each station was defined.
2. For each grid in this rectangle, the upstream drainage area (UPA) from the network from Yamazaki et al. (2019) was
compared to the area reported in the GRDC, and the upstream area accordance is computed:
 - 90 ○ Upstream area error = $|1 - \text{GRDC reported area} / \text{gridded network upstream area}|$
 - Area accordance = $\text{minimum} \{ \text{GRDC reported area}, \text{gridded network upstream area} \} / \text{maximum} \{ \text{GRDC}$
 $\text{reported area}, \text{gridded network upstream area} \}$
3. All cells with an area accordance of less than 50% were dismissed from further evaluation.)
4. The distance to the original location of the station was computed.
5. An objective criterion (OC) for ranking was computed by $\text{OC} = (1 - \text{Area accordance}) + 2 * \text{distance}$

- 95 6. The grid cell with the lowest OC value was taken as the corresponding grid cell for the station location on a high-resolution network
7. If no station location was found in this step, the search radius was increased to 30 arc seconds (~10 km), and the lowest OC value was taken as the corresponding grid cell.

2.1.2 Manual procedure for the remaining stations

- 100 For the ~7.5% of the stations that failed both rounds of searching, we carried out the following manual inspections:
- 3% of the stations in the GRDC database (327 stations) have a reported area of -999. For these stations, we used the next biggest river. We checked manually with GIS, but we did not check all station information manually (e.g., station name, river name, and altitude).
 - 1.5% of stations that failed the automatic search but had a valid upstream area record (169 stations), we manually checked and assigned a location in the range of up to 120 km from the original site (to address any typographical error, e.g., 51.57° instead of 52.57°)
 - For 3% of the stations (352 stations), we could not find an adequate location on the high-resolution network - due perhaps to errors in the GRDC database or insufficient network maps (e.g., missing canals, braided rivers, diversion, and confluent rivers)

110 2.1.3 Output: Polygons of basins

For 10,349 basins, we assigned polygons based on the reallocated station locations on the high resolution (3 arc seconds) with the Python library flwdir from Eilander et al. (2021) and the river direction mosaic maps from Yamazaki et al. (2019). Like the original from Lehner (2012), we produced two versions: a) polygons that follow the exact grid cell contours with high memory requirements, and b) a version with smoothed edges and low memory consumption. The resulting shapefiles were produced in the ESRI shapefile format and include the station information from GRDC. This process addresses errors a), b), and c) (noted above) and provides an update to the shapefiles of Lehner (2012)

2.2 Upscaling station location to a coarser grid cell resolution

The main idea of creating a new set of high-resolution watershed boundaries was not to update the work of Lehner (2012) but to use a different method of assigning station discharge time series to the correct grid cell in grid-based hydrological models. Global hydrological models use 30 arc minutes resolution in the ISIMIP3 project (Warszawski et al., 2014). The trend for global modeling is to move toward higher resolutions at 5' and hyper resolution ($\leq 1\text{km}$) (Bierkens, 2015). For regional studies (Hanasaki et al., 2022; Guillaumot et al., 2022), the resolution is already 1 km or below. Approaches to upscaling to coarser resolutions are mainly based on comparing reported and upstream network areas (Fekete and Vörösmarty, 1999; Zhao et al., 2017).

125

With the flwdir tool from Eilander et al. (2021) and with the idea of Munier and Decharme (2021) of comparing the similarity of shapes, it is possible to introduce another objective criterion - the similarity of high-resolution watershed boundaries and low-resolution boundaries. Using the method of comparing upstream areas, we can partly address error (d) upscaling error but not errors (e) and (f).

130

For an automatic upscaling process, we followed this protocol:

- We defined a minimum upstream area for the station we wanted to use in the low-resolution hydrological model (e.g., $\geq 9,000 \text{ km}^2$ for 30' (~180 cells), $\geq 1,000 \text{ km}^2$ for 5' (~100 cells)).
- A search radius of $5 * 5 = 25$ grid cells of the coarse resolution network was used with the high-resolution allocated station located in the middle.
- For each coarse grid cell, the coarse watershed and upstream were derived, and the upstream area accordance was computed.
- The second objective criterion was the Intersection over Union ratio (Rezatofighi et al., 2019; Munier and Decharme, 2021). Intersection over Union ratio = Area Intersection / Area Union
- The closer to 1 the value of Intersection over Union ratio is, then the more similar the shapes are.
- To reduce the two objective criteria to one solution, the minimum Euclidian distance between the best possible solution (at 0,0) and the two objective criteria was calculated

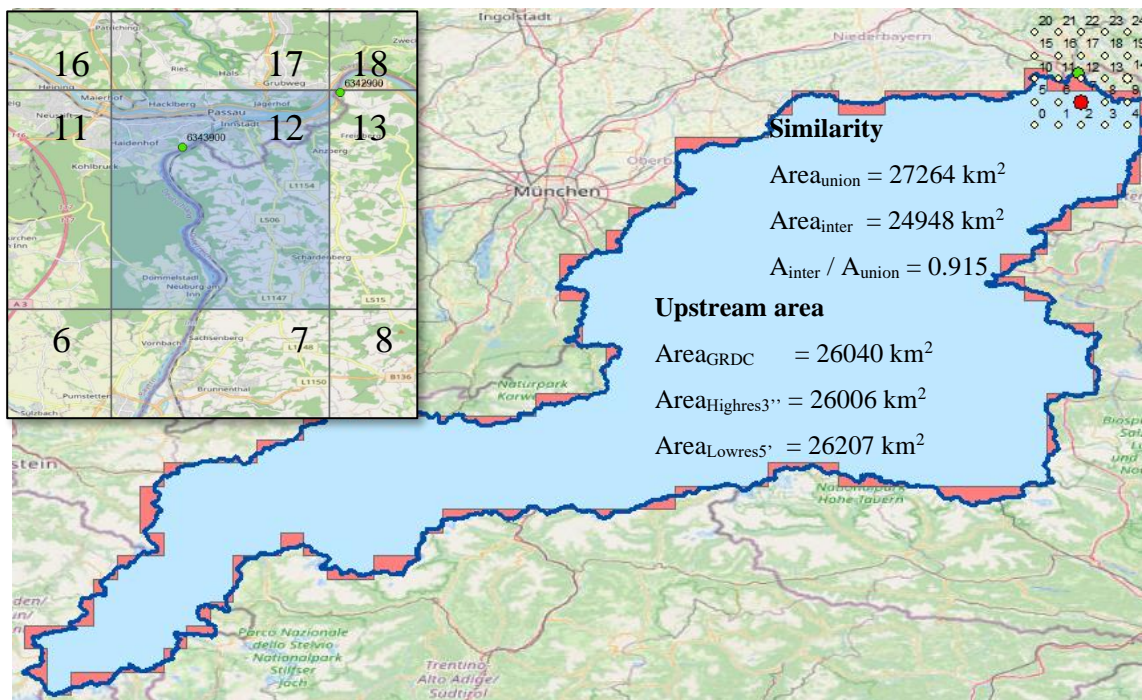

135

140

$$ED = \sqrt{(1 - Area\ accordance)^2 + (1 - similarity)^2}$$

- For the example in Figure 1: Passau Inn: $ED_{\min} = 0.085$ at location No 7
- The coordinates on low-resolution with minimum Euclidian distance were chosen as the station coordinates for this grid size resolution

145

150

Figure 1: Intersection over Union ratio for the River Inn basin at Passau, Germany, GRDC 6343900. The dark blue line is the watershed of the Inn to Passau at a 3'' high resolution. The light blue is the intersection between the low-resolution Inn at 5' and 3'', and red signifies the union of the 5' basin with the 3'' basin.). © OpenStreetMap contributors 2022. Distributed under the Open Data Commons Open Database License (ODbL) v1.0.

155

As a result, we obtain a pair of coordinates for each station on a coarser resolution. Here we chose 5' and 30'. For 5', the network from Eilander et al. (2021) was used based on the high-resolution network from Yamazaki et al. (2019), while for 30', the DDM30 network from Döll and Lehner (2002) was used, as this is the agreed network for the ISIMIP2 and ISIMIP3 (Frieler et al., 2016) hydrological modeling effort.

160 2.3 Selecting station for calibration of a hydrological model based on metadata

In the previous step, we selected stations based solely on location metadata. For the next selection step, we included meta information of time series like length, end date, and the number of missing values in a time series. For calibration or validation, the unsuitable stations were those with only short time series, those that ended too far in the past, and those with too many missing values. The criteria for “too short” and “too old” are subjective and can be chosen in another way, as in Alfieri et al. (2020), but if the criteria are not strong enough, a post-selection can be done. If they are too rigid, the settings part of the Python code can be changed. Fortunately, all the necessary information is included in the metadata file from GRDC.

2.3.1 Deselection and ranking criteria

We included several criteria for selecting or deselecting a station. We derived the first two criteria from the previous analysis of the station location.

- 170 - The accordance of the upstream area on the chosen resolution with the area reported from GRDC: here, we chose a relatively forgiving Area accordance. If the upstream area of the selected resolution had a criterion of more than 40%, this criterion is fulfilled. In most cases, the area was above this ratio, but we did not want to deselect stations where the GRDC record might be accurate.

- 175 - The similarity index between the high-resolution shapefiles and the shapefile of the chosen resolution: the high-resolution shapefile was built on the 3'' MERIT network data. The 30' had a different source and went through an upscaling approach. Therefore, more significant discrepancies between the high-res shapefile and the low-res 30' were possible.

We included two selection criteria from the metadata information about the time series.

- 180 - The time series should have at least five years of monthly or daily records.
 - The end date of a time series should be later than 1985.

Table 1: Selection criteria based on low-resolution

| Name of criterion | Selected at 30' | Selected at 5' |
|----------------------|-----------------|----------------|
| Similarity | 70% | 80% |
| Area accordance | 40% | 40% |
| Years in time series | 5 years | 5 years |
| End date | 1985 | 1985 |

2.3.2 Division of stations

185 The stations may be too close to each other for it to be worth calibrating both. We checked the similarity of the low-res shapefiles. If they were equal to or more than 95% similar, we decided to calibrate only one station and keep the other for validation purposes. To choose which of the similar stations we kept for calibration, we introduced a ranking/scoring system. If a station had a more extended time series or a more recent end date (see Table 2 for all the ranking criteria), we chose the station with the higher score.

190 **Table 2:** Scoring where two stations are too similar

| Name of scoring | 0 points at | 1 point for every | Max/Min points |
|----------------------|-------------|-------------------|----------------|
| Similarity | 80% | 2% | 10 |
| Area accordance | 80% | 2% | 10 |
| Years of time series | 5 years | 5 years | 10 |
| End date | 1985 | 3 years | 12 |
| Missing % | 100% | Neg. point for 5% | -20 |

2.3.3 Output: List of stations to be appropriated for calibration

195 As a result of this step, we obtained two tables for 30' and 5' that distinguished the stations as useful for calibration, stations that could be used for validation, and stations that were not recommended for calibration or validation. All evaluation was solely based on the metadata file provided by GRDC.

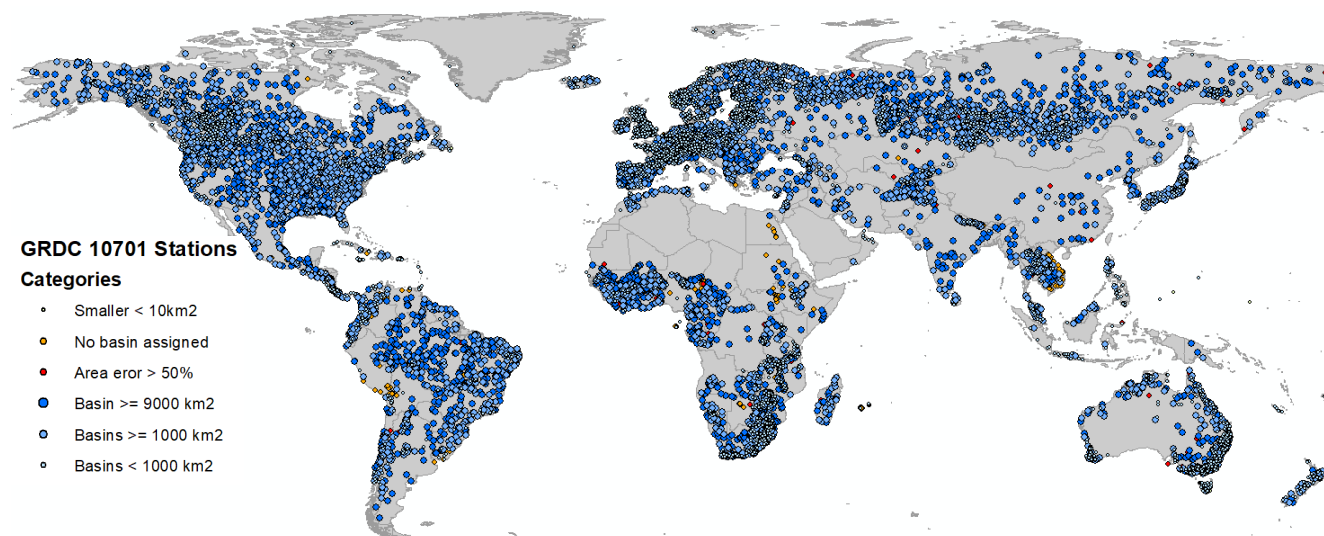

3. Results

3.1 Station allocation on high resolution

The 2022 GRDC station dataset has 10,701 stations in total. We used only those stations with an upstream area equal to 10 km² (thus discounting 124 stations), but we kept the stations without data for the upstream area (327 stations). Using automatic
200 detection of the most appropriate high-resolution MERIT network on 3'' and with manual search (for 169 stations), we still had 228 stations we could not assign to a basin.

For further analysis, we had 10,349 stations with a counterpart in a location on the MERIT network and an assigned basin on 3'', and 49 of these basins did not have a reported area in GRDC. From the remaining 10,300 stations, we calculated the area
205 in accordance between the GRDC upstream area and the area calculated on the high-resolution network using UPA maps from Yamazaki et al. (2019). We kept only those with an area accordance ≥ 0.4 (1,0241 stations). For hydrological modeling, this error might be too big. Still, we assumed there are some errors in the reported area of GRDC and that these stations could be deselected in a further step, if necessary.

210

Figure 3: Location and categories of 10701 GRDC stations (World administrative boundaries by <https://www.opendatasoft.com>)

Figure 4: Histogram of (a) accordance with GRDC upstream area and (b) distance from the corrected location to the GRDC location

The histogram of upstream area accordance in Figure 4a and Table 1 shows that a high number of stations (43%) have area accordance that is equal to or more than 99% (an area error of less than only 1%). Compared with the work from Lehner (2012), we obtained a slightly higher percentage of accordance in this class but almost twice as many stations (4,332 vs. 2,422). 88% (85% for Lehner (2012)) still had good accordance of 90% or more. 330 stations had an area accordance of less than 75%, 18 stations of less than 50%, while 49 stations had no area reported.

Figure 4b shows the distance in meters from the reported station coordinates in GRDC and the station location according to the high-resolution network. A necessary shift in stations might be required because a) the river network is not high-resolution enough to capture the river (see Figure 5d), or the river width is greater than 90 meters, and it would be necessary to shift the station location from the river shore into the middle of the river to match with the high-resolution network. However, we assumed that most distance errors greater than 500 meters come from the stations being wrongly allocated. Table 1 shows that the percentage of area accordance negatively correlates with the distance median.

Table 3: Comparison of stations with accordance in area of high-resolution basins with area reported from GRDC

| Percentage of Area Accordance | Number of Stations This Study | % This study | Median of Distance [m] | Number of Stations Lehner (2012) | % Lehner (2012) |
|-------------------------------|-------------------------------|--------------|------------------------|----------------------------------|-----------------|
| ≥ 99 | 4332 | 42 | 98 | 2422 | 35 |
| ≥ 95 | 7920 | 77 | 180 | 5043 | 72 |
| ≥ 90 | 8980 | 87 | 203 | 5888 | 85 |
| ≥ 85 | 9446 | 92 | 382 | 6287 | 85 |
| ≥ 75 | 9862 | 96 | 418 | 6627 | 95 |
| ≥ 50 | 10174 | 99 | 661 | 6922 | 99 |
| ≥ 0 | 10300 | 100 | 1306 | 6976 | 100 |
| no area | 10349 | | | 7025* | |

* of 7163 station in Lehner (2012), 7025 also match with the new dataset

260

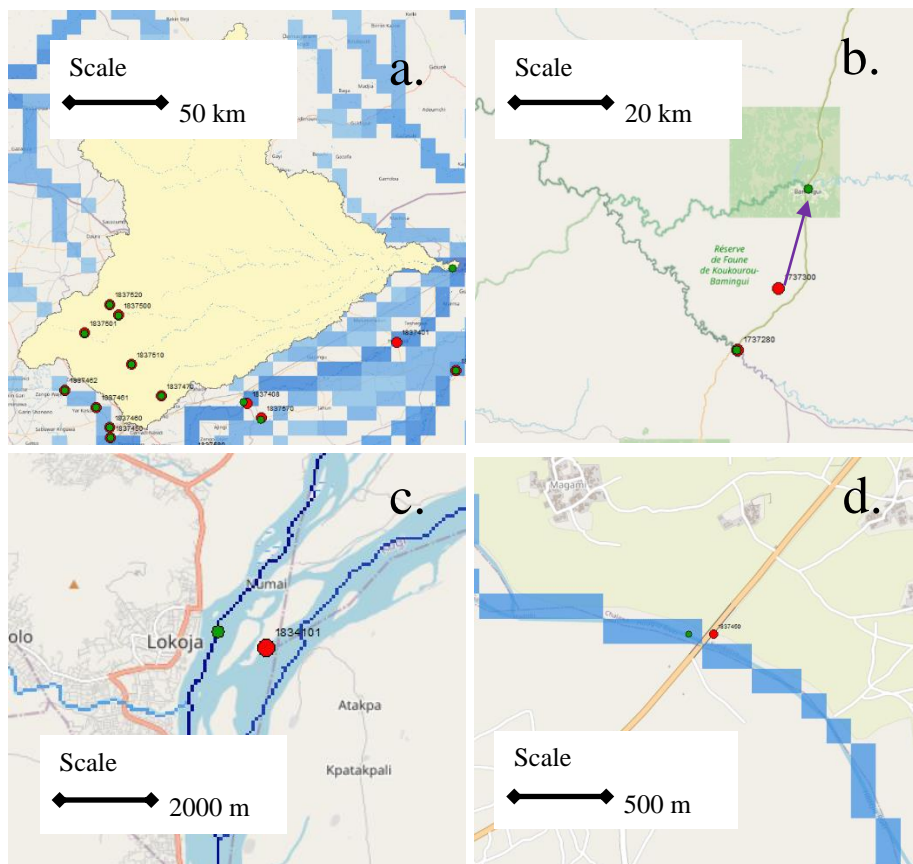

Figure 5: Possible errors in station location. © OpenStreetMap contributors 2022. Distributed under the Open Data Commons Open Database License (ODbL) v1.0.

Figure 5 shows some of the possible errors as well as the need to correct station location that will be used in hydrological models:

Part a) GRDC station 1837401 Hadejia, Nigeria, has a reported upstream area of 30,435 km². The closest river to the city of Hadejia has a high-resolution upstream area of 19,500 km². The next location with a closer upstream area to the reported one (29,000 km²) is 50 km to the northeast. Thus, here, either the station location or the reported area is wrong.

Part b.) GRDC station 1737300 Bamingui, Central African Republic, with a reported area of 4,380 km², has no river of this size at a closer distance. We thus chose the river near the city of Bamingui with a high-resolution upstream area of 6,075 km² at a distance of 25.7 km from the GRDC station location.

Part c) shows the station location of GRDC 1834101 Lokojo, Niger. The station seems to be on the River Benué, a tributary of the Niger River. According to Udo et al. (2021), the station is located on the Niger River, upstream of the junction of the Niger and Benué. Lehner (2012) assumed the station is downstream of the junction. No area is reported as being associated with this station, but the area could be 337,000 km² (Benué), 1651,000 km² (upstream Niger), or 1990,000 km² (downstream Niger).

Part d) shows the GRDC station 1837450 at Challawa Bridge in Nigeria at the exact location underneath a bridge over the River Challawa. However, the high-resolution network of 90 meters shows no river on this grid cell, and the station location
280 must thus be shifted 90 meters to the west.

Another example are GRDC stations 1396200, 1396201, and 1396210, which have the same reported location but different river station names and upstream areas.

For GRDC station 4208919 on the Dunkirk River, Canada, we found a typographical error. Instead of 58N, it should be 56N.
285 Station Siramakana, Mali, at the river Baoule GRDC station 1112330 is, according to Hydroscience_Montpellier (2022), around 50 km from the station location mentioned in the GRDC dataset.

The remaining 10,241 stations are not equally distributed globally. There are regions where water cannot be measured as streamflow, such as Greenland, the Sahara, the Arabic peninsula, the Kalahari, and Central Australia. In other regions, we
290 know that streamflow is measured, but GRDC does not have the records (some parts of Italy, Indonesia), and some regions where we do not even know if there are measurements (e.g., North Korea). Some basins, especially in North America and Europe, have a dense reported discharge station network (e.g., the Danube). Figure 6 shows the number of subbasins of GRDC stations placed inside the other.
295 Danube, just like the concept of stacked dolls (Matryoshka dolls).

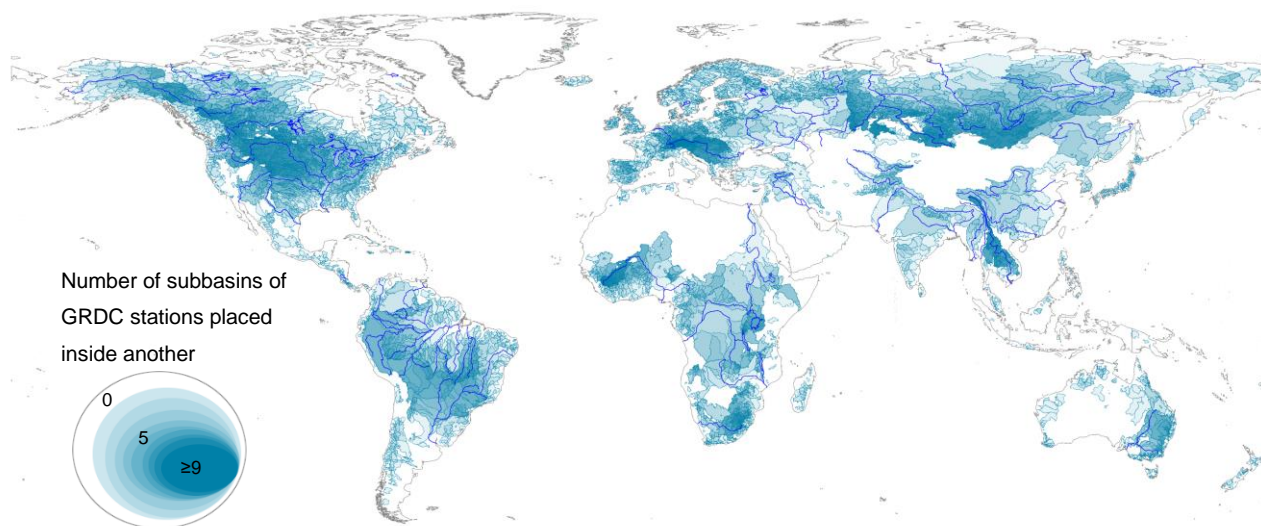

Figure 6. Watershed shapefile of 10241 station using GRDC stations and MERIT network map
(World administrative boundaries by <https://www.opendatasoft.com>)

300 3.3 Station allocation on low resolution 5' and 30'

We allocated 10,241 stations with an area $\geq 10\text{km}^2$, and after creating shapefiles for each station, we created shapefiles and a station record for low-resolution of 30' and 5'. For the resolution of 30', we used a threshold of an upstream basin area of $\geq 9,000\text{ km}^2$ (around three grid cells on 30'). For 5', we used a threshold of $\geq 1,000\text{km}^2$ (~11 grid cells on 5'). This selection was subjective, and other papers have slightly different assumptions (Alfieri et al., 2020).

305

With the similarity method, we can avoid a basin being allocated to a station that fits better by the upstream area but is not very similar to the basin shapefile at high resolution. Figure 7 shows this for two examples. The South Platte River GRDC No. 4122130 joins the North Platte River GRDC No. 4122150 at the city of North Platte, Nebraska, USA, and before the junction, they run in parallel. If we take the location of the station GRDC No. 4122130 on 30', we obtain the North and South Platte River basin together (Platte River). We must therefore move the station to allocate it to the correct basin. The reported upstream area of the station is $61,901\text{ km}^2$. If we had selected only by upstream area, we would have chosen the North Platte River (upstream area of 30': $66,815\text{ km}^2$) in preference to the South Platte River (upstream area of 30': $49,745\text{ km}^2$). Figure 7a shows that the selected 30' basin in darker blue (South Platte River) with the lower upstream area fits better with the high-resolution basin.

315

Figure 4b shows a station mismatch selected by the upstream area at 5'. The river Pisuerga in Spain, GRDC No. 6212740, has a reported upstream area of $15,638\text{ km}^2$. Again, we must move the station, as the river network at 5' does not match the station location. If we select by upstream area, the Douro River, with an upstream area on 5' of $15,448\text{ km}^2$, fits better than the Pisuerga River, with an upstream area on 5' of $15,908\text{ km}^2$. Selecting by area and shape similarity points to the correct basin, shown in dark blue in Figure 4b.

320

Figure 7: Mismatch of basin allocation. © OpenStreetMap contributors 2022. Distributed under the Open Data Commons Open Database License (ODbL) v1.0.

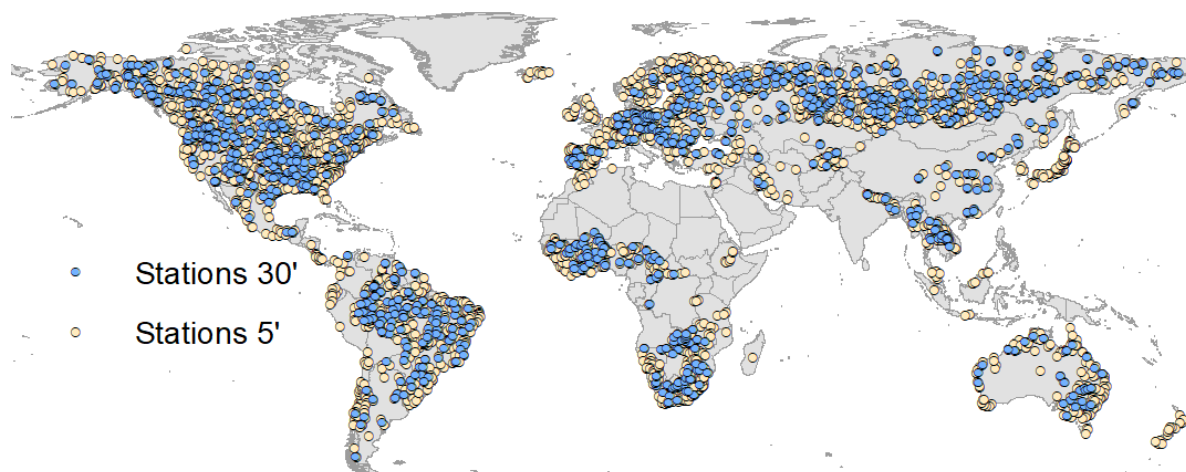

For the coarser resolution of 5', we selected 6,414 stations with a basin area $\geq 1,000$ km². For the resolution of 30', we selected
325 2,741 stations with a basin area $\geq 9,000$ km². We assigned polygons based on the upscaled river network for those two
resolutions. We provided the list of stations with adjusted station locations and the 5' and 30' watershed boundaries as
shapefiles.

3.4 Selecting stations for calibration on low resolution 5' and 30'

Based on the selection criteria of tables 1 and 2, we included meta information of the station time series (length and end date
330 of the time series, number of missing values, daily or monthly values). As mentioned in the method section, the selection
criteria were subjective, but the Python code for changing the criteria tables is available on GitHub.

For the low resolution of 30', from the 2,724 stations (with an upstream area of ≥ 9000 km²), we selected 953 stations for
calibration. Another 105 stations could be used for validation purposes. The latter stations are not in the first calibration
335 category because they are equal to or more than 95%, similar to a station chosen for calibration. We dismissed 1,666 stations
from the calibration because they do not fulfill the necessary criteria given in Table 1. For the low-resolution of 5', we selected
3,917 out of 6,415 stations. Another 175 stations were available for validation, and we dismissed 2,323 stations.

Figure 8 and the histograms in Figure 9 show the global distribution. North America, Brazil, Europe, Russia, and Australia are
well covered, but Asia and Africa only partly. On 5' resolution, 441 stations are in Africa, and 1,270 and 746 are in North
340 America or Europe.

345 **Figure 8:** Selected station for calibration on 30' (949 stations) and 5' (3,917 stations)
(World administrative boundaries by <https://www.opendatasoft.com>)

Figure 9: Histogram of selected calibration stations (a) 949 stations for 30' (b) 3,917 stations for 5', classified by upstream area and continent

350 4. Conclusion

This paper describes the procedure used to generate a dataset of station locations of observed discharge to be used at different resolutions for calibrating large-scale hydrological models. It is based on the metadata of GRDC stations and MERIT Hydro. The Python source code and dataset produced are freely available for download through a GitHub and Zenodo repository.

355 The first step toward generating a high-resolution collection of watershed shapefiles was to update the work of Lehner (2012) to include more basins (10,241 stations vs. 7,163) based on a higher resolution river network database (3'' MERIT Hydro from Yamazaki et al. (2019) vs. 15'' the HydroSHEDS from Lehner et al. (2008), including the changed GRDC IDs from September 2021. The second step, of generating a lower-resolution collection of watershed shapefiles based on the Intersection over Union ratio, was inspired by the ideas of Rezafofighi et al. (2019) and Munier and Decharme (2021). It is a better approach than
 360 selecting a station location on low-resolution river network systems based only on the upstream area and distance to the original location. Here, we provide the low-resolution watershed boundaries on 30' and 5' and the source code to produce results for different resolutions and projection systems. The third step, selecting suitable stations for calibration and validation, was also based on the Intersection over Union ratio. This selection of stations can now be used more effectively to calibrate grid-based hydrological models at different resolutions.

365

We are very grateful for the work of GRDC in collecting and making available a considerable number of stations. Around 8,000 of the 10,701 stations fit very well and have less than a 5% upstream area difference between the reported upstream area and the MERIT Hydro upstream area. 10,000 stations have less than 30% upstream area difference. For 228 stations, however, we could not find a suitable location, and for another 437 stations, the reported area and calculated area are very different (25%
 370 error). Most stations (8544) could be located on the high-resolution MERIT network within a 1 km range. However, 843

stations have a corrected station location more than 5 km distance to the original position. We propose a quality check for these stations; otherwise, the time series cannot be used for any application.

5. Code and data availability

The MERIT Hydro - global hydrography dataset is available for download at http://hydro.iis.u-tokyo.ac.jp/~yamadai/MERIT_Hydro (Yamazaki et al., 2019) and was last updated on 17 May 2019. The metadata information on 10,701 was provided by the Global Runoff Data Centre (GRDC, <https://www.bafg.de/GRDC>) (04/04/2022). The watershed boundaries based on Lehner et al. (2011) can be downloaded from GRDC. The source code, tables, and shapefile datasets for high-resolution 3'' and low-resolution 5' and 30' are stored on Zenodo with the associated DOI <https://doi.org/10.5281/zenodo.6906577>. In addition, we provide the source code on a GitHub repository https://github.com/iiasa/CWATM_grdc_calibration_stations as release version 1.0. Please keep in mind that the Zenodo repository is the location where users can retrieve exactly the data that have been used for this study.

Acknowledgments

The authors acknowledge the Global Runoff Data Centre (GRDC, Koblenz, Germany) for providing the metadata and time series of 10701 discharge stations. We appreciate all the other open-source projects (especially the flwdir open-source project from Eilander et al. (2021)) which we used to collect ideas and which, for our part, we hope to cross-fertilize with our ideas. We are grateful for all the freely available data sets (especially from the MERIT Hydro database). We also thank the students of St. Pölten New Design University, class of Prof. E. Bravi, for providing advice on creating the figures.
