**Abstract.** Ice losses from the Greenland and Antarctic Ice Sheets have accelerated since the 1990s, accounting for a significant  
60 increase in global mean sea level. Here, we present a new 29-year record of ice sheet mass balance from 1992 to 2020 from  
the Ice Sheet Mass Balance Inter-comparison Exercise (IMBIE). We compare and combine 50 independent estimates of ice  
sheet mass balance derived from satellite observations of temporal changes in ice sheet flow, in ice sheet volume and in Earth's  
gravity field. Between 1992 and 2020, the ice sheets contributed  $21.0 \pm 1.9$  mm to global mean sea-level, with the rate of mass  
65 loss rising from  $105 \text{ Gt yr}^{-1}$  between 1992 and 1996 to  $372 \text{ Gt yr}^{-1}$  between 2016 and 2020. In Greenland, the rate of mass loss  
is  $169 \pm 9 \text{ Gt yr}^{-1}$  between 1992 and 2020 but there are large inter-annual variations in mass balance with mass loss ranging  
from  $86 \text{ Gt yr}^{-1}$  in 2017 to  $444 \text{ Gt yr}^{-1}$  in 2019 due to large variability in surface mass balance. In Antarctica, ice losses continue  
70 to be dominated by mass loss from West Antarctica ( $82 \pm 9 \text{ Gt yr}^{-1}$ ) and to a lesser extent from the Antarctic Peninsula ( $13 \pm$   
 $5 \text{ Gt yr}^{-1}$ ). East Antarctica remains close to a state of balance [with a small gain of  \$3 \pm 15 \text{ Gt yr}^{-1}\$](#)  but is the most uncertain  
component of Antarctica's mass balance. [The dataset is publicly available at <https://doi.org/10.5285/77B64C55-7166-4A06-9DEF-2E400398E452> \(The IMBIE Team, 2021\).](#)

## 1 Introduction

The Antarctic and Greenland Ice Sheets store the vast majority (99%) of Earth's freshwater ice on land. The rate of change in  
ice sheet mass - or ice sheet mass balance - is the net difference between mass loss through solid ice discharge at the grounding  
75 line, melting at the bed and at the ice-ocean interface and the surface mass balance (SMB; precipitation minus meltwater  
runoff, sublimation, evaporation, and erosion). Over the past three decades (between the 1990s and 2010s), ice losses from  
Antarctica and Greenland increased six-fold (The IMBIE Team, 2018, 2020), raising the global sea level (WCRP Global Sea  
Level Budget Group, 2018) and with it the risk of coastal flooding worldwide (Kulp and Strauss, 2019; Vitousek et al., 2017;  
Hanson et al., 2011). In Antarctica, the losses have arisen primarily due to ocean-driven melting of ice shelves (Adusumilli et

85 al., 2020; Paolo et al., 2015) and their collapse (Cook and Vaughan, 2010), which have accelerated the ice flow (Hogg et al.,  
2017; Selley et al., 2021; Rignot et al., 2004), retreat (Konrad et al., 2018; Milillo et al., 2022; Jenkins et al., 2018) and  
drawdown (Konrad et al., 2017; Shepherd et al., 2019) of numerous marine-terminating ice streams. In Greenland, increasing  
air temperatures (Hanna et al., 2021) and decreasing cloud cover (Hofer et al., 2017) have exacerbated summertime surface  
melting (Leeson et al., 2015; Tedesco and Fettweis, 2020) and runoff (Trusel et al., 2018; Slater et al., 2021), in tandem with  
90 the speedup (Rignot and Kanagaratnam, 2006) and retreat (King et al., 2020) of outlet glaciers responding to a warming ocean  
(Straneo and Heimbach, 2013). While ice sheet response to climate forcing remains the least constrained component of the  
twenty-first-century sea level budget (Pattyn and Morlighem, 2020; Fox-Kemper et al., 2021), maintaining the long-term  
observational record of ice sheet mass balance is critical to improving ice sheet model skill (Edwards et al., 2021; Ritz et al.,  
2015) and confidence in projections of sea level rise (Aschwanden et al., 2021; Slater et al., 2020; Shepherd and Nowicki,  
95 2017).

Thanks to the launch of new satellite missions and the development of improved geophysical corrections and models of SMB  
and glacial isostatic adjustment (GIA), it is now possible to routinely monitor ice sheet mass changes using observations of  
ice-flow derived from satellite radar and optical imagery (e.g. Gardner et al., 2018; Moon et al., 2012; Mouginot et al., 2017),  
surface elevation changes (derived from satellite altimetry) (e.g. Sandberg Sørensen et al., 2018; Smith et al., 2020), and

100 fluctuations in Earth's gravity field (derived from satellite gravimetry [from GRACE and its follow on](#)) (e.g. Tapley et al., 2019;  
Velicogna et al., 2020; Sasgen et al., 2020). The Ice Sheet Mass Balance Inter-comparison Exercise (IMBIE) has shown that  
there is good agreement between these satellite methods (Shepherd et al., 2012) and that combining independent satellite-based  
ice sheet mass balance estimates reduces uncertainty in estimates of Greenland and Antarctica's contribution to sea level rise.  
By adopting a common framework to support the comparison and aggregation of ice sheet mass balance estimates generated

105 by different participants, it is possible to assess differences between techniques and the impact of using different geophysical  
corrections, [SMB models](#), or GIA models in ice sheet mass balance estimation to produce a reconciled time-series of ice sheet  
mass changes. [SMB models are required for estimating the net mass balance in the input-output method while GIA models are  
necessary to correct ice sheet mass balance estimates derived from satellite gravimetry and to a lesser extent those derived  
from satellite altimetry. The GIA is the result of solid Earth mass redistribution caused by changes in ice mass since the last  
glaciation. Gravimetry fields record the combined effect of mass redistribution due to the GIA and recent changes in ice sheet  
mass balance. The GIA contribution therefore needs to be modelled separately and removed from the gravimetry fields,  
especially since it is of the same order of magnitude as the ice sheet mass balance signal \(Caron and Ivins, 2020; Sutterley et  
al., 2014a\). Altimetry elevation change estimates also need to be corrected for the GIA. However, contrary to gravimetry  
estimates, altimetry estimates are less sensitive to GIA as it manifests as an uplift \(or subsidence\) rate of the order of a few  
millimetres per year, much smaller than the elevation changes recorded.](#) The most recent IMBIE assessments for the Antarctic

110  
115 Ice Sheet and the Greenland Ice Sheet covered the periods 1992 to 2017 and 1992 to 2018, respectively, and reported a  
combined contribution of  $17.8 \pm 1.8$  mm to global mean sea level (GMSL) between 1992 and 2017 (The IMBIE Team, 2018,

2020). Here, we extend these records to cover the same extended period (1<sup>st</sup> January 1992 to 31<sup>st</sup> December 2020) for both ice sheets. In the rest of the paper, all of time periods cited refer to the period extending from 1<sup>st</sup> January of the first year quoted to 31<sup>st</sup> December of the second year quoted.

120 In the years since our most recent assessment there have been notable changes in ice sheet mass in both hemispheres, and in the availability of satellite observations and ancillary datasets with which to detect these changes. In Greenland, for example, atmospheric blocking and reduced summertime snowfall (Tedesco and Fettweis, 2020) led to near-record levels of meltwater runoff in 2019 (Slater et al., 2021) which, in combination with progressively increasing ice discharge (Mouginot et al., 2019), 125 set a new record for annual ice losses during the satellite era (Sasgen et al., 2020). In Antarctica, pervasive mass losses have continued in the Amundsen Sea Sector (Groh and Horwath, 2021) as a consequence of further grounding line retreat (Milillo et al., 2022) and the associated glacier speedup (Joughin et al., 2021). A follow on to the GRACE satellite mission (GRACE-FO) was launched in May 2018 (Tapley et al., 2019), the ICESat-2 satellite laser altimeter mission was launched in September 2018 (Smith et al., 2020), and updated products have been released for many others - including swath altimetry from CryoSat- 130 2 (Gourmelen et al., 2018). To accompany these observations, there have been updated models of GIA (e.g. Caron and Ivins, 2020) to correct mass and elevation changes associated with solid earth movement, of firm densification (e.g. Stevens et al., 2020) to correct changes in elevation for surface processes, and of SMB (e.g. Fettweis et al., 2020; Mottram et al., 2021) to aid mass budget and mass balance partitioning calculations.

135 Here, we make use of new satellite observations, new methods and models to provide an updated IMBIE assessment of Greenland and Antarctic ice sheet mass balance, extending our most recent records by 3 and 4 years, respectively. We provide a description of the datasets incorporated in this updated assessment and of the aggregation methods employed. We also discuss differences between the ice sheet mass balance estimates derived from altimetry, gravimetry and the input-output method, and we present extended reconciled time-series of ice sheet mass change. We discuss the limitations of our dataset and outline a 140 roadmap for future improvements. Finally, we contrast our findings with trends in GMSL and compare them with projections of future ice sheet mass changes from the Intergovernmental Panel on Climate Change's (IPCC) Sixth Assessment Report (AR6).

## 2 Data

Fluctuations in ice sheet mass are a key indicator of ice sheet stability and can be inferred using a range of satellite techniques (Shepherd et al., 2012). Satellite altimetry measures ice sheet elevation change, computed at orbit crossing points by calculating the difference in ice sheet elevation at a crossover point between ascending and descending satellite passes (e.g. Wingham et al., 1998), using clusters of data points acquired along all ground tracks (e.g. Pritchard et al., 2009), or by differencing height models separated over time (e.g. Csatho et al., 2014). Mass balance is estimated by accounting for changes in bedrock elevation (e.g. Caron and Ivins, 2020) and then by either prescribing the density associated to the elevation fluctuation (e.g. Shepherd et

**Deleted:** gravimetry

**Deleted:** Finally,

al., 2019) or by making a model-based correction for changes in firn compaction (Sørensen et al., 2011). The technique is unique in charting patterns of mass imbalance with fine (monthly) temporal sampling and fine ( $10^2$  km $^2$ ) spatial resolution, and there are continental-scale measurements dating back to the early 1990s. Satellite measurements of ice velocity computed from sequential radar and optical imagery (e.g. Rignot and Kanagaratnam, 2006) are the basis of ice sheet input-output

155 assessments (e.g. Rignot et al., 2019; Mouginot et al. 2019). Ice velocities are combined with estimates of ice thickness (e.g. Morlighem et al., 2017) to compute changes in marine-terminating glacier discharge, and then with regional climate model

estimates of surface mass balance sources (snowfall, rainfall) and sinks (runoff, sublimation, evaporation, and erosion) (e.g. Fettweis et al., 2020; Mottram et al., 2021) to measure temporal changes in net mass balance. The technique provides monthly to annual temporal sampling and drainage basin scale spatial resolution, and there are continental-scale measurements dating

160 back to the late 1970s. During the last decade, new satellite missions with a more frequent revisit time (down to 6 days using image pairs from Sentinel-1a and Sentinel-1b available during the period 2016 to 2021 until the end of Sentinel-1b mission)

have been used to improve the temporal resolution of ice velocity measurements, allowing to investigate seasonal fluctuations in ice velocity (King et al., 2018; Lemos et al., 2018) and produce monthly estimates of ice discharge at the continental scale.

Mankoff et al. (2021) even produced daily estimates of ice sheet mass balance from the input-output method by resampling the velocity data, however the original temporal resolution of ice velocity measurements does not exceed 12 days. Satellite

gravimetry measures fluctuations in Earth's gravitational field, computed using either global spherical harmonic solutions (e.g. Velicogna and Wahr, 2006) or using spatially discrete mass concentration units (e.g. Luthcke et al., 2006). Ice sheet mass changes are determined after making model-based corrections for GIA (e.g., Caron and Ivins, 2020) and for the leakage of mass trends occurring elsewhere in the climate system, especially those arising from ocean mass variability and changes in

170 land hydrology. The technique provides fine (monthly) temporal sampling and moderate ( $10^5$  km $^2$ ) spatial resolution, dating back to 2002 with the launch of the GRACE mission and the more recent launch of its follow on GRACE-FO in 2018.

## 2.1. Input Data

To compile our assessment of Greenland Ice Sheet mass balance we use 27 satellite-based estimates of ice sheet mass change, including 8 estimates based on satellite altimetry, 16 based on satellite gravimetry, and 3 based on the input-output method.

175 Compared to the most recent IMBIE assessment, 12 of these estimates have been updated to include more recent data for Greenland. This set of updated estimates is made of 2 estimates from the input-output method, 1 altimetry estimate, and 9

gravimetry estimates including data from the new GRACE Follow-On space gravimetry mission (GRACE-FO). For our assessment of Antarctica's mass balance, we use 23 satellite-based estimates altogether, with 6 derived from altimetry, 16 from gravimetry, and 1 from the input-output method. More than half of these estimates have been extended in time compared to

180 IMBIE-2. These updated estimates for Antarctica include the input-output method estimate, 2 altimetry estimates, and 10 gravimetry estimates combining GRACE and GRACE-FO data. In total, this new IMBIE assessment includes data from 14 satellite missions, spanning the years 1992 to 2020 – with results from all three geodetic techniques available between 2003

and 2018 in Greenland and 2002 and 2018 in Antarctica – and, for the first time, includes data from the GRACE-FO mission launched in 2018. A wide range of GIA models have been used to correct gravimetric and volumetric mass balance estimates. The models use in this assessment are all forward models, which combine a rheology model of the solid Earth with a model of past ice mass change. In this assessment, only two SMB models have been used in the input-output method estimates included – the RACMO (Regional Atmospheric Climate Model) and MAR (Modèle Atmosphérique Régional) models (Table 1).

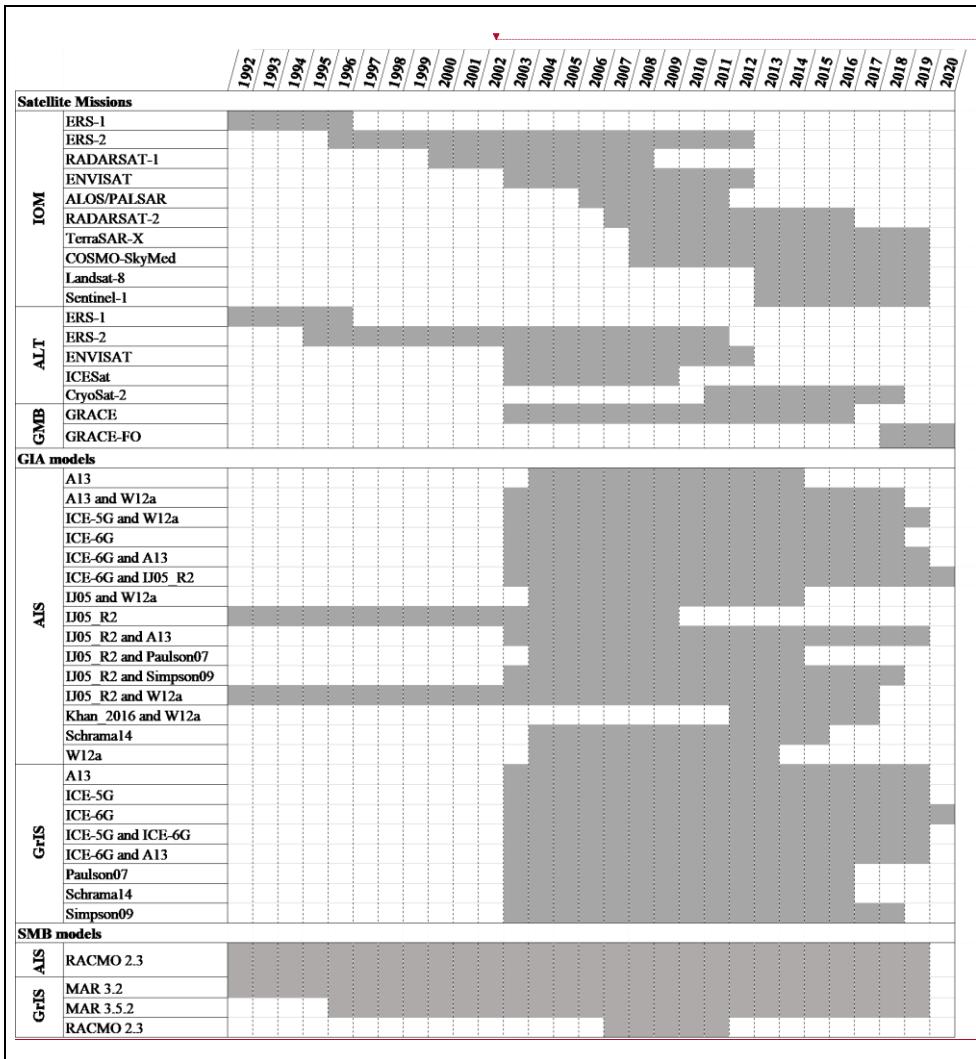

195 **Table 1. Synthesis of satellite datasets, GIA, and SMB models used to derive the individual estimates of ice sheet mass balance included in this study. Details and references of the GIA and SMB models are available in Appendix A.**

**Deleted:** (Table 1)

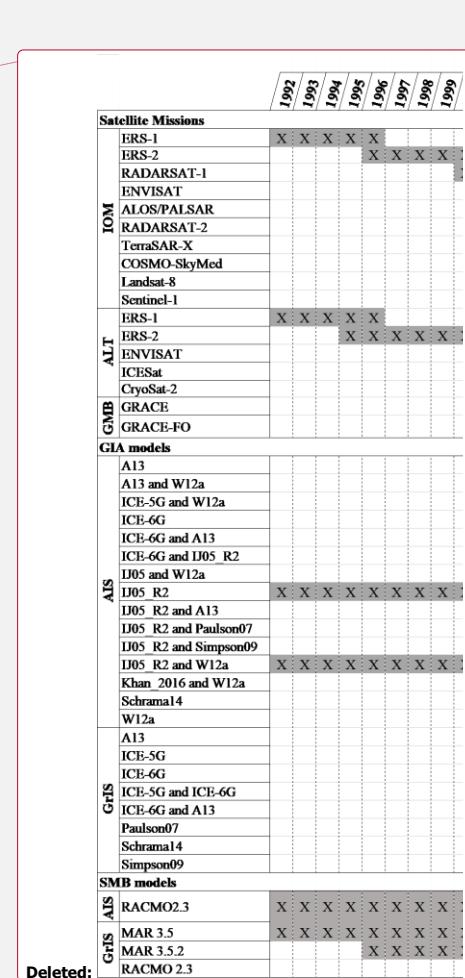

**Deleted:** ¶

**Moved down [1]:** To achieve a meaningful comparison of ice sheet mass balance estimates, we analyse mass trends using common definitions of the Antarctic, West Antarctic, East Antarctic, Antarctic Peninsula and Greenland Ice Sheet boundaries (AIS, WAIS, EAIS, APIS and GrIS, respectively). We use two ice sheet drainage basin sets, both previously used in the past IMBIE assessments (Shepherd et al., 2012; IMBIE Team, 2018; 2020). The first drainage basin set was derived based on ICESat surface elevation data and includes 27 basins in Antarctica covering an area of 11,885,725 km<sup>2</sup> and 19 in Greenland over an area of 1,703,625 km<sup>2</sup> (Zwally et al., 2012) and is retained for consistency with the first IMBIE assessment (Shepherd et al., 2012). The second set defines 18 basins in Antarctica covering 11,892,700 km<sup>2</sup> and 6 in Greenland covering 1,723,300 km<sup>2</sup> (Rignot et al., 2011a; Rignot et al., 2011b). The two ice sheet delineation differ by 1.1 % and 0.1 % of total ice sheet extent for the Greenland and Antarctic Ice Sheets, respectively, and thus using either of these definitions leads to a negligible difference in mass balance (The IMBIE Team, 2018; 2020).¶

**Deleted:** ¶

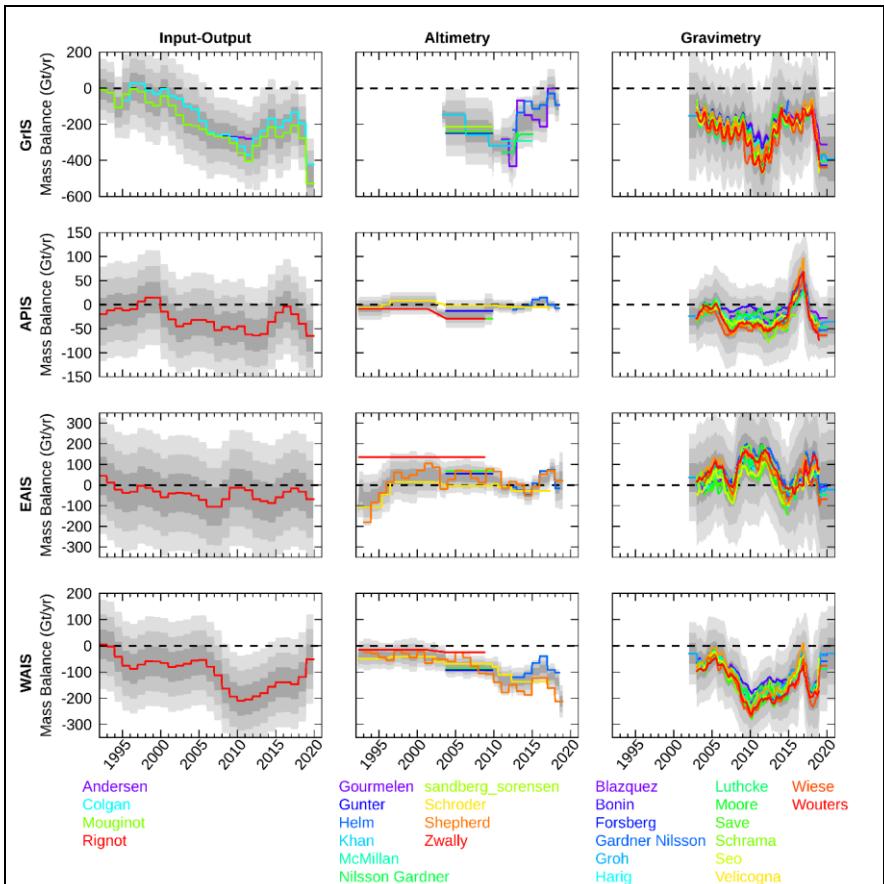

To achieve a meaningful comparison of ice sheet mass balance estimates, we analyse mass trends using common definitions of the Antarctic, West Antarctic, East Antarctic, Antarctic Peninsula, and Greenland Ice Sheet boundaries (AIS, WAIS, EAIS).

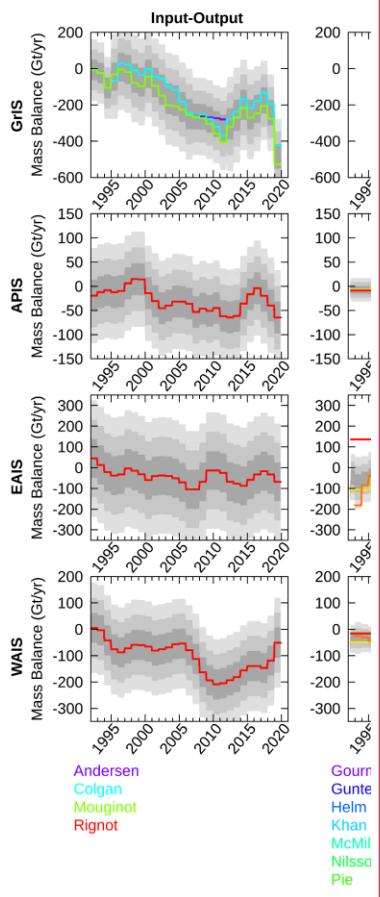

Moved (insertion) [1]

APIS, and GrIS, respectively). We use two ice sheet drainage basin sets, both previously used in the past IMBIE assessments (Shepherd et al., 2012; IMBIE Team, 2018; 2020). The first drainage basin set was derived based on ICESat surface elevation data and includes 27 basins in Antarctica covering an area of 11,885,725 km<sup>2</sup> and 19 in Greenland over an area of 1,703,625 km<sup>2</sup> (Zwally et al., 2012) and is retained for consistency with the first IMBIE assessment (Shepherd et al., 2012). The second set defines 18 basins in Antarctica covering 11,892,700 km<sup>2</sup> and 6 in Greenland covering 1,723,300 km<sup>2</sup> (Rignot et al., 2011a; Rignot et al., 2011b). The two ice sheet delineation differ by 1.1 % and 0.1 % of total ice sheet extent for the Greenland and Antarctic Ice Sheets, respectively, and thus using either of these definitions leads to a negligible difference in mass balance (The IMBIE Team, 2018; 2020). IMBIE participants were free to use either of these two definitions, and we combine mass trends over the GrIS, AIS, WAIS, EAIS, and APIS together regardless of what definition was chosen. The different estimates included in this assessment are presented on Figure 1.

**Figure 1. Individual rates of ice sheet mass balance from the input-output, altimetry, and gravimetry groups over the GrIS, APIS, EAIS, and WAIS included in this study. The grey shading shows the estimated 1 $\sigma$ , 2 $\sigma$ , and 3 $\sigma$  ranges of the aggregated time-series per group in dark, mid, and light grey, respectively. The uncertainty is calculated as the root mean square of the contributing errors at each monthly epoch.**

**Deleted: A**

### **Deleted: our final aggregated estimate**

**Deleted:** are shaded

## 2.2 Output Data

240 The output data consists of a single reconciled estimate of ice sheet mass balance covering the period 1<sup>st</sup> January 1992 to 31<sup>st</sup> December 2020 for the GrIS, AIS, APIS, WAIS, EAIS, and the sum of the GrIS and AIS. Two CSV files are provided for each ice sheet region, one with the data provided in Gigatons (Gt) and one with the data provided in equivalent sea level contribution in millimetres (mm). These files contain annual rates of mass balance and cumulative mass changes with their corresponding uncertainties.

## **3 Methods**

245 IMBIE participants contributed time-series of either relative mass change,  $\Delta M(t)$ , or of rate of mass change,  $dM(t)/dt$ , with their associated uncertainty, integrated over at least one of the ice sheet regions defined in the standard drainage basin sets. To produce a reconciled estimate of ice sheet mass change from these individual estimates, we compare and aggregate  $dM(t)/dt$  from each satellite technique. [The IMBIE assessment software used to produce the dataset presented in this study is available at <https://doi.org/10.5281/zenodo.7342481>](https://doi.org/10.5281/zenodo.7342481). We apply a consistent processing scheme to all submitted datasets and for all ice sheet regions which consists of: i) computing  $dM(t)/dt$  for all datasets that were submitted as  $\Delta M(t)$ , ii) aggregating time-series 250 of mass trends within each class of satellite observations, iii) combining the altimetry, gravimetry, and mass budget time-series to derive a single reconciled time-series of mass trends, and iv) integrating this reconciled time-series of mass trends to produce the final reconciled time-series of cumulative mass change. In what follows, we summarise each of these processing steps:

### *i) Computing time-series of mass trends*

255 First, we derive time-series of monthly rates of ice sheet mass change,  $dM(t)/dt$ , for all datasets that were submitted as  $\Delta M(t)$  to allow the aggregation of datasets within each satellite observations class as  $dM(t)/dt$  computed using a standardised approach. At each epoch, we estimate  $dM(t)/dt$  by fitting a linear trend to the  $\Delta M(t)$  data falling within a sliding window of 36 months, centred around the given epoch, using a weighted least-squares approach, with each point weighted by its error. The error on the derived time-series is taken as the regression error which incorporates the original measurement error and the 260 linear model structural error [computed as the standard error of the linear regression](#). Finally, the derived time-series of mass trends are truncated by half the window width at the start and end of their period.

### *ii) Aggregating time-series of mass trends from similar satellite observations*

265 We aggregate the standardised time-series of mass trends within the altimetry, gravimetry, and mass budget groups separately to produce three time-series over each ice sheet region. We calculate each aggregated time-series by taking the error-weighted average of monthly rates of ice sheet mass change computed using the same technique. The associated error is calculated as the root mean square of the contributing time-series errors.

270 *iii) Combining the altimetry, gravimetry, and mass budget time-series of mass trends*

275 We combine the altimetry, gravimetry, and input-output time-series to produce a single reconciled time-series of mass trends by taking the error-weighted mean of the available estimates at each epoch. We estimate the error on the reconciled mass trend time-series at each epoch as the root mean square error divided by the square root of the number of independent techniques for which a mass trend estimate is available. From this reconciled time-series of mass trends, we compute rates of mass balance over each calendar year and over different time periods as the average of the monthly rates falling within the defined time interval, with the associated error as the average of the contributing errors divided by the square root of the numbers of years of the time period. Finally, when summing mass trends of multiple ice sheets, the combined uncertainty is estimated as the root sum square of the uncertainties for each region.

280 *iv) Generating the final reconciled time-series of cumulative mass change*

285 We generate a time-series of cumulative ice sheet mass change by integrating our reconciled time-series of mass trends over time for each ice sheet. We estimate the cumulative errors as the root sum square of annual errors, assuming that errors are not correlated over time. Errors quoted in the text refer to the  $1\sigma$  estimated error.

## 4 Results

First, we compare individual estimates of ice sheet mass balance within each of the three geodetic technique experiment groups, 285 separately, to assess the level of agreement among estimates derived using the same technique. Within each group, we compare annual rates of mass change and their standard deviation for each ice sheet region. The input-output group includes significantly fewer mass balance estimates than the other technique experiment groups, but these estimates have the advantage of providing information on the partitioning of mass trends between signals related to SMB and ice dynamics, and they also cover relatively long periods of time. Ice discharge is measured from satellite observations of ice velocities combined with estimates of ice 290 thickness at glaciers' termini, and SMB is derived from regional climate model outputs. To estimate the SMB anomaly in Greenland, two estimates used MAR (version 3.2 and version 3.5.2) and one used RACMO (version 2.3). In Antarctica, the input-output estimate used RACMO (version 2.3). In addition to using different SMB models, those estimates also define different reference periods to calculate the SMB anomalies. All of the mass balance estimates derived in this group were originally posted at annual resolution and we resample them over monthly epochs to aggregate them with estimates from the other groups. We include 3 input-output method estimates of GrIS mass balance, all at annual resolution and that together span the period 1992 to 2020 and overlap during the period 2007 to 2011. During their common period, annual rates of mass change determined from these three input-output datasets have a median difference of 28.5 Gt yr<sup>-1</sup> with a standard deviation of 35 Gt yr<sup>-1</sup>. For Antarctica and its ice sheet components, we include one input-output mass balance estimate which covers the entire 1992 to 2020 period at annual resolution.

310 The altimetry group includes 8 mass balance estimates for the GrIS that together span the years 2003 to 2018, with 4 of these  
311 solutions derived from radar altimetry, 2 from laser altimetry, and 2 from a combination of both. We include 6 altimetry mass  
312 balance estimates for the AIS which together cover the period 1992 to 2019. In total we include 6 solutions for the EAIS, 6 for  
313 the WAIS, and 5 for the APIS. Of these, 2 solutions are derived from radar altimetry, 1 from laser altimetry, and 3 from a  
314 combination of both. To derive rates of surface elevation change, various methods were applied to the laser and radar altimetry  
315 data including repeat-track, plane fit, or overlapping footprints techniques. For Greenland, half of the participants corrected  
316 the altimetry time-series for the GIA effect while for Antarctica, all participants applied a GIA correction. Next, to derive mass  
317 trends from rates of surface elevation change, either a constant density or a spatially and time varying density field from a  
318 density model forced by a regional climate model, were applied. These solutions have varying temporal resolutions ranging  
319 from 1 month to 7.1 yr for an average effective temporal resolution of 3.0 yr for Greenland and 2.6 yr for Antarctica. The  
320 temporal resolution of the altimetry group is thus lower than annual, mainly due to the fact that solutions derived from laser  
321 altimetry data were all provided as constant rates spanning the duration of ICESat-1 mission while the radar altimetry solutions  
322 have a higher temporal resolution of 0.35 yr for Greenland and 0.47 yr for Antarctica. As there is no overlap period during  
323 which all altimetry estimates are available, we compare solutions derived solely from radar altimetry and solutions  
324 incorporating laser altimetry data separately. In Greenland, radar altimetry solutions have a median difference of 144 Gt yr<sup>-1</sup>  
325 and standard deviation of 67 Gt yr<sup>-1</sup> during their two-year overlap period (2013 to 2014) while the median difference between  
326 laser and combination solutions is 29 Gt yr<sup>-1</sup> with a standard deviation of 29 Gt yr<sup>-1</sup> during their 6-year overlap (2004 to 2009).  
327 In Antarctica, the spread between laser solutions is largest at the EAIS with a standard deviation in annual rates of 38 Gt yr<sup>-1</sup>  
328 between 2004 and 2008, followed by the WAIS and APIS with standard deviations of 23 Gt yr<sup>-1</sup> and 10 Gt yr<sup>-1</sup>, respectively.  
329 On the other hand, radar altimetry solutions show a larger spread at the WAIS (21 Gt yr<sup>-1</sup>) than at the EAIS (14 Gt yr<sup>-1</sup>) during  
330 their overlap period (2013 to 2018).

331 The gravimetry group has the largest number of estimates, with 16 for each ice sheet that together span the period 2002 to  
332 2020. All gravimetry solutions were submitted as time-series of cumulative mass change at monthly resolution resulting in a  
333 collective effective resolution of 0.08 yr. All participants submitted estimates for all ice sheet regions, with 10 participants  
334 analysing spherical harmonic gravity field solutions using a wide range of approaches and 6 participants using mass  
335 concentration units (usually referred to as mascons) directly estimated from the GRACE and GRACE-FO level-1 K-band  
336 ranging data. Various GIA, hydrology leakage, and ocean leakage models were used to correct the gravimetry data for external  
337 signals. Overall, there is good agreement between rates of ice sheet mass balance derived from satellite gravimetry. In  
338 Greenland, we compare the different gravimetry solutions over the period 2012 to 2014 and find that annual rates of mass have  
339 a median difference of 36 Gt yr<sup>-1</sup>, and standard deviation is 30 Gt yr<sup>-1</sup>. In Antarctica, the different gravimetry solutions overlap  
340 over a decade from 2004 to 2014 during which their annual rates of mass balance have a median difference of 41 Gt yr<sup>-1</sup>. When  
341 comparing over the different regions of the Antarctic continent, the difference is greatest at the EAIS with a median difference  
342 of 31 Gt yr<sup>-1</sup> and standard deviation of 26 Gt yr<sup>-1</sup>. In the other regions, gravimetry estimates are in better agreement at the APIS

with a ~~median~~ difference of ~~8~~ Gt yr<sup>-1</sup> and standard deviation of 10 Gt yr<sup>-1</sup>, followed by the WAIS where the ~~median~~ difference between estimates reaches ~~19~~ Gt yr<sup>-1</sup> and their standard deviation is ~~17~~ Gt yr<sup>-1</sup>.

Comparing mass balance estimates derived from similar satellite observations reveals that in Greenland, the ~~median difference~~ between estimates is the largest for the altimetry group and the smallest for the input-output group. In Antarctica, the ~~median difference~~ between altimetry estimates is less than ~~38~~ Gt yr<sup>-1</sup> and less than 41 Gt yr<sup>-1</sup> for gravimetry estimates during their respective overlap periods. However this comparison is limited by the varying temporal resolutions of the different datasets – especially for the altimetry group for which constant rates of mass change over long periods of time dampen temporal variation in ice sheet mass changes – and by the small number of input-output estimates – in particular in Antarctica where only one estimate is available. This limits our ability to link differences between estimates derived from the same geodetic technique to methodological differences, or to the use of different geophysical corrections or auxiliary datasets.

**Deleted:** three techniques

**Deleted:** aggregated

390 Next, we assess differences between the aggregated time-series derived within each class of satellite observations during the periods when estimates from all three geodetic techniques are available – from 2003 to 2018 for Greenland and from 2002 to 2019 for Antarctica (Figure A1). We compare rates of mass change during these overlap periods, which are 5 and 10 years longer than in the previous IMBIE assessments, respectively (Figure 3). **We report the standard deviation of the aggregated-altimetry, gravimetry and input-output estimates rates of mass change and compare it to the reconciled rate of mass change and its uncertainty (computed as described in Section 3).** In Greenland, rates of mass balance determined from altimetry, gravimetry, and the input-output method are in close agreement between 2003 and 2018, with a standard deviation of  $19 \text{ Gt yr}^{-1}$  and a reconciled rate of mass loss of  $221 \pm 22 \text{ Gt yr}^{-1}$  from all three techniques. In Antarctica, the reconciled rate of mass loss between 2003 and 2019 is  $115 \pm 24 \text{ Gt yr}^{-1}$  but the spread of the altimetry, gravimetry and mass budget estimates is 4 times larger than in Greenland ( $79 \text{ Gt yr}^{-1}$ ). Over the different regions of Antarctica, the spread of estimates of ice sheet mass 395 balance increases with the size of the region considered, with standard deviations of  $54 \text{ Gt yr}^{-1}$ ,  $18 \text{ Gt yr}^{-1}$ , and  $16 \text{ Gt yr}^{-1}$ , at the EAIS, WAIS, and APIS, respectively. Across all ice sheets, the input-output estimate is the most negative and the altimetry the most positive except at the EAIS, where the gravimetry estimate is the most positive. The greatest departure occurs at the EAIS where the three geodetic techniques disagree on even the sign of the mass change, with a maximum difference of  $105 \pm 400 33 \text{ Gt yr}^{-1}$  between rates of mass change from the input-output method and gravimetry estimates. This indicates that the EAIS remains a challenging region for which to monitor mass changes, likely due to the large extent of this region, the poorly constrained GIA signal and paleo-ice reconstruction (Bentley et al., 2014; Martín-Español et al., 2016; Small et al., 2019), and the relatively small mass imbalance in comparison to natural fluctuations in SMB in East Antarctica (Mottram et al., 2021).

Deleted: 2

When examining the aggregated time-series of rate of mass change at annual resolution, we find the highest temporal correlation between the three time-series at the WAIS ( $0.6 < r^2 < 0.9$ ). In addition, the gravimetry and input-output annual rates are also well-correlated at the APIS and GrIS ( $r^2 > 0.5$ ). However, the altimetry mass balance time-series is poorly correlated with both the aggregated gravimetry and input-output time-series at the APIS, EAIS, and GrIS ( $r^2 < 0.2$ ). The better correlation between the gravimetry and input-output time-series can be explained by their higher temporal resolutions, sufficient to resolve annual fluctuations in ice sheet mass balance which are substantial in these regions. Nonetheless, we find that almost all individual estimates of annual rates of mass balance included in this study fall within one standard deviation ( $1\sigma$ ) of our reconciled estimate given their respective individual errors, with 100 %, 96 %, 100 %, 96 %, and 99 % of those annual rates of mass change falling within  $1\sigma$  at the GrIS, AIS, APIS, EAIS, and WAIS, respectively.

We integrate the combined mass balance estimates from gravimetry, altimetry, and the input-output method (Figure 2) to determine the cumulative mass lost from Antarctica and Greenland since 1992 (Figure 4). Antarctic mass loss continues to be dominated by ice discharge from West Antarctica where the signal is strongest – rising from  $37 \pm 19$  Gt  $\text{yr}^{-1}$  between 1992 and 1996 to a maximum of  $131 \pm 21$  Gt  $\text{yr}^{-1}$  between 2012 and 2016 (Table 2), before slowing slightly to  $94 \pm 25$  Gt  $\text{yr}^{-1}$  during the last 5 years of our survey between 2017 and 2020. At the Antarctic Peninsula the increase in losses since the early 2000s that

Deleted: 1

Deleted: 3

is generally associated with ice-shelf collapse (Rignot et al., 2004; Cook and Vaughan, 2010; Adusumilli et al., 2018) was masked briefly between 2012 and 2016, when the average rate of mass loss was reduced by  $15 \text{ Gt yr}^{-1}$  to  $6 \pm 13 \text{ Gt yr}^{-1}$  in part due to an extreme snowfall event in 2016 (Wang et al., 2021; Chuter et al., 2021), before returning to  $21 \pm 12 \text{ Gt yr}^{-1}$  between 2017 and 2020. East Antarctica remains the least certain component of Antarctic Ice Sheet mass balance, where the average  
 435 30-year mass trend is  $3 \pm 15 \text{ Gt yr}^{-1}$ . In all, the Antarctic Ice Sheet lost  $2671 \pm 530 \text{ Gt}$  of ice between 1992 and 2020, raising the global sea level by  $7.4 \pm 1.5 \text{ mm}$ ; after doubling in the mid-2000s from  $62 \pm 41 \text{ Gt yr}^{-1}$  to  $130 \pm 45 \text{ Gt yr}^{-1}$ , increased Antarctic ice losses – largely driven by an acceleration in ice discharge from the Amundsen Sea Sector (Mouginot et al., 2014)  
 440 – have persisted to the present-day. The rate of Greenland ice loss has remained highly variable during the last 5-year period of our updated assessment, ranging from  $86 \pm 75 \text{ Gt yr}^{-1}$  in 2017 to a new maximum of  $444 \pm 93 \text{ Gt yr}^{-1}$  in 2019 driven by exceptional surface melting during the summer (Tedesco and Fettweis, 2020). The majority of ice sheet losses have arisen from Greenland during our 29-year survey:  $4892 \pm 457 \text{ Gt}$  in total at an average rate of  $169 \pm 16 \text{ Gt yr}^{-1}$ . Combined, Antarctica and Greenland lost  $7563 \pm 699 \text{ Gt}$  of ice between 1992 and 2020, raising the global sea level by  $21 \pm 2 \text{ mm}$ .

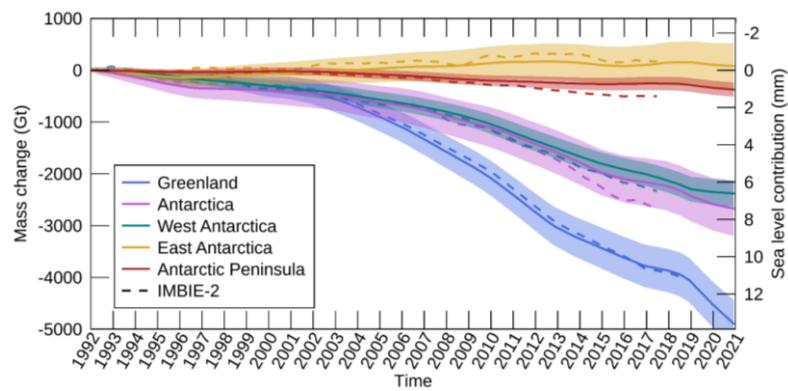

Figure 4. Cumulative ice sheet mass changes. The estimated  $1\sigma$  uncertainty of the cumulative change is shaded. The dashed lines show the results from our previous assessments (IMBIE-2).

## 5 Discussion

### 5.1. Comparison to previous IMBIE assessment

Finally, we assess the consistency of our results with our most recent assessment of ice sheet mass balance (IMBIE-2) to evaluate the impact of incorporating updated datasets and using an updated processing scheme. During their overlapping periods – 1992 to 2017 for Antarctica and 1992 to 2018 for Greenland – the results of this study and IMBIE-2 are in agreement within their respective uncertainties with rates of mass change of -150.0 ± 16 Gt yr<sup>-1</sup> and -150 ± 12 Gt yr<sup>-1</sup> for GrIS, respectively and rates of -86 ± 19 Gt yr<sup>-1</sup> and -103 ± 22 Gt yr<sup>-1</sup> for AIS, respectively. Next, comparing rates of mass balance within calendar years shows that results from this study and our previous assessment are consistent across all years for all ice sheets, except for two years at the start of our record (1992 and 1995) at the GrIS for which the difference between our mass balance assessments exceeds their respective uncertainty bounds. On average, the magnitude of the differences in annual rates of mass balance is 36 Gt yr<sup>-1</sup> at GrIS, 33 Gt yr<sup>-1</sup> at AIS, 12 Gt yr<sup>-1</sup> at APIS, 31 Gt yr<sup>-1</sup> at EAIS, and 23 Gt yr<sup>-1</sup> at WAIS. The relatively small differences between our previous and current mass balance assessments originate from a combination of our inclusion of updated datasets and the implementation of an updated processing scheme in this study. In all ice sheet regions, participant datasets have been updated compared to our previous assessment. In addition, in this study we apply a common processing scheme to the AIS and GrIS, while in our previous study the mass balance assessments were aggregated with and without inverse-error weighting in the respective regions. ¶

scheme to the AIS and GrIS, while in our previous study the mass balance assessments were aggregated with and without inverse-error weighting in the respective regions.

## **5.2 Comparisons to sea level contribution and projections of future sea level rise**

**Deleted: ¶**

490 Our assessment of ice sheet mass balance also provides a means of tracking the contribution of the ice sheets to GMSL. Here, we discuss the relative contributions of Greenland and Antarctica to GMSL by comparing our results to the GMSL trend from the AVISO product (<https://www.aviso.altimetry.fr/msl/>, last access: 12<sup>th</sup> April 2022). Although numerous satellite-altimetry-based time-series of GMSL are available, differences between these products are less than 5 % of the GMSL trend (Ablain et al., 2019) and so the choice of one particular source does not affect our present discussion. From our updated assessment,

495 Greenland and Antarctica have contributed  $0.74 \pm 0.07 \text{ mm yr}^{-1}$  to GMSL during the AVISO record (1993-2020), contributing 14 % and 8 % to the overall trend, respectively. This is consistent with findings from previous studies which examined the relative contributions of the different components of the sea level budget (WCRP, 2018; Horwath et al., 2022). Compared to the pre-2000s period (1993-1999) when the ice sheets' contribution to GMSL was only  $0.26 \pm 0.11 \text{ mm yr}^{-1}$  (9 % of the GMSL trend), Greenland and Antarctica now (2010 to 2020) contribute  $1.09 \pm 0.12 \text{ mm yr}^{-1}$  (24 % of the GMSL trend) – four times

500 higher. In particular, the acceleration of the ice sheets' contribution to GMSL was driven by increased ice losses from the GrIS (Chen et al., 2017; Dieng et al., 2017, Hamlington et al., 2020) with its contribution rising from  $0.12 \pm 0.08 \text{ mm yr}^{-1}$  pre-2000s to  $0.68 \pm 0.08 \text{ mm yr}^{-1}$  in the 2010s. In all periods post-2000, we find that the ice sheets make up at least 20 % of the GMSL rise and during the period 2007-2011 in particular, ice losses accounted for 47 % of the GMSL rise due to accelerated ice losses from Greenland and West Antarctica during those 5 years (Table 2).

505 Satellite observations of ice sheet mass balance are important for evaluating ice sheet models and their climate model forcing (Shepherd and Nowicki, 2017; Slater et al., 2020; Aschwanden et al., 2021). In their 2021 assessment (AR6), the IPCC projected ice losses from Antarctica and Greenland due to SMB and glacier dynamics under a range of emission scenarios every ten years, beginning in 2020 (Fox-Kemper et al., 2021) (Figure 4). As a result, we compare satellite mass balance rates from the decade prior (2010-2020) to those at the beginning of the projection period (2020-2030) (Table 3). In Antarctica, the

510 observed sea level contribution during the last 10 years of our survey is  $0.42 \pm 0.09 \text{ mm yr}^{-1}$ , closest to the median sea level contribution projected by the IPCC for the following decade ( $0.6 \text{ mm yr}^{-1}$ ). We note the large spread between the lower (10th percentile) and upper (90th percentile) ranges of the projected sea level contribution from Antarctica during this period – between  $-0.1 \text{ mm yr}^{-1}$  and  $2.2 \text{ mm yr}^{-1}$ , respectively – even in their first decade. Although Greenland ice losses were highly variable between 2010 and 2020, they raised the global sea level at an average rate of  $0.68 \pm 0.08 \text{ mm yr}^{-1}$ , closest to the

515 median sea level contribution between 2020 and 2030 predicted by the IPCC ( $0.7 \text{ mm yr}^{-1}$ ). If the recent acceleration in Greenland ice losses were to continue ( $1.2 \pm 0.2 \text{ mm yr}^{-1}$  between 2019 and 2020), however, they would track above the upper

range predicted by the IPCC this decade (1.0 to 1.1 mm yr<sup>-1</sup> for all emission pathways). If ice sheet losses were to continue on the median IPCC trajectory, the polar ice sheets will raise global sea levels by between 148 and 272 mm by 2100 (Figure 5).

**Deleted: 4**

520 Because the AR6 projections incorporate a long-term dynamic ice sheet response based on observations from the last 40 years (Fox-Kemper et al., 2021), it follows that our assessment tracks closest to the median range in the near-term; as the overlap period between our survey and AR6 predictions is only one year, a longer period of comparison is required to establish the actual trajectory the ice sheets are following and the suitability of the time period used to assess the long-term dynamic response. Remaining uncertainties in the Antarctic Ice Sheet response to climate forcing still drive the spread of climate model 525 projections, which range between -5 and 631 mm for both ice sheets at 2100.

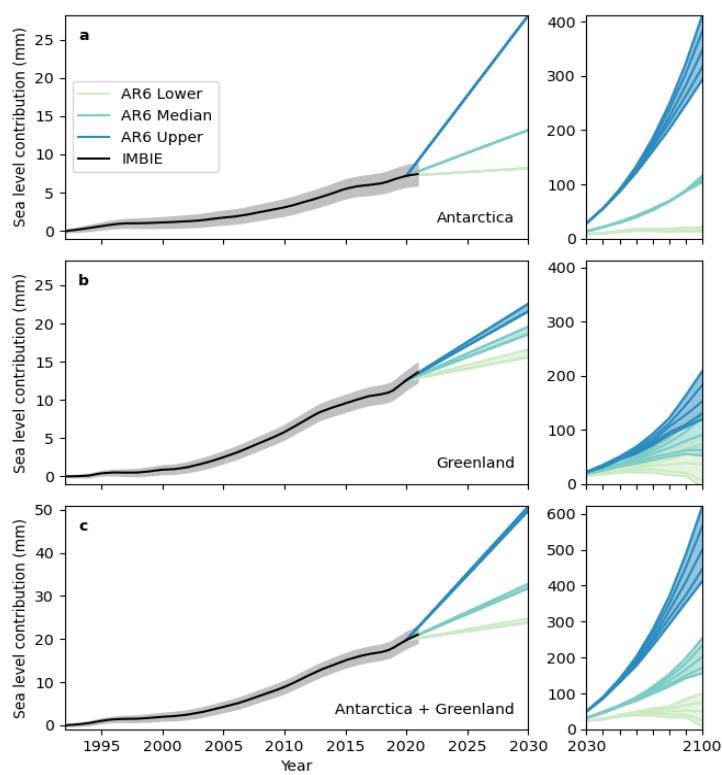

Figure 5. Comparison of observed sea level contributions from a) the Antarctic Ice Sheet, b) Greenland Ice Sheet, c) Antarctic and Greenland Ice Sheets from this study (IMBIE) and predicted by the IPCC AR6 between 1992 and 2030 (left) and 2030 and 2100 (right). The AR6 upper, median and lower estimates are taken from the 90<sup>th</sup> percentile, median, and 10<sup>th</sup> percentile values of the ensemble range, respectively.

### 5.3 Limitations of this study and roadmap for future improvements

530 In this section, we discuss the limitations of our dataset and a roadmap to improve ice sheet mass balance assessments. The inclusion of the peripheral glaciers and ice caps in the vicinity of the Greenland and Antarctic Ice Sheets is ambiguous in our assessment as not all individual estimates of ice sheet mass balance included here account for those. This relates to the varying ability of satellite techniques to resolve mass balance over those small glaciated areas. Space gravimetry has a coarse spatial resolution of a few hundred kilometres which is not sufficient to separate signals of mass change originating from the ice sheet and its peripheral glaciers. On the other hand, the altimetry estimates included in this assessment exclude the peripheral glaciers and ice caps due to the complex terrain of these glaciers and their relatively small size compared to the footprint size of traditional pulse-limited altimeters. Finally, the input-output estimates do include mass changes from these glaciers, mostly by estimating their changes in SMB. Despite covering a relatively small area (around one tenth of the area of the ice sheets) (Pfeffer et al., 2014), these glaciers contribute significantly to global mean sea level rise with ice losses originating from the

535 Greenland and Antarctic Ice Sheets amounting to  $36 \pm 6$  Gt yr<sup>-1</sup> and  $21 \pm 5$  Gt yr<sup>-1</sup> during the period 2010-2019, respectively (Hugonnet et al., 2021). In addition, ice losses have accelerated in the periphery of the Greenland Ice Sheet, with glacier mass loss increasing by 64 % between 2003-2009 and 2018-2021 (Khan et al., 2022). These glaciers therefore need to be accounted for without ambiguity in future IMBIE assessments to remove systematic biases between the different satellite techniques linked to their (non-)inclusion in individual mass balance estimates. Recent progress in satellite altimetry, with the

540

development of CryoSat-2 swath radar altimetry for measuring mass changes of mountain glaciers (Foresta et al., 2016; Jakob et al., 2021) and the launch of ICESat-2, already contribute to a better mapping of those glaciers. New community initiatives, 550 such as GlamBIE (the Glacier mass balance Inter-comparison Exercise), will further contribute to separating mass changes between the ice sheets and glaciers lying at their periphery by offering a consensus-estimate that could be removed from the gravimetry estimates that currently account for both.

Continuing efforts to understand the remaining differences between altimetry, gravimetry, and the input-output method is 555 critical to provide more robust observational estimates of the contribution of the ice sheets to GMSL. Producing estimates with a better temporal resolution by using data from the newest satellite missions, reprocessing the satellite record with the newest geophysical corrections, and using a better uncertainty characterisation, will undoubtedly help further reconcile satellite 560 assessments of ice sheet mass balance produced from different techniques. To achieve this, it is also important to assess the impact of SMB and GIA models. SMB processes are responsible for a large proportion of Greenland's ice losses (and to a lesser extent of Antarctica's ice losses) (Enderlin et al., 2014; Shepherd et al., 2020), and thus pursuing the efforts of recent model inter-comparisons (Fettweis et al., 2020; Mottram et al., 2021) is key to improve the agreement between input-output 565 estimates but also to partition mass trends into SMB and ice dynamics components as it provides critical information on the dominant processes at play. A model-inter-comparison of GIA models would also be timely as new approaches have been developed in recent years to determine the GIA signal (Whitehouse, 2018). New data-driven solutions that rely on present day geodetic observations (e.g. Riva et al., 2009; Vishwakarma et al., 2022), and solutions derived from coupling a GIA model to an ice sheet mode (de Boer et al., 2017) have become available. Examining the variability of GIA solutions determined from 570 forward models, data inversion, and coupled models will help reducing uncertainties in space gravimetry estimates of ice sheet mass balance.

Finally, improving the spatial resolution of the IMBIE assessment by producing time-series of mass changes within the individual basins of the Greenland and Antarctic Ice Sheets will also contribute to further identify areas of similarities and 575 disagreement between satellite techniques (Sutterley et al., 2014) and will support the identification of spatial biases in satellite estimates of ice sheet mass balance. In addition, regional assessments of ice sheet mass balance could support the evaluation and calibration of ice sheet models, contributing to reducing uncertainties in future sea level rise projections (Edwards et al., 2021; Nias et al., 2019).

## 6 Conclusions

575 We combine 50 estimates of ice sheet mass balance, 26 for Greenland and 24 for Antarctica, to produce a new reconciled estimate of ice sheet mass balance showing that the ice sheets lost  $7,563 \pm 699$  Gt of ice between 1992 and 2020. Ice losses have accelerated at both ice sheets over this 29-year record and the rate of ice loss is now 5 times higher in Greenland and 25 % higher in Antarctica compared to the early 1990s. Our assessment shows that the altimetry, gravimetry, and input-output

method are in close agreement in Greenland with a spread of 19 Gt yr<sup>-1</sup> over their common time period, which represents only 580 10.9 % of the rate of imbalance. In Antarctica, the spread between techniques is 4 times larger than in Greenland, mostly due to large differences between estimates for the East Antarctic Ice Sheet. To further explore and interpret differences between geodetic techniques, producing altimetry estimates with a higher temporal resolution (especially during the first half of the satellite altimetry record), better GIA constraints for the gravimetry estimates, and additional estimates of ice sheet mass balance via the input-output method would improve the comparison and aggregation of ice sheet mass balance estimates. 585 Continuously monitoring the mass balance of the ice sheets and producing annual updates of Greenland and Antarctica mass balance is critical to track their contribution to global mean sea level and constrain projections of future sea-level rise.

## 7 Data Availability

The aggregated Greenland and Antarctic Ice Sheets mass balance data and associated errors generated in this study are freely available at the NERC Polar Data Centre, <https://doi.org/10.5285/77B64C55-7166-4A06-9DEF-2E400398E452> (The IMBIE 590 Team, 2021).

## 8 Code Availability

The code used to compute and aggregate rates of ice sheet mass change and their errors is freely available at <https://github.com/IMBIE>.

## Author Contribution

595 The executive committee of IMBIE (A.S., E.R.I., N.J.S., I.N.O, C.A., M.B., M.H., I.J., M.D.K., G.K., S.N., A.J.P., E.R., T.S., K.M.S., B.E.S., L.S.S., I.V., P.L.W.) designed the study. A.S., L.S.S., A.G., L.G., N.G., B.C.G., V.H., S.A.K., H.K., M.M., J.N., N.P., L.S., and S.B.S. contributed altimetry estimates. M.H., I.V., A.B., R.F., A.G., A. Groh, C.H., C.L., B.D.L., J.N., I.S., H.V.S., K.S., E.J.O.S., T.C.S., B.D.V., D.W., and B.W contributed gravimetry estimates. E.R., A.P.A., W.C., J.M., and B.S. contributed input-output estimates. M.B., C. Agosta, X.F., H.G., C.K., P.L.L., S.H.M., R.M., and B.N. contributed SMB 600 estimates. G.A., B.S.L., D.M., W.R.P., G.S., M.W., and W.W. contributed GIA estimates. I.N.O. and M.E.P. performed the mass balance data collation, I.N.O. prepared the datasets comparison. T. Slater performed the AR6 data analysis and prepared Fig 4 and Table 3. I.N.O. led the writing and prepared the other figures and tables. I.N.O., A.S. and T. Slater wrote the manuscript. All authors participated in the data interpretation and commented on the manuscript.
