11 **Abstract.** Surface downward shortwave radiation (DSR) and photosynthetically active radiation (PAR) play
12 critical roles in the Earth's surface processes. As the main inputs of various ecological, hydrological, carbon,
13 and solar photovoltaic models, increasing requirements for high spatiotemporal resolution DSR and PAR
14 estimation with high accuracy have been observed in recent years. However, few existing products satisfy all of
15 these requirements. This study employed a well-established physical-based look-up table (LUT) approach to the
16 GeoNEX gridded top-of-atmosphere bidirectional reflectance factor data acquired by the Advanced Himawari
17 Imager (AHI) and Advanced Baseline Imager (ABI) sensors. It produced a data product of DSR and PAR over
18 both AHI and ABI coverage at an hourly temporal step with a 1 km spatial resolution. GeoNEX DSR data were
19 validated over 63 stations, and GeoNEX PAR data were validated over 27 stations. The validation showed that
20 the new GeoNEX DSR and PAR products have accuracy higher than other existing products, with root mean
21 square error (RMSE) of hourly GeoNEX DSR achieving 74.3 W/m^2 (18.0%), daily DSR estimation achieving
22 18.0 W/m^2 (9.2%), hourly GeoNEX PAR achieving 34.9 W/m^2 (19.6%), and daily PAR achieving 9.5 W/m^2
23 (10.5%). The study also demonstrated the application of the high spatiotemporal resolution GeoNEX DSR
24 product in investigating the spatial heterogeneity and temporal variability of surface solar radiation. The data
25 product can be accessed through NASA Advanced Supercomputing Division GeoNEX data portal
26 <https://data.nas.nasa.gov/geonex/geonexdata/GOES16/GEONEX-L2/DSR-PAR/> and

28 (<https://doi.org/10.5281/zenodo.7023863>, Wang & Li, 2022).

29 **1. Introduction**

30 Surface downward shortwave radiation is of great importance to the surface energy balance and hence is the
31 required input of various surface models. Downward shortwave radiation (DSR) is defined as solar radiation
32 received at the Earth's surface within the wavelength range of 300–4000 nm. It is the fundamental driving force
33 of many global ecological, hydrological, and biochemical processes (Huang et al., 2019; Wang et al., 2021;
34 Liang et al., 2019) and provides one of the most promising renewable energy sources, solar energy.
35 Photosynthetically active radiation (PAR) is the visible component of DSR in the spectral range of 400–700 nm.
36 It also serves as the main input for terrestrial ecosystem modeling, carbon cycle modeling, and yield estimations
37 because of its functionality in photosynthesis (Prince and Goward, 1995; Gu et al., 2002).

38 The need for a high spatiotemporal DSR has increased noticeably in recent years. For example, high
39 temporal resolution of solar resource data is required by new power system models, such as the Integrated Grid
40 Modeling System (IGMS) (Palmitier et al., 2017). Additionally, information about the short-term fluctuation of
41 DSR is critical for storage analysis of large grid-connected photovoltaic plants through ramp-rate control
42 (Marcos et al., 2014). High spatial resolution DSR data are prerequisites for producing small-scale solar energy,
43 which has received increased attention in recent years (Jain et al., 2017). Hence, the combination of high spatial
44 and temporal DSR estimations is important for the economic and stable operation of the solar grid (Buster et al.,
45 2021). However, because of the comparatively coarse resolution of existing products, the spatial and diurnal
46 variations in DSR at large scales have not been fully studied. Moreover, as the driving parameters of various
47 land models, DSR and PAR data with high spatial and temporal resolutions are essential for estimating many
48 other surface variables at high spatial and temporal scales, such as land surface temperature (Jia et al., 2022a,
49 2022b), ground-level ozone mapping (Wei et al., 2022), and evapotranspiration (Huang et al., 2019).

50 Satellite-based estimation of surface incident shortwave radiation has rapidly developed in recent decades.
51 Polar-orbiting satellite sensors, such as the Moderate Resolution Imaging Spectroradiometer (MODIS), provide

52 one of the most popular data sources because of their extended global coverage and availability of mature high-
53 level atmospheric and surface products (Liang et al., 2006; Zhang et al., 2014; Zhang et al., 2018). Many
54 existing DSR and PAR products, such as the Breathing Earth System Simulator (BESS) (Ryu et al., 2018),
55 Global Land Surface Satellite Downward Shortwave Radiation (GLASS) (Zhang et al., 2019), and MODIS land
56 surface Downward Shortwave Radiation (MCD18) (Wang et al., 2020) were generated based on MODIS
57 observations. With the future retirement of MODIS, studies have started to focus on estimating DSR from the
58 Visible Infrared Imaging Radiometer Suite as well (Li et al., 2022). An advanced very high-resolution
59 radiometer (AVHRR) is also a valuable data source for DSR estimation owing to its long-term data record
60 (Yang et al., 2018). The Clouds, Albedo, and Radiation Edition 2 (CLARA) data products were based on
61 AVHRR (Karlsson et al., 2017). However, the above-mentioned products usually generate daily DSR by
62 interpolating from instantaneous estimation because of the limited overpass counts of polar-orbiting satellites.
63 Because of their limitation to capture diurnal DSR variation, the root mean square error (RMSE) of these
64 products can hardly reach $25 W/m^2$ (Li et al., 2021).

65 A lot of effort has been made to develop the high temporal resolution DSR estimation. The hourly Earth's
66 Radiant Energy System (CERES) and the International Satellite Cloud Climatology Project HXG product on a
67 three-hour scale (Tang et al., 2019) are generated by incorporating high-level satellite products and other
68 ancillary data set. The unique Lagrange point orbit of Earth Polychromatic Imaging Camera (EPIC) onboard the
69 Deep Space Climate Observatory (DSCOVR) are also utilized to generate hourly DSR and PAR (Hao et al.,
70 2018, 2019). Geostationary sensors provide new opportunities for estimating the DSR and PAR. Previous
71 studies have successfully estimated surface shortwave radiation from geostationary sensors, such as
72 multifunctional transport satellites (Huang et al. 2011; Li et al., 2015) and MSG Spinning Enhanced Visible and
73 InfraRed Imager (Schmetz et al. 2002). With the launch of new-generation geostationary satellites, more studies
74 have shifted to the Advanced Himawari Imager (AHI), Advanced Baseline Imager (ABI), and Advanced
75 Geosynchronous Radiation Imager (AGRI), which provide higher spectral, spatial, and temporal resolutions
76 with geometric and radiometric accuracies comparable to those of their polar-orbiting counterparts. Zhang et al.
77 (2020) estimated the DSR from both AHI and ABI data using an optimization method. Letu et al. (2022)
78 generated a suite of radiation datasets from AHI aerosol and cloud products. However, the RMSE of the hourly
79 DSR estimation based on the above-mentioned methods is generally around $100 W/m^2$ and the daily average is
80 still around $25\text{-}30 W/m^2$. A recent study that employed a machine learning method to estimate half-hourly DSR
81 achieved a validation RMSE of approximately $67 W/m^2$, but their validation sites were limited and depended
82 on the training sites (Chen et al., 2021). In addition, although various methods have been developed, no uniform
83 products have been generated based on new-generation geostationary satellites. This is partly due to the
84 differences in the spectral configuration or scan strategy between the carried sensors and the non-transferability
85 of some existing retrieval methods. The requirement of data storage for products with high spatial and temporal
86 resolutions is another reason that impedes the development and generation of such data products.

87 To address those challenges, we employed the physical-based look-up table (LUT) method, which uses top
88 of atmosphere (TOA) reflectance as the main input and does not rely on high-level atmospheric products, such
89 as aerosol or cloud optical parameters. Hence, it is fast and transferable across different sensors, and eliminate
90 possible data gaps resulted from the unavailability of the high-level atmospheric products. The TOA reflectance
91 data are obtained from the National Aeronautics and Space Administration (NASA) Advanced Supercomputing
92 (NAS) Division GeoNEX platform, which archives a collection of gridded data from multiple geostationary
93 satellites with consistent file formats and map projections (Yip, 2019). The generated GeoNEX DSR/PAR
94 product covers both the AHI and ABI areas in the same format at 1 km and hourly resolution. Compared with
95 existing products, the GeoNEX DSR/PAR product presents the highest accuracy at both hourly and daily scales.
96 This study also took advantage of the high spatial and temporal information provided by the new product and
97 investigated the spatiotemporal variability of DSR. The data product was archived in the NASA GeoNEX data
98 portal. The remainder of this paper is organized as follows: Section 2 introduces the data and methods used to
99 develop the GeoNEX DSR/PAR products; Section 3 presents validation and comparison results for the new data
100 product; Section 4 uses two examples to demonstrate the application of the high spatiotemporal resolution
101 product in investigating DSR variability; Section 5 describes the data products and access information. Finally,
102 Section 6 concludes the study with a summary.

103 2. Data and method

104 2.1 Method

105 This study employs the LUT approach initially developed by Liang et al. (2006). The method was further
106 refined by extending the LUTs, considering the impacts of water vapor and surface elevation, and applied to
107 produce the NASA MODIS DSR/PAR product (MCD18) (Wang et al., 2020). To estimate surface fluxes, two
108 parameterization schemes model the radiative transfer process and simplify the interactions of radiation between

109 the atmosphere and the surface.

110 The first parametrization scheme (Eq. 1) builds the relationship between the TOA spectral reflectance R ,
 111 surface spectral reflectance r , and three parameters related to atmospheric conditions from the clearest condition
 112 to the cloudiest conditions at a given viewing geometry: path reflectance $R_0(\lambda)$, atmospheric spherical albedo
 113 $\rho(\lambda)$, and transmittance $\gamma(\lambda)$ for the spectral band. They are functions of the viewing geometry (i.e., solar zenith
 114 angle (SZA θ_s), view zenith angle (VZA), and relative azimuth angle (RAA)), water vapor, and elevation. The
 115 values of the three parameters were stored in the first LUT.

$$116 \quad R(\lambda) = R_0(\lambda) + \frac{r(\lambda)}{1-r(\lambda)\rho(\lambda)} \cos(\theta_s)\gamma(\lambda)/\pi \quad (1)$$

117 The second parameterization scheme (Eq. 2) estimates the surface broadband radiation F from surface
 118 reflectance r and three atmospheric parameters: path irradiance F_0 , atmospheric spherical albedo ρ , and
 119 atmospheric transmittance γ at given θ_s . E_0 is the extra-terrestrial solar broadband irradiance, which is adjusted
 120 by the distance to the sun. The second LUT was built to retrieve three atmospheric parameters with known SZA:
 121 water vapor, elevation, and visibility index retrieved from the first LUT.

$$122 \quad F = F_0 + \frac{r\rho}{1-r\rho} E_0 \cos(\theta_s)\gamma \quad (2)$$

123 To generate hourly DSR and PAR, we first calculated the instantaneous visibility index at 10- or 15-
 124 minutes (the refreshing frequency of a satellite sensor) by comparing the actual TOA radiance from the sensor
 125 with the series of simulated radiances stored in the first LUT (Eq.1). The visibility indexes were then averaged
 126 to the hourly interval. Hourly DSR and PAR were estimated by searching for the second LUT using the hourly
 127 averaged visibility index.

128 2.2 Data

129 2.2.1 Input data

130 The input variables and corresponding data sources are listed in Table 1. The gridded TOA reflectance of
 131 the ABI and AHI and the corresponding viewing geometry data were archived through the NASA GeoNEX data
 132 portal (Wang et al., 2020). The ABI onboard the GOES-16 geostationary meteorological satellites is equipped
 133 with 16 spectral bands. It produces full disk scanning every 10 or 15 min covering the area from 60°N, 138°W,
 134 to 60°S, 18°W. The AHI onboard Himawari-8 has 16 spectral bands. It produces full disk scanning every 10
 135 min, covering regions from 60°N, 78°E to 60°S, 198°E. The blue band with a central wavelength of 0.47 μ m
 136 and 1 km spatial resolution for both ABI and AHI was used in this study to infer the atmospheric visibility
 137 index. The MCD43 and surface reflectance climatology products provided surface albedo information. The
 138 surface reflectance was obtained from the MODIS product (Schaaf & Wang, 2015). Climatological surface
 139 reflectance data were used when no valid MODIS observation was available (Jia et al., 2022). The total column
 140 water vapor data were retrieved from MERRA2 (Global Modeling and Assimilation Office, 2015), and the
 141 surface elevation data were obtained from the Global 30 Arc-Second Elevation (GTOPO30) (EROS, 2017).

142 Table 1. The summary of input data

Name	Variable	Spatial Resolution	Temporal Resolution
AHI/ABI TOA reflectance	TOA reflectance	1km	15min or 10min
View geometry	Solar zenith angle, sensor zenith angle, relative azimuth angle	1km	15min or 10 min
MCD43C3	Surface albedo	0.05 degree	Daily
MERRA2	Total column water vapor	0.5 x 0.625 degree	Hourly
GTOPO30	Surface elevation	30 arc seconds	Static
Surface reflectance climatology	Surface reflectance	0.05 degree	Static/daily

143

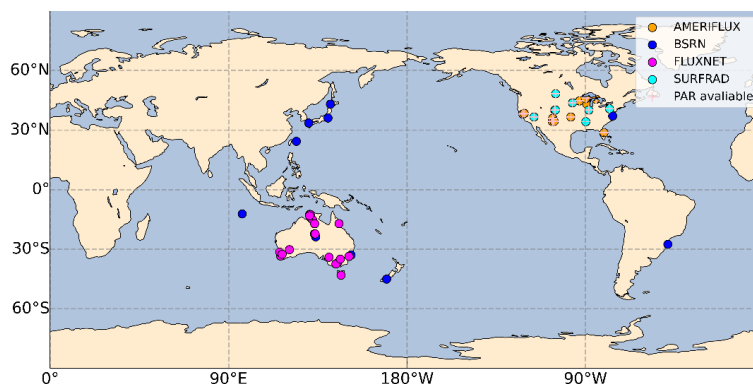

144 2.2.2 Validation data

145 Measurements from 63 stations in the ABI or AHI spatial domain were collected to validate GeoNEX
 146 DSR/PAR products. Among these, 34 sites were located in the ABI coverage domain and 29 sites in the AHI
 147 coverage area (Fig. 1). The stations belong to four networks, with 25 sites from AMERIFLUX, 11 sites from the
 148 Baseline Surface Radiation Network (BSRN), 20 sites from FLUXNET, and 7 sites from the Surface Radiation

149 Network (SURFRAD). All 63 sites had DSR data. The processes of ground measurement data quality checks
150 including daily and monthly aggregation follow Li et al. (2021). Only 27 sites recorded PAR measurements.
151 Seven sites from SURFRAD measure the PAR flux directly while the rest sites from AMERIFLUX record PAR
152 data in quantum units (photosynthetic photon flux density, $\mu\text{mol m}^{-2}\text{s}^{-2}$). The conversion between the
153 quantum units to the energy units follows Dye (2004).

154

155
156
157

Figure 1. The map of ground stations used for validating the GeoNEX DSR/PAR product.

158 2.2.3 Other products

159 Existing DSR products were used in this study for comparison with the new GeoNEX product. The
160 EPIC/DSCOVER generates DSR and PAR globally at 0.1° spatial resolution and 1-2h temporal resolution. A
161 random forest approach was applied to the data obtained by the EPIC sensor onboard the DSCOVER (Hao et al.,
162 2018, 2019). The CERES SYN1deg product provides hourly, 3hourly, daily, and monthly radiation data at the
163 surface, TOA, and various atmospheric layers with a 1° spatial resolution. The data on surface shortwave fluxes
164 were calculated with Langley Fu-Liou radiative transfer code from polar-orbit and geostationary satellite data, as
165 well as other ancillary information (Rutan et al., 2015). CERES-SYN data has been extensively validated in
166 previous studies, showed the highest accuracy compared with the most existing products; hence, it has been widely
167 used as a baseline product (Riihelä et al., 2017; Sun et al., 2018; Li et al., 2021). The National Oceanic and
168 Atmospheric Administration (NOAA) GOES-R series Level 2 product (ABI-L2-DSR) was also evaluated in this
169 study. The full disk data were produced on a global latitude/longitude grid at 0.5° resolution, employing two
170 retrieval path methods to estimate DSR (GOES-R Algorithm Working Group and GOES-R Program Office,
171 2017). A new version of MCD18A1 has also been included in the comparison (Wang et al., 2020). It applied a
172 similar LUT method over MODIS TOA reflectance and estimated DSR at a global scale at 1 km spatial resolution
173 with 3hourly and daily interpolated temporal resolutions.

174 In addition, this study employed NOAA GOES-R Series Level 2 clear sky mask data to investigate the
175 performance of various DSR/PAR products under different cloud conditions. The product contains images in the
176 form of binary cloud masks. To match it with hourly DSR products, the 15 min full disk data were aggregated.
177 The sample was classified as under cloudy conditions if all four observations in an hour were cloudy and as clear
178 if all four observations within an hour were clear. The rest were classified as partial cloudy conditions.

179 3. Quality assessment

180 3.1.1 Overall validation

181 Both hourly and daily GeoNEX DSR were validated with ground measurements, as shown in the scatter
182 plots of the ABI and AHI domains (Fig. 2). The R^2 values for the hourly validations of ABI and AHI were
183 0.929 and 0.950, respectively. RMSE were 78.2 and 69.4 W/m^2 and relative RMSE (rRMSE) were 19.7% and
184 16.2%. After aggregating to the daily values, the uncertainties in estimating DSR were further reduced, while
185 the R^2 increased to 0.968 and 0.972 for ABI and AHI, respectively. The RMSE (rRMSE) achieved 18.4 (9.6%)
186 and 17.2 (8.3%) W/m^2 . To the best of our knowledge, it is the first satellite product of DSR with the rRMSE
187 lower than 10% (Li et al., 2021). The validation accuracies over ABI and AHI coverage are similar, with
188 slightly better accuracy over AHI. This is partly due to the more homogeneous and constant atmospheric
189 conditions in the AHI domain. After aggregating into daily intervals, the differences between the two sensors
190 decreased. The accuracy of the DSR estimation varies with cloud conditions. As shown in Fig. 3, the rRMSE

191 over cloudy sky (30.6%) is triple that over clear sky (10.9%), and the rRMSE of partial cloud samples (18.3%)
 192 fell in the middle of accuracies under clear and cloudy skies. The elevated errors for cloudy-sky cases partly
 193 originate from the assumption of homogenous and plane-parallel clouds in the radiative transfer code (Chen et
 194 al., 2019; Van Laake & Sanchez-Azofeifa, 2004). The linear interpolation processes in searching through the
 195 two LUTs may also lead to uncertainties in the results.

196 Figure 4 presents the validation results of the GeoNEX PAR estimation. The R^2 for hourly PAR estimation
 197 was 0.927, and the RMSE (rRMSE) was 34.7 (19.7%) W/m^2 . The R^2 for daily estimation was 0.956, and the
 198 RMSE (rRMSE) was 9.5 (10.8%) W/m^2 . Since the PAR values of some sites are converted from the
 199 photosynthetic photon flux density which has systematic uncertainties (Dye, 2004), we also include the
 200 validation results only over SURFRAD sites where PAR flux is provided directly. The accuracies of both hourly
 201 and daily PAR estimations were higher than those of the existing products and experimental studies (Li et al.,
 202 2015; Hao et al., 2018).

210
 211 Figure 4. Scatter plots of the estimated and observed daily and hourly PAR values for ABI coverage

212 **3.1.2 Comparison with existing products**

213 We also compared the new GeoNEX DSR product with four existing DSR products at hourly and daily
 214 scales over identical samples. The statistics are summarized in Table 2. The correlation between the CERES
 215 hourly DSR product and the ground measurements had an R^2 value of 0.904 and RMSE of $91.6 W/m^2$,
 216 followed by EPIC/DSCOVER with $R^2 = 0.798$ and RMSE = $130.8 W/m^2$. ABI-L2-DSR had an R^2 value of
 217 0.748 and RMSE of $148.8 W/m^2$. The proposed GeoNEX DSR outperformed all existing products (Letu et al.,
 218 2022; Zhang et al., 2021; Hao et al., 2019) with R^2 of 0.928 and RMSE of $78.3 W/m^2$. The relatively lower
 219 performance of the ABI-L2-DSR data may be partly because the ABI-L2-DSR is an instantaneous estimation
 220 and has a coarse spatial resolution of 0.5° . Table 3 presents a comparison of hourly products under different
 221 cloud conditions. CERES and GeoNEX achieved comparable accuracy under clear-sky conditions. Over cloudy
 222 skies, the GeoNEX product exhibits superior accuracy with an RMSE of $95.2 W/m^2$. The RMSE of CERES
 223 and EPIC were as high as 112.8 and $159.0 W/m^2$, respectively.

224 For daily estimation, MCD18, which retrieves DSR from the polar orbiting sensor at the highest spatial
 225 resolution of 1 km, was also included in comparison with CERES and EPIC. Other mature daily DSR products,
 226 such as GLASS, CLARA, and BESS, were not included in this study because they have shown comparable or
 227 inferior performance to CERES (Li et al., 2021). Similar to the hourly results, GeoNEX DSR outperformed all
 228 existing datasets with R^2 of 0.965 and RMSE of $18.9 W/m^2$.

229 We emphasize that the GeoNEX DSR/PAR algorithm was not trained or tuned with the field
 230 measurements used for comparison. The validation and comparison results show that this new GeoNEX
 231 shortwave radiation product provides a highly accurate DSR estimation from satellites, with hourly RMSE
 232 lower than $80 W/m^2$ and daily RMSE lower than $20 W/m^2$.

233 Table 2. Summary of the comparison results between the GeoNEX DSR product and other DSR products

Product	R^2	BIAS (W/m^2)	RMSE (W/m^2)
Instantaneously			
ABI-L2-DSR	0.75	-13.9	148.8
Hourly			
CERES	0.90	2.7	91.6
EPIC	0.80	2.8	130.8

GeoNEX	0.93	-3.4	78.3
Daily			
CERES	0.94	3	24.5
MCD18	0.91	-5.2	32.6
ABI-L2-DSR	0.77	-7.4	48.1
EPIC	0.83	5.9	41.5
GeoNEX	0.97	-2.4	18.9

234
 235

Table 3. Comparison of the GeoNEX DSR product with other DSR products under different cloud conditions.

Product	BIAS (W/m^2)		RMSE (W/m^2)		BIAS (W/m^2)		RMSE (W/m^2)		BIAS (W/m^2)		RMSE (W/m^2)	
	R^2				R^2				R^2			
	clear				cloud				partial cloud			
CERES	0.97	-11.1	52.4		0.82	19.0	112.8		0.91	-10.1	91.8	
EPIC	0.94	-45.8	86.2		0.69	50.7	159.0		0.85	-15.6	115.9	
GeoNEX	0.97	-12.8	52.9		0.87	2.9	95.2		0.93	-7.5	76.5	

236

237 To evaluate their capability to monitor the temporal variability of DSR, the diurnal cycles of GeoNEX,
 238 EPIC, and CERES DSR estimations were plotted together with in-situ measurements at seven SURFRAD sites
 239 in June 2018 (Fig. 5). Although all three products could depict the diurnal trends of DSR, their performances
 240 diverged substantially over the days with high DSR variability (i.e., days of year (DOY) 174 and 175) and
 241 mountainous areas (i.e., TBL). EPIC was prone to overestimation when potential clouds existed. CERES agreed
 242 well with the in-situ measurements, but could not capture the sharp changes in DSR as accurately as GeoNEX
 243 due to coarse spatial resolution of CERES data.

244

245
 246
 247
 248

Figure 5. The diurnal cycles of GeoNEX, EPIC, and CERES estimations compared with in-situ measurements at seven SURFRAD sites in June 2018. Cloudy conditions are marked in dark grey and partially cloudy conditions are light grey.

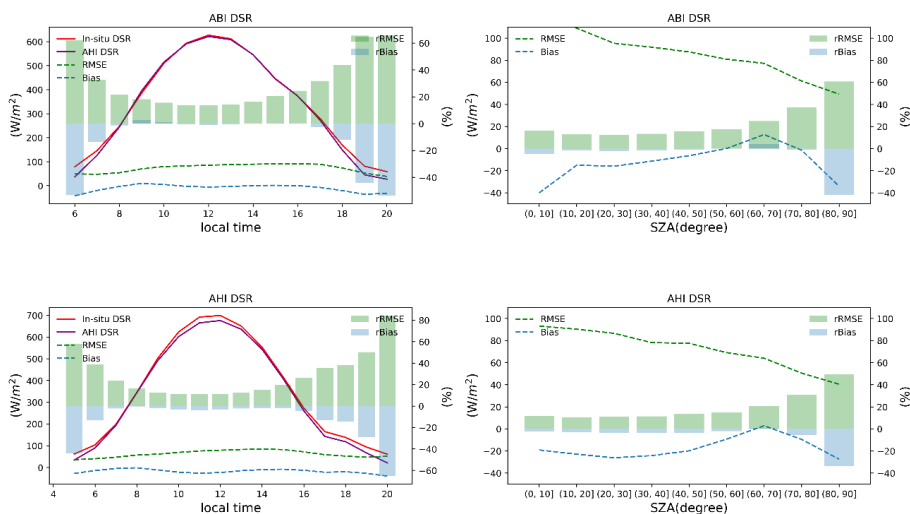

249 3.1.3 Impact of viewing geometry on estimation errors

250 The diurnal variation of the GeoNEX DSR estimation was examined and is presented in Fig. 6. The hourly

251 averaged DSR matched well with the in-situ measurements for both ABI and AHI. No noticeable changes in the
 252 RMSE and BIAS were observed throughout the day. However, owing to the small average DSR values at the
 253 start and end of a day, the rRMSE increases dramatically. This phenomenon occurs in most DSR products,
 254 partly due to the Lambertian assumption adopted in the radiative transfer model.

255
 256

257
 258 Figure 6. The diurnal variation and the impact of SZA on AHI and ABI DSR estimation

259 Geostationary satellites maintain a static position relative to the Earth, and thus each pixel in the image has
 260 a fixed value of VZA. Figure 7 presents the rRMSE and rBias of each site located under AHI and ABI coverage.
 261 The pink stars represent the positions of the AHI and ABI sensors. For the rRMSE, a radial distribution is
 262 presented. A large rRMSE existed at sites far from the sensors. The same result was obtained for the rBias
 263 distribution. Underestimation was observed over the sites near the sensor, whereas overestimation was observed
 264 for sites far from the sensor. Overall, more uncertainties may exist at higher latitudes, as the geostationary
 265 sensors are located at the equator. To quantitatively analyze the influence of VZA, regression lines between
 266 VZA and rRMSE/rBias are plotted in Fig. 8. Positive slopes exist for both rRMSE and rBias. The p-values for
 267 both the rRMSE and rBias are less than 5%, which demonstrates that these positive correlations are significant.

268

272
 273 Figure 8. The impact of VZA on DSR estimation. The regression equation and p-value are shown.
 274

275 **3.1.4 Impact of spatial and temporal resolutions on estimation errors**

276 Previous studies have suggested that the accuracy of DSR estimation is influenced by the spatial and
 277 temporal aggregation scales (Li et al., 2021; Zhang et al., 2021). For instantaneous PAR and DSR estimation,
 278 the optimal scale for applying 1-D transfer models is approximately 20 km (Chen et al., 2019; Zhang et al.,
 279 2021). For daily estimation, Li et al. (2021) demonstrated that generally lower spatial resolution can result in
 280 higher accuracy for most existing products, but it is noticeable that the products validated in previous studies are
 281 usually interpolated from instantaneous estimation. To further examine the influence of spatial and temporal
 282 resolution on surface shortwave radiation estimation, this study compared the accuracy of DSR estimation at
 283 different scales (Fig. 9 and Table 4). This agrees well with previous findings that temporal aggregation exerts a
 284 greater impact on accuracy than spatial aggregation (Zhang et al., 2021). The hourly rRMSE was approximately
 285 18%, while the monthly are approximately 6%. The higher the temporal resolution, the greater the influence of
 286 the spatial resolution on the estimation accuracy. As shown in Fig. 9, the differences in RMSE among different
 287 spatial resolutions decreased as the temporal resolution decreased. At the hourly scale, the highest rRMSE
 288 reached 19.8% at 100 km and the lowest was 17.1% at 10 km, whereas at the monthly scale, the DSR estimation
 289 was nearly independent of the spatial scale. Moreover, compared with previous analysis of instantaneous
 290 interpolated daily DSR estimation (Li et al., 2021), our results at a daily scale are less variable among different
 291 spatial scales, suggesting that the aggregation of hourly DSR is a possible solution to mitigate the impact of
 292 spatial resolution on daily DSR estimation and enables daily DSR estimation at spatial resolutions as high as 1
 293 km.

294

100km	0.92	-8.4	83.8	0.96	-4.0	20.4

299

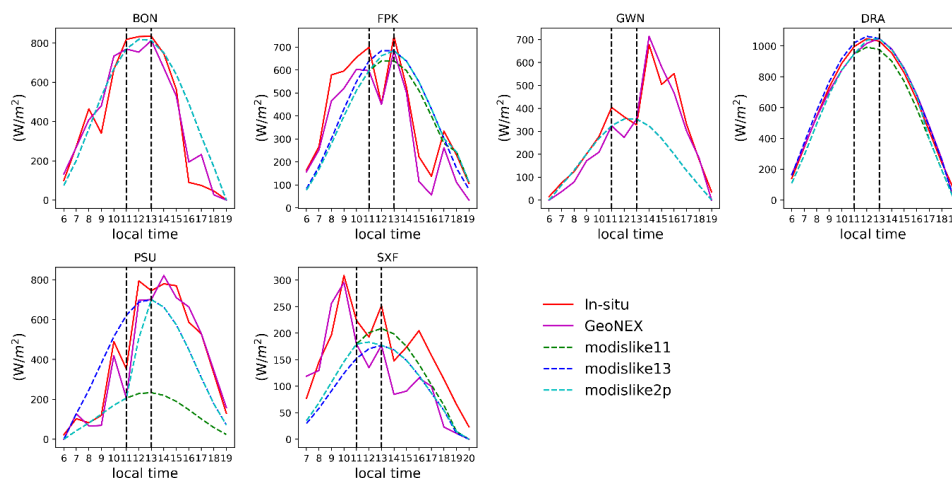

300 4. Application demonstrations

301 The importance of spatial and temporal heterogeneity of the DSR has been demonstrated in many studies
 302 (Gueymard et al., 2011; Yan et al., 2018; Sweerts et al., 2019). However, such issues have not been fully
 303 investigated owing to the limited spatial and temporal resolutions as well as relatively low accuracy of the
 304 existing products. The new GeoNEX DSR/PAR product, with their unique characteristics, provide a valuable
 305 opportunity to re-examine these issues. Here, two examples are used to demonstrate the applications of the high
 306 spatial-temporal resolution DSR product. In Section 4.1, we investigated how the overpass time and counts of
 307 polar-orbiting satellites affect the accuracy of estimating the daily DSR values. In Section 4.2 we studied the
 308 spatial heterogeneity of DSR at various temporal scales.

309 4.1 Effects of overpass time on estimating daily DSR

310 The quality of existing DSR products derived from polar-orbiting satellite data relies heavily on temporal
 311 upscaling schemes to calculate the daily DSR from instantaneous observations (Wang et al., 2010). We took
 312 advantage of the high frequency of the GeoNEX DSR product to simulate how the estimates of daily DSR
 313 change with overpass time and counts.

314 The modislike11 and modislike13 data are generated using visibility indexes at local times 11:00 and
 315 13:00, corresponding to the Terra and Aqua passing time, as the constant atmospheric condition of the whole
 316 day. The Modislike2p data were generated to emulate the cases where observations from both Terra and Aqua
 317 are available. It uses the visibility index at 11:00 to represent the atmospheric condition before 11:00 and the
 318 visibility index at 13:00 to represent that after 13:00. Between 11:00 and 13:00, The visibility index was linearly
 319 interpolated (Wang et al., 2010). A similar interpolation method was used to generate the MCD18 products
 320 (Wang et al., 2020). The mechanism is shown in Fig. 10, where different data were compared over the seven
 321 SURFRAD stations on June 19th. The results show that all methods work well under no-cloud conditions, such
 322 as at the DRA site, where the visibility index at 13:00 and 11:00 can represent the entire day's atmospheric
 323 condition. However, large uncertainties arise when atmospheric conditions vary substantially during the day.
 324 Such uncertainties may be reduced with additional observations in the modislike2p scenario, as in the case of
 325 the PSU. Nevertheless, the limited number of observations is one of the major error sources for estimating the
 326 daily DSR from polar-orbiting satellite data.

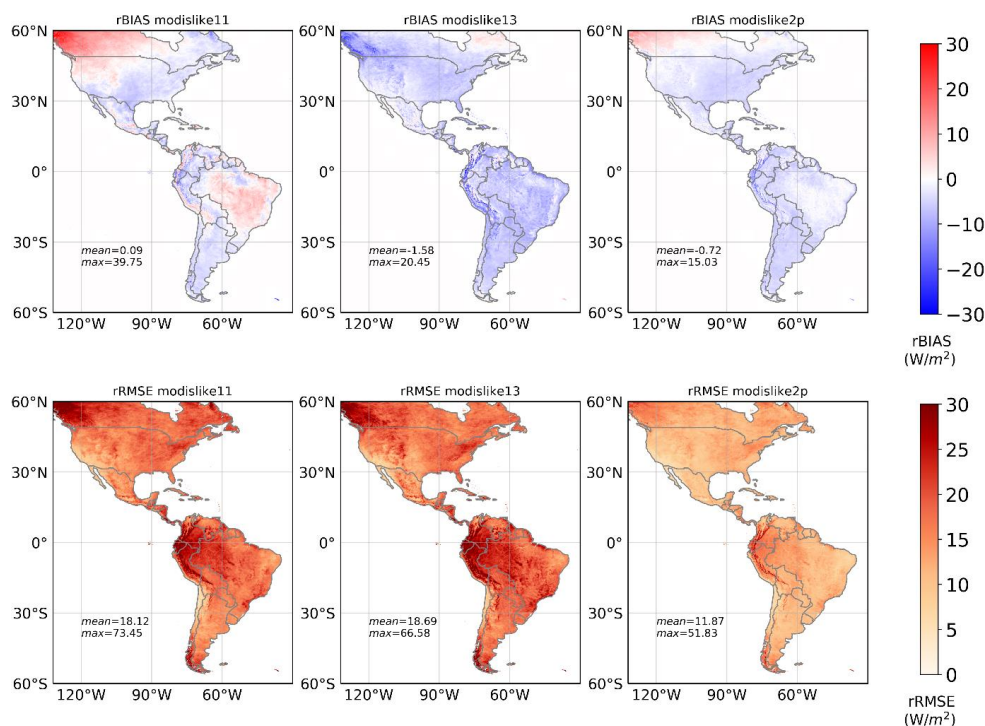

327
 328
 329

Figure 10. Comparison between modislike hourly DSR and GeoNEX DSR over seven SURFRAD stations on June 19th.

330 The relative bias (rBias) and RMSE (rRMSE) of the daily averaged DSR between modislike interpolated
 331 data and ABI data throughout the year were calculated (Fig. 11). The rBias maps showed that the
 332 representativeness of the visibility index at 11:00 varied spatially. More overestimations were observed over
 333 high-elevation areas, and underestimations were observed at the edge of these areas, which may be because the
 334 morning clouds have not been formed or could not reach certain heights. Moreover, the visibility index at 13:00
 335 h was not sufficiently representative. The rBias map shows that interpolation from the visibility index at 13:00
 336 will lead to underestimation over all study areas, which is attributed to more cloud formation in the afternoon.
 337 The rRMSE maps demonstrate the efficiencies of incorporating two passes when interpolating daily DSR from
 338 polar-orbiting sensors, as the modislike2p generates less variability compared with ABI-based daily DSR;
 339 however, the average rRMSE reaches 10%. For both modislike10 and modislike 13, the high rRMSE is around
 340 the mountainous areas, the maximum rRMSE is approximately 70%, and the average rRMSE is approximately
 341 18%.

342

Figure 11. The temporal representation maps are generated by calculating rBias and the rRMSE between modislike10, modislike13, and modislike2p daily interpolated data and ABI data.

348 4.2 Spatial heterogeneity of DSR

349 Existing global or regional shortwave radiation products mostly have a spatial resolution coarser than 5
 350 km, which meets the requirements of some terrestrial models. However, other studies may require data with a
 351 much higher spatial resolution. For instance, whether the character of a solar resource at one location can be
 352 representative of nearby locations is a critical question for solar grid design and deployment. Attempts have
 353 been made to analyze the spatial heterogeneity of DSR, but most have focused on regional scales or used coarse
 354 resolution data as inputs (Kariuki & Sato, 2018; Sarr et al., 2021; Tapia et al., 2022). With the help of the high
 355 spatiotemporal resolution GeoNEX DSR data, we were able to quantify the spatial heterogeneity of DSR at a
 356 large spatial scale over different temporal scales.

357 We employed the metric used in the previous studies (Gueymard et al., 2011; Yan et al., 2018) to calculate
 358 the coefficient of variance (COV) to represent spatial heterogeneity of DSR. COV is defined as:

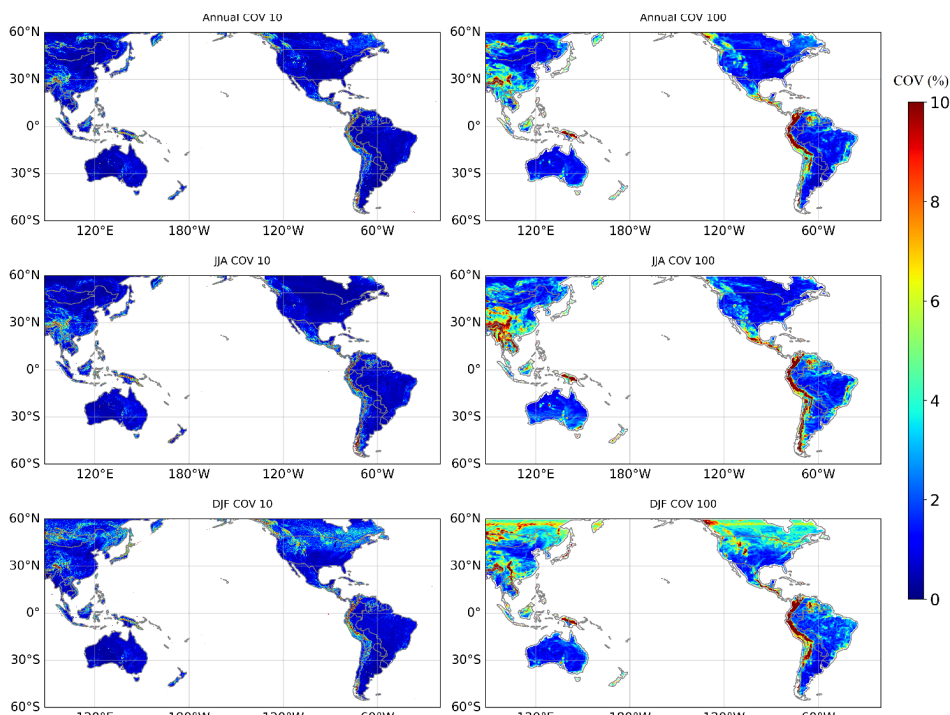

359

$$COV = \frac{\sigma_n}{E_n} * 100$$

360 where n denotes the number of pixels surrounding the central pixel. N was set as 10×10 and 100×100 km,
 361 respectively, to examine spatial heterogeneity at different scales. σ_n and E_n are the standard deviation and mean
 362 of these n pixels, respectively.

363 Annual and seasonal spatial representation maps were generated at 10×10 and 100×100 km, which
 364 highlight areas susceptible to high heterogeneity in the DSR (Fig. 12). A high COV usually corresponds to
 365 mountainous and high elevation areas. For the annual COV in the 10×10 matrix over CONUS, the lowest COV
 366 occurs in central Missouri and increases towards the east and west coasts. Some regions at the edge of the
 367 American Cordillera, such as Denver, have a high COV. A high COV extends from northern Rocky in Canada
 368 along the American Cordillera to Mexico and further reaches the entire Andes Mountains in South America.
 369 Over Asia and Oceania under the AHI coverage (Fig. 12), a high COV is present at the edge of the Tibetan
 370 Plateau, especially along the Himalayan Mountains and extends to the Annamite range. It also occurs in
 371 mountainous regions of island countries such as Indonesia, Japan, and New Zealand. The patterns between
 372 10×10 km and 100×100 km were similar, with greater variability and extent in the latter representation maps.
 373 Larger COV pixels appear along the Appalachian Mountains in the US, eastern mountainous areas in Brazil, the
 374 northern part of the Tibetan Plateau in China, and southeast Australia. The analysis here suggests the need for
 375 high-spatial-resolution DSR data for these regions. Some seasonal changes in the COV values were also
 376 observed. We plotted aggregated June, July, and August (JJA) as well as December, January, and February
 377 (DJF) aggregated variation maps, as shown in Fig. 12. In general, a higher variance was observed in the
 378 Northern Hemisphere during DJF and in the Southern Hemisphere during JJA. It impacts high latitude most. It
 379 is also noticeable that a horizontal line appears at approximately 55°N in both AHI and ABI 100×100 km maps
 380 during DJF. This might correspond to the polar front where a sharp gradient in temperature occurs and suggests
 381 that these two air masses with different temperatures leads to significant DSR variation at the surface at a 100
 382 km scale.

383
 384
 385

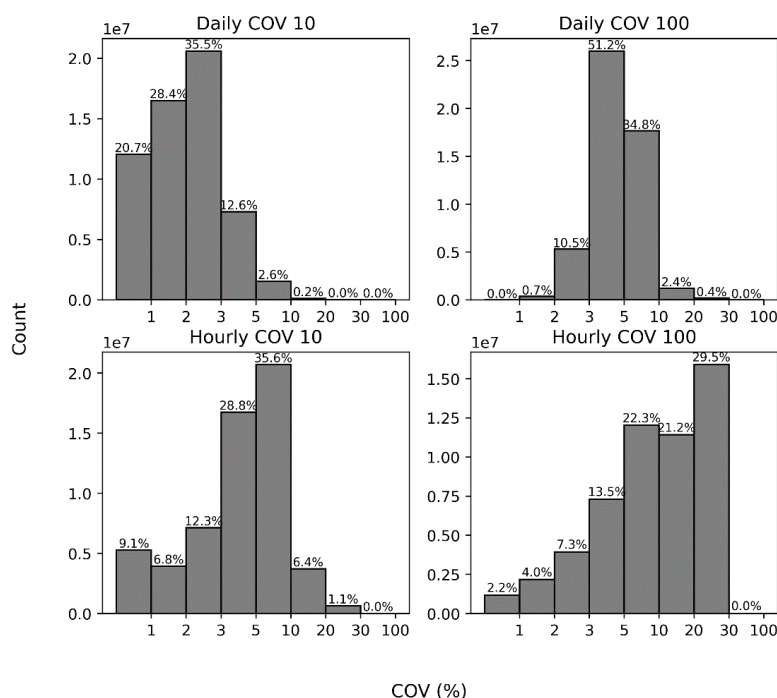

Figure 12. Spatial representation maps at 10km and 100km scales during June, July, August (JJA) and December, January, and February (DJF)

386 Figure 13 shows the distribution of daily and hourly COV frequencies at 10 and 100 km in all study areas.
 387 For the daily COV at 100 km, 86% of the areas were within the range of 3%-10%. For daily COV at 10 km,

388 85% of areas showed a COV lower than 3%, and most areas had a COV distributed within the range of 2%-3%.
 389 For the hourly COV at 100 km, 73% of the areas had a COV higher than 5%, and most areas were distributed
 390 within 20%-30%. For the hourly COV at 10 km, 64% of the areas had a COV within the range of 3%-10%. The
 391 values between 5%-10% were dominant for COV. The results demonstrate that the higher the temporal
 392 resolution, the more severe the spatial heterogeneity issues. DSR products with spatial resolutions of
 393 approximately 100 km are not sufficient for analysis at temporal scales higher than daily for most areas. The 10
 394 km DSR products may be sufficient for analysis using daily DSR data, but for those with hourly data,
 395 uncertainties in COV of 5%-10% existed for most areas. The results further demonstrate the importance of high-
 396 spatial-resolution products, particularly at high temporal resolution.

397
 398
 399

 402 relative frequency.

403 5. Data availability

404 The GeoNEX DSR/PAR data product can be downloaded from
 405 <https://data.nas.nasa.gov/geonex/geonexdata/GOES16/GEONEX-L2/DSR-PAR/> and
 406 <https://data.nas.nasa.gov/geonex/geonexdata/HIMAWARI8/GEONEX-L2/DSR-PAR/>
 407 (<https://doi.org/10.5281/zenodo.7023863>, Wang & Li, 2022). It is a gridded product organized in a tile system
 408 that follows the convention of standard GeoNEX data sets. Each tile contains 600x600 pixels, representing a
 409 region of 6° by 6°. Detailed information regarding the gridding system can be found at
 410 <https://www.nasa.gov/geonex/dataproducts>. Each file contains three scientific datasets: the DSR hourly array,
 411 PAR hourly array, and quality control (QC) array. Users should use the filling value of -9999 to check whether
 412 DSR/PAR is successfully retrieved. The DSR or PAR values should be multiplied by a scale factor (0.1) before
 413 use. The QC was used to indicate the input source of the surface reflectance data (0 labeled data from the
 414 MODIS product and 1 from climatology data).

415 6. Conclusions

416 A gridded high spatiotemporal resolution product of DSR and PAR was produced from new-generation
 417 geostationary ABI and AHI data archived through the NASA GeoNEX platform using a physical-based LUT

418 approach. Hourly DSR and PAR were estimated at 1km resolution over the ABI and AHI coverage domains
419 (60°N to 60°S, 78°E to 18°W). Validation demonstrated that the new GeoNEX DSR and PAR products were
420 highly reliable. The RMSE of hourly DSR estimation is $74.3 W/m^2$ (18.0%) and that of daily DSR estimation is
421 $18.0 W/m^2$ (9.2%) when evaluated against 63 sites from four different networks. The hourly PAR achieves
422 $34.9 W/m^2$ (19.6%) and daily PAR achieves $9.5 W/m^2$ (10.5%) validated over 27 sites. It should be noted that
423 the GeoNEX DSR and PAR data were retrieved using a physical LUT approach and did not require any training
424 or tuning based on any of the validation sites. The independent validation results suggest the superior accuracy
425 of the new data product over other existing products, such as CERES, MCD18, EPIC, and NOAA-L2-DSR.

426 The high-quality gridded dataset of surface incident shortwave radiation provides new opportunities to
427 study its spatial and temporal variability. We demonstrate the application of this new product using two
428 examples. We first mapped the errors in estimating the daily DSR from the polar-orbit satellite data. It was
429 found that one observation per day led to an average relative RMSE of 18 %, and an increase in the daily
430 observation number to two reduced the relative RMSE to 10%. In addition, we characterized the spatial
431 heterogeneity of the DSR based on the new GeoNEX DSR product. It was shown that mountainous and high-
432 latitude areas are more susceptible to high spatial-temporal variation. DSR products with a resolution of
433 approximately 100 km are insufficient for daily and monthly analyses. Analysis at an hourly temporal scale
434 requires DSR data with spatial resolutions finer than 10 km.
