Abstract

This report summarizes an updated inventory of glaciers and perennial snowfields of the contiguous United States. The inventory is based on interpretation of mostly aerial imagery provided by the National Agricultural Imagery Program, U.S. Department of Agriculture with some satellite imagery in places where aerial imagery was not suitable. The inventory includes all perennial snow and ice features greater than 0.01 km^2. Due to aerial survey schedules and seasonal snow cover, imagery acquired over a number of years were required. The earliest date is 2013 and the latest is 2020, but more than 73% of the outlines were acquired from 2015 imagery. The inventory is compiled as shapefiles within a geographic information system that includes feature classification, area, and location. The inventory identified 1331 (366.52 km^2) glaciers, 1776 (31.00 km^2) perennial snowfields, and 35 (3.57 km^2) buried-ice features. The data including both the shapefiles and tabulated results are publicly available at https://doi.org/10.15760/geology-data.03 (Fountain & Glenn, 2022).

1. Introduction

Glaciers are an important feature of the landscape for several reasons. Geologically, they modify the landscape through erosion and deposition (Alley et al., 2019; Benn & Evans, 2010). Although these processes are typically slow, sudden episodes can occur such as moraine failure due to fluvial erosion resulting in catastrophic debris flows (Beason et al., 2018; Chiarle et al., 2007; O'Connor et al., 2001). Hydrologically, glaciers can be viewed as frozen reservoirs of water that naturally regulate streamflow on seasonal to decadal time scales (Dussaillant et al., 2019; Fountain & Tangborn, 1985; Moore et al., 2009). Glacial runoff increases during warm periods and diminishes during cool, wet periods. Thus, glacial watersheds have less seasonally variable runoff than ice-free watersheds. Also, glacial runoff cools stream temperatures in the driest and hottest part of the summer after seasonal snowpacks have vanished (Cadbury et al., 2008; Fellman et al., 2014). As glaciers shrink, they have less ability to buffer seasonal runoff variations and watersheds become more susceptible to drought. Globally, the loss of perennial ice from the landscape is a major contributor to sea level rise (Meier, 1984; Parkes & Marzeion, 2018; Zemp et al., 2019).

Glacier inventories have been valuable for assessing glacier contribution to sea level change (Hock et al., 2009; Pfeffer et al., 2014), and for assessing regional hydrology (Yao et al., 2007; Moore et al., 2009). They also provide a baseline for quantifying future glacier changes. Glacier inventories have been compiled for many regions of the world (Bolch et al., 2010; Smiraglia et al., 2015; Sun et al., 2018). An exception has been western United States (US), defined here as

https://doi.org/10.5194/essd-2022-369
Preprint. Discussion started: 8 February 2023

those conterminous states west of the 100th meridian. Despite a vigorous history of glacier studies (e.g., Armstrong, 1989; Rasmussen, 2009), glacial geology (e.g. Davis, 1988; Bowerman and Clark, 2011; Osborn et al., 2012), and regional inventories (e.g. DeVisser & Fountain, 2015; Fagre et al., 2017; Post et al., 1971) the glacier cover for the entire western US has not been updated in several decades.

The earliest scientific identification of glacier-populated regions in the western US date to King (1871) and, more comprehensively, to Russell (1898). The first summary of glacier areas for each state was in 1961 (Meier, 1961). However, the data sources and methods used to compile the inventories are unknown. Denton (1975) summarized all known glacier studies in the western US, but did not tabulate glacier areas. Krimmel (2002) updated Meier's study and provided total glacier area for the various mountain ranges by summaring a variety previous studies published over a 10+ year time span. It is not clear whether the inventory is complete and no data on individual glaciers are provided. Fountain et al. (2007, 2017) compiled the first comprehensive inventory of glaciers in the western US. The data were derived from historical U.S. Geological Survey (USGS) 1:24,000 scale maps compiled over a 40-year period from the 1940s to the 1980s (Gesch et al., 2002; Usery et al., 2009). Because the USGS mapping was based on one-time aerial imagery, the misinterpretation of seasonal snow as perennial was extensive in some regions. The most current study, Selkowitz & Forster (2016), used Landsat satellite imagery compiled over a four-year period, 2010-2014, and an automated detection scheme to define perennial snow and ice. However, automated schemes are known to misclassify debris-covered ice as ice-free landscape underestimating glacier area (Earl & Gardner, 2016; Paul et al., 2007; Rabatel et al., 2017).

This report presents the results of an updated and comprehensive inventory of glaciers and perennial snowfields of the western US for the purpose of defining their current extent and to provide of baseline for estimating future changes. The report summarizes our methods, uncertainties, tabulated results, and data availability.

2. Methods

The location of the glaciers and perennial snowfields were initially identified by a geographic information system (GIS) database from Fountain et al. (2007). New outlines were manually digitized from color digital orthographic aerial photographs available from the National Agricultural Imagery Program (NAIP), U.S. Department of Agriculture, Farm Service Agency program (NAIP, 2017). Since 2009, the imagery is collected on cycles of two to three years. The spatial resolution is at least 1 m (ground sampling distance) with a horizontal accuracy of 6 m of photo-identifiable ground control points (USDA, 2021). NAIP imagery was downloaded from Data Gateway (https://datagateway.nrcs.usda.gov/GDGHome_DirectDownLoad.aspx). In a few cases, NAIP imagery was not suitable due to seasonal snow, deep shadows, or image warping caused by orthophoto rectification, therefore other sources were used including Maxar satellite imagery (Maxar Technologies, Inc) with a spatial resolution of 0.5 – 1 m. In one situation, we used the most recent imagery available in Google Earth (Google, Inc), resolution ~ 1m, because no other imagery was suitable.

https://doi.org/10.5194/essd-2022-369
Preprint. Discussion started: 8 February 2023

We manually identified all glaciers, ice patches, and perennial snowfields equal or larger than 0.01 km^2. Glaciers are defined as perennial snow and ice that moves (Cogley et al., 2011). A feature was considered perennial if it was present on the original 1:24,000 USGS topographic maps and present on all Google Earth imagery. Movement was identified by the presence of crevasses. Perennial snowfields and ice patches do not exhibit movement, as indicated by a lack of crevasses observed in the imagery. We do not distinguish between snowfields and ice patches and refer to both as perennial snowfields.

Contiguous glacier cover, most commonly on volcanoes, was separated into individual glaciers if they had unique names as indicated on the USGS maps. The orientation of crevasse patterns was used to define flow divides. In the absence of these patterns, shaded relief digital elevation models were used to examine slope changes. These models were derived from aerial lidar data, flown under contract to the USGS (Bard, 2017b, 2017a, 2019; Robinson, 2014) or the Oregon Department of Geology and Mineral Industries (DOGAMI, 2011).

We encountered a number of challenges to our classification and delineation of the glaciers and perennial snowfields. Although crevasses were used to define movement, in a few cases it appeared that they penetrated through the feature to the bedrock underneath suggesting a mechanical break up. In these cases, the feature was classified as a snowfield. In the high alpine regions of California, Colorado, and Wyoming, the terminus of some glaciers was hard to define. Rather than abruptly terminating, the ice seems to thin and smoothly transitions into the surrounding rock talus (see Wyoming in the appendix). It was unclear whether a thin debris layer blanketed the ice or cobbles and boulders protruding through the thin ice. The boundary was mapped along the edge of identifiable ice.

Although not a common problem, one particular difficulty was distinguishing glaciers from rock glaciers (Brardinoni et al., 2019). A rock glacier is a mass of rock debris in a matrix of ice that flows (Cogley et al., 2011). They can be difficult to distinguish from a debris-covered glacier, one that has extensive rock debris over the ablation zone, that lower part of a glacier with exposed ice in late summer. We adopted the following topographic classification. If the slope of the apparent glacier/snowfield graded into the slope of the rock glacier, with no change in sign, then we considered it part of the rock glacier. On the other hand, if the slope changed sign at the bottom of the apparent glacier/snowfield, such that the topography formed a dip before reaching another topographic high that marks the start of a rock glacier, then it was considered independent feature (see Colorado in the appendix).

In a number of cases we observed buried ice adjacent to a glacier (see Oregon in the appendix). The texture was hummocky and very different from surrounding bedrock and adjacent ice. Occasionally a crack in the surface revealed subsurface ice. We decided to include these features as a separate classification, ‘buried ice’, because their size was large relative to the glacier, they were probably once part of the glacier, and may be important local sources of meltwater for streamflow.

The glaciers and perennial snowfields outlines were digitized using ArcMap (ESRI, Inc), a geographic information system, at scales varying from 1:300 to 1:2000 depending on image

https://doi.org/10.5194/essd-2022-369
Preprint. Discussion started: 8 February 2023

quality and complexity. The projection used was the native projection of the image, North American Datum of 1983 (NAD83) for NAIP, and World Geodetic System 1984 (WGS84), with the relevant local Universal Transverse Mercator (UTM) zone, for Maxar and Google Earth. When Maxar or Google Earth imagery were used, final outlines were projected into the NAD83 coordinate system. In situations where it was hard to interpret feature geometry, Google Earth was very helpful because its terrain feature provides an oblique perspective that can be tilted and rotated. Each outline was checked independently by the two senior authors of this report, and in some cases by a third collaborator. If an outline was revised, then it was returned to its original author for review and correction, and the process iterated until all parties agreed.

Uncertainty The uncertainty in glacier area was calculated as one-half the absolute difference between initial and final revised digitized area (the range) divided by the final area and expressed as a percentage. For some glaciers where no revision was necessary a 1% uncertainty was assigned to account for digitizing error, which is known to be relatively small (DeVisser & Fountain, 2015; Hoffman et al., 2007). For the relatively few glaciers where a small section of perimeter was masked by deep shadow, seasonal snow patches, rock debris, or poor imagery, a higher uncertainty was assigned by visually comparing the area in question to the total possible area of the glacier. The estimated uncertainty, up to 16%, was determined by digitizing the minimum and maximum perimeters from a sample of glaciers with similar issues. Uncertainty about the position of a flow divide was considered 5%, due to the topographic ambiguity along a divide, and estimated from several digiting efforts. For perennial snowfields a 30% uncertainty is assigned because the seasonal snow commonly covers the smaller patch of perennial snow and the seasonal snow varies greatly from year to year. The snowfield uncertainty was arbitrary in order to note their presence and location, but preclude them from area change calculations because area differences are typically smaller than the assigned uncertainty.

Our initial inventory was then compared sequentially to two other independent inventories to test for errors of omission or commission. The first comparison was to the Selkowitz and Forster (2016) inventory (SFI). However, we had to reconcile the different methods of each inventory prior to comparison. Buried-ice features were eliminated from our inventory because the SFI did not map buried ice. Features removed from the SFI include, features < 0.01 km^2 to match our minimum area threshold; a small number of glaciers and snowfields located in Canada; the few glacier classifications of ponds, lakes and dry lakebeds. Notably, the SFI did not split contiguous ice masses, such as glacier-covered volcanoes, into individual glaciers, consequently we do not expect the number of features in the SFI and our inventory to match. Once the two inventories were reconciled, those glaciers and perennial snowfields unique to one inventory were examined for inclusion in a revised inventory. Features selected from the SFI were digitized using the same imagery we used for our inventory.

The revised inventory was then compared to the 2016 National Land Cover Database (NLCD), which did not map glaciers and perennial snowfields per se, but mapped the distribution of perennial snow and ice (Jin al., 2019). However, the NLCD used a smaller number of images over time for any one location such that we consider the assessment of ‘perennial’ has a high uncertainty. Also, the landscape class of snow and ice received less attention than other classes (e.g. agriculture) such that the timing of imagery acquisition may be earlier in the summer than

https://doi.org/10.5194/essd-2022-369
Preprint. Discussion started: 8 February 2023

optimal and misclassification of clouds as snow and ice may be present (personal communication C. Homer and J. Dewitz, 2015). Again, the features unique to one inventory were examined for inclusion and those features selected from the NLCD were digitized using the same imagery we used for our inventory.

3. Results

Our initial inventory identified 2267 glaciers and perennial snowfields totaling 391.95 km^2. About 70% (1576) overlapped the features in the SFI. After examining all features unique to each inventory, we revised our inventory to include 2373 (394.99 km^2) glaciers and perennial snowfields. Comparing the revised inventory to the 2016 NLCD resulted in adding another 134 (2.53 km^2) features, which included 12 (0.38 km^2) glaciers. The final inventory includes 2542 glacial features composed of 1331 (366.52 km^2) glaciers, 1176 (31.01 km^2) perennial snowfields, and 35 (3.57 km^2) buried ice deposits (Table 1; Figure 1). Most glaciers and perennial snowfields, 1554 (62%) were outlined using 2015 NAIP imagery with the remainder outlined using mostly NAIP imagery from 2013 to 2020. The state of Washington has the greatest number and area of glaciers, perennial snowfields, and buried ice.

The final inventory conflicts with the current database of the Geographic Names Information System (US Geological Survey, 2022). The inventory excludes 52 officially named glaciers because 2 have disappeared, 25 were classified as perennial snowfields, the area of 18 was less than 0.01 km^2, and 7 were considered rock glaciers (Table 2). In some cases, a named glacier or snowfield had split into multiple pieces since the original USGS mapping; all pieces were assigned the same name in the inventory (see appendix, sections 6.7 and 6.8).

Table 2. List of officially named glaciers not classified as glaciers and excluded from the final inventory. Names come from the Geographic Names Information System, (US Geological Survey, 2022). The 'Reason' column lists why the named glacier is no longer considered a glacier in our inventory.

4. Data products and availability

The data are available in three formats. The geospatial data and attribute tables are available in the shapefile (Esri) format and in an open source GeoJSON format. The attribute table is also available as an EXCEL file. These data products can be obtained from https://doi.org/10.15760/geology-data.03 (Fountain and Glenn, 2022) and from the Global Land Ice Measurements from Space website (to be submitted) http://glims.colorado.edu/glacierdata/

5. Summary

We have compiled a new and comprehensive inventory of glaciers and perennial snowfields in the western US from aerial and satellite imagery. Results show that 2542 glacial features are currently present and include 1331 (366.52 km^2) glaciers, 1176 (31.01 km^2) perennial snowfields, and 35 (3.57 km^2) buried ice deposits. Most of the data were acquired from 2015 NAIP imagery with the remainder from NAIP imagery and a few satellite images acquired over the period of 2013 to 2020. The state of Washington has the greatest number and area of glaciers and perennial snowfields. This product updates an older inventory based on USGS 1:24000 maps compiled in the middle-late 1900's. The new inventory is a significant improvement in accuracy because the archive of historical imagery in Google Earth allowed us to classify glaciers versus perennial snowfields. Finally, this new inventory provides a baseline for assessing glacier change in the coterminous US.

6. Appendix

This appendix, organized by US State, then by mountain range, summarizes the specific imagery used, challenges encountered in feature identification and outline digitization. The most recent suitable NAIP was used in each case. Where such imagery was not suitable Maxar imagery was used. In the Wallowa Mountains, Oregon, neither was NAIP suitable nor was Maxar available so images from Google Earth were used. The Selkowitz and Forster (2016) inventory is referred to as the SFI and the National Land Cover Database inventory (Jin et al., 2019) is referred to as the NLCD.

California

Imagery and DEMs used are listed in Tables A1, A2, A3.

Cascade Range

Mount Shasta

https://doi.org/10.5194/essd-2022-369
Preprint. Discussion started: 8 February 2023

The 2020 black and white Maxar imagery was most useful because of the minimal seasonal snow cover. The 2018 NAIP imagery was helpful in situations where the 2020 imagery was obscured by shadow, distortion, or misaligned, and when color was needed to improve interpretation. The 2010 lidar DEM (Robinson, 2014; Table A3) was used to create a multidirectional hillshade to improve perspective and interpretation (Figure A1). The rock debris on the termini of most glaciers and rock debris on some of the upper parts of the glaciers were challenging to interpret. It was hard to determine whether ice was present under the debris and whether that ice is part of the active glacier. Spatial patterns of debris, debris contrasts, and melt streams flowing from the debris were used to estimate the glacier boundaries.

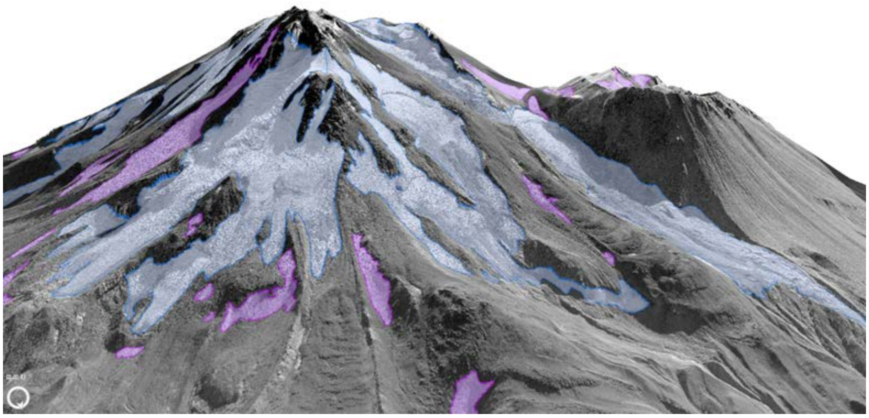

Figure A1. Mt. Shasta glaciers in bluish white, perennial snowfields/ice patches in lavender draped over a 3D rendering created from 2010 lidar (Robinson, 2014).

Sierra Nevada

The 2014 NAIP imagery was the best imagery due to low snow cover. In some cases, features were difficult to outline because of shadow or image quality. In these cases, 2013/2012 Google Earth imagery were used. Some glaciers were reclassified as rock glaciers by Trcka (2020). These were re-examined and where we agreed they were removed from the initial glacier inventory. Defining whether the feature was a glacier or rock glacier was often difficult, see Colorado section for more discussion.

Trinity Alps

The 2018 imagery was the best for the least snow cover. Justin Garwood (Garwood et al., 2020) provided outlines for two glaciers, Grizzly and Salmon. The area of the most recent outline of the Salmon Glacier was < 0.01 km^2 and was not included in this inventory. By 2018 all of the other features mapped by the USGS (Fountain et al., 2017) were less than 0.01 km^2 or had disappeared. An additional feature was added based on the 2016 NLCD (Jin et al. 2019).

6.2 Colorado

The 2015 NAIP was generally free of seasonal snow. Where it persisted at the terminus of a few glaciers, images for the same year in Google Earth aided perimeter interpretation. Imagery used are listed in Table A4.

Elk Mountains

No glacial features were mapped in the Elk Mountains by the USGS (Fountain et al., 2017). One glacier and four perennial snowfields were added from the SFI.

Front Range

The most recent inventory for the Front Range was Hoffman et al. (2007), which used aerial photographs to map the 2001 extent of glaciers. Many features in the Front Range are difficult to classify. The issue is the difference between a glacier or perennial snowfield and a rock glacier. Those that are part of the rock glacier are deleted from the glacier inventory. Those that seem to be separate from rock glaciers are retained. This is a judgement call. From a hydrological point of view, if a snow-ice patch that is part of a rock glacier was counted separately from a rock glacier, it is double counting a water feature.

The most challenging situation to interpret occurs when the glacier or perennial snowfield is located up-elevation from the rock glacier. If the slope of the snowfield smoothly transitions to the slope of the rock glacier, with no change in sign of the slope, we consider that one feature, a rock glacier (Figure A2). If the terrain dips below the snowfield, changing sign to rise to a topographic high below which the rock glacier clearly emerges, then they are two separate features. The patch does not appear to feed the rock glacier with ice (ice melt maybe, but not ice), because the ice would have to flow uphill to reach the rock glacier (Figure A3).

6.3 Idaho

The imagery quality was generally snow free. Of the glacier mapped by the USGS (Fountain et al., 2017) only two remain and are classified as perennial snowfields. The Borah Glacier was officially named in 2021, but is < 0.01 km^2, and is not included in the inventory. Table A5 lists the imagery used.

6.4 Montana

Inage quality varied between mountain ranges due to differences in snow cover. Tables A6 and A7 list the imagery used.

Beartooth-Absaroka Range

The 2015 NAIP imagery was the best overall imagery due to the least snow, but Google Earth was occasionally used as well. Google Earth had imagery dated to 9/11/2015; often with less seasonal snow than the NAIP imagery. To counter any mismatch in projection, outlines digitized in Google Earth were imported to ArcGIS and projected to match the NAIP projection.

Bitterroot Range

https://doi.org/10.5194/essd-2022-369
Preprint. Discussion started: 8 February 2023

There were no glacial features were mapped in the Bitterroot Range by the USGS (Fountain et al., (2017). One glacier and three perennial snowfields were added based on the NLCD.

Cabinet Range

The USGS mapped four glacial features ≥ 0.01 km^2 (Fountain et al., 2017). Inspection of the 2015 only one was ≥ 0.01 km^2. Seven glaciers and perennial snowfields were added; five were identified in our initial inventory, the other two were identified by the SFI and NLCD, respectively. All were less than 0.05 km^2.

Crazy Mountains

The 2013 NAIP imagery was the best imagery available and included limited seasonal snow. The 2019 Maxar imagery had too much seasonal snow.

Lewis Range (Glacier National Park)

The most recent published glacier inventory is a 2015 USGS inventory (Fagre et al., 2017). They outlined the main-body of named-glaciers using 2015 Maxar imagery. We digitized the outlines of all glaciers and perennial snowfields using 2015 Maxar imagery where available. Elsewhere, 2015 and 2013 NAIP imagery were used; both years had lots of seasonal snow cover. Two major glaciers, Blackfoot (Figure A4) and Harrison (Figure A5) glaciers, separated into pieces as it retreated since it was originally mapped by the USGS (Fountain et al., 2007).

Madison Range

The 2013 NAIP imagery was the only good imagery due to extensive snow in the other years. No glaciers or perennial snowfields were found. Of the two features ≥ 0.01 km^2 mapped by the USGS (Fountain et al., 2017), the 2013 imagery showed that one feature is a rock glacier and the other was less than 0.01 km^2.

Mission-Swan-Flathead Ranges

Based on the least snow cover, the 2013 NAIP was better in the Mission and Flathead Ranges, and the 2015 NAIP was better in the Swan Range. No glaciers or perennial snowfields remain in the Flathead Range.

Open Access Earth System Science Data Discussions

6.5 Oregon

Tables A8, A9, and A10 list the imagery and DEM used.

Cascade Range

Mount Hood

The most recent glacier outlines for Mt. Hood were based on 2015 and 2016 Maxar color imagery with interpretation aid using Google Earth. Due to seasonal snow some professional judgement was required in places.

Mount Jefferson

Seasonal snow was extensive in places. The 2018 NAIP had extensive seasonal snow and generally only useful near the terminus of some glaciers. Used 2018 Maxar imagery that showed little seasonal snow, but a little cloudy that masked a bit of Whitewater Glacier. Also used Google Earth to help interpret some of the features.

Three Sisters

Used Maxar 2018 imagery, but where image stretching along the feature's headwall 2018 NAIP imagery was used. Two versions of the Maxar imagery for the same day are 3available, one color, one black and white. Color was georectified but suffered stretching along some headwalls. A light early season snowfall occurred before the Maxar image and the snow accumulated in some places just enough to obscure the surface. So, the glacier or snow patch outline was the minimum of the two images with occasional interpolation across the snowy surface to the nearest glacier edge.

An example of buried ice on South Sister is shown in Figure A6.

Mount Thielsen

The Lathrop Glacier was named in 1981. At the time of the USGS mapping and now it is <0.01 km^2, and not counted as part of the inventory. Furthermore, Lathrop Glacier has been known to disappear in some years and therefore fails the definition of a glacier.

Wallowa Mountains

No NAIP imagery was useful and Maxar did not image this region. We used the 8/30/2013 image from Google Earth, which was excellent with little snow. Features were digitized in Google Earth and then imported into ArcGIS. Because we used NAIP as the base imagery, we revised the outline from the projection in WGS84 (Google Earth) to NAD83 UTM Zone 11 (NAIP).

Preprint. Discussion started: 8 February 2023

Figure A6. Lost Creek Glacier, South Sister, Oregon. Note buried ice and lack of crevasses to the left of the grey-blue ice, suggesting ice that is no longer moving and therefore not part of the dynamic glacier. The white box surrounds an area that has collapsed due to subsurface melt. The inset enlargement shows a cliff edge of exposed dirty ice (white arrow) indicated by a darker color suggesting wet sediment and a finer texture than the surface debris. The black arrow shows the width of the cleaner ice for scale. Image is from © Google Earth, 8/9/2021.

6.6 Washington

The 2015 NAIP imagery was typically excellent with little snow cover, whereas the 2017 NAIP had more snow and the 2019 imagery had lots of snow. For most outlines, 2015 NAIP imagery was used. In some places, the 2017 NAIP imagery had less snow and was used instead. Maxar imagery was of limited use and often wasn't better than the 2015 or 2017 NAIP. Tables A11, A12, and A13 list the imagery and DEMs used.

Cascade –Northern

The glaciers and perennial snowfields were previously inventoried by (Dick, 2013).

Mount Baker

The 2015 NAIP imagery was the best and had little seasonal snow. Google Earth 2009 and 2019 imagery were used to help interpretation. A multidirectional hillshade and 3-meter contour lines derived from a lidar DEM (Bard, 2017b; Table A13); were used to help define flow divides between glaciers, debris covered-ice, and buried ice. There are notable differences between the NAIP imagery and DEM data, particularly in steep terrain, areas of dark shadow, and debris-covered areas. The DEM helped correct these positional errors and the benefit of supplying more information on surface texture.

Several buried-ice features were identified. The ice appeared to have decoupled from the active glacier. In a few cases, debris-covered ice is included in the glacier outline because the ice appears to be directly connected to the glacier, and there was evidence of movement.

Dragontail Peak
The GNIS locates Snow Creek Glacier at a point on the edge of the southeast glacier (Fountain et al., 2007). In the 2015 imagery, the point is on bedrock, making it unclear which glacier the GNIS is naming. The USGS identifies both glaciers as Snow Creek Glacier. We labeled both glaciers as the Snow Creek Glacier.

Glacier Peak
For the Glacier Peak region, a multidirectional hillshade and 3-m contour lines derived from a 2015 lidar DEM (Bard, 2017A; Table A13) was used as a guide to define flow divides.

Hurry-up Peak
The point location of the South Glacier provided by the GNIS is over bedrock. We assume the point refers to the glacier located ~150 m to the north of the point.

Cascade –Southern

Goat Rocks
Imagery from 2015 was best, but more snow than desired. Too much snow in 2017 but some ice is exposed. The 2019 imagery was way too snowy and was considered useless for glacier digitization.

The outlines are almost entirely based on 2015 imagery, and a few on 2017, where needed. Used 2009 NAIP imagery to help define the headwalls at the Conrad, McCall, and Packwood glaciers. Heard (2000) previously mapped the glacier perimeters. The maximum extent of the seasonal snow covering the terminal regions was not digitized. Typically digitized at scales of 1:600 to 1:800. Note that narrow arms of the snowfields were not typically digitized knowing that they would probably disappear a few days to a week from the time of imagery.

Mount Adams
No suitable NAIP imagery was found, instead 2019 Maxar imagery was used. In addition to the Maxar imagery, a multidirectional hillshade and 3-m contour lines derived from a 2016 lidar DEM (Bard 2019, Table 13A) were used as a guide when delignating flow divides. Occasionally, 2009 Google Earth imagery was also useful. Extensive snow covered the mountain when the 2016 lidar was flown masking some of the glacier termini. However, the DEM was helpful in correcting the imagery where poorly aligned with the terrain.

Multiple buried-ice features were identified near the terminus of several glaciers where ice appeared to have decoupled from the main active glacier. Large areas below the glaciers (Mazama, Adams, and Pinnacle) likely have debris-covered ice. We focused on the features which were likely to contain ice based on meltwater streams exiting near the features and hummocky terrain which appeared to indicate melt. Ground-based images from taken between 2014 to 2018 helped decision-making. The images were particularly helpful in identifying a debris-covered ice cliff at Adams Glacier.

Mount Rainier

In general, the 2019 NAIP and the Maxar (2018-09-25) were used for the outlines (Table A12). Although the GNIS includes the Nisqually Icefall as a separate feature, we included the icefall as part of the Nisqually Glacier (Figure A7).

Mount St. Helens

We used a GIS layer of geological mapping units that included snow and ice from the USGS (David Sherrod, personal communication, 2021) to help guide our search. The Crater Glacier (INV_ID E562842N5115499) was heavily debris covered, and obscured by shadow in some areas.

Olympic Mountains

A 2015 inventory of the region was compiled because more recent imagery (NAIP and Maxar) were not useful due to seasonal snow. Our updated inventory differs from that published in Fountain et al. (2017) in two ways. First, they outlined and grouped the glaciers and perennial snowfields according to watershed rather than individual glacier. Their goal was to estimate glacier change relative to a previous study by Spicer (1986) and had to follow Spicer's approach. Second, all outlines were rechecked and compared to SFI and the NLCD resulting in minor changes.

6.7 Wyoming

Wind River Range

Tables A14 and A15 list the imagery used. The 2015 NAIP imagery had little snow in contrast to 2019 imagery. Shadows are common in the 2015 imagery and can be very dark. Occasionally the 2019 imagery was used to define the glacier-bedrock headwall boundary. The 2019 Maxar imagery was essentially identical to the NAIP and because its black and white not as useful. Imagery from 2017 and 2018 were a bit too snowy around the glacier margin to be useful. The 2018-09-06 Maxar imagery covered the entire range, with some clouds.

In the southern Wind River Range, a new snow dusting was often present, occasionally making it difficult to outline snowfields and glaciers, but mostly snowfields. Distinguishing seasonal snow from perennial snow was a judgement call. The thin seasonal snow was identified if a slight coloration similar to underlying rock/soil was present or many small patches (a few square meters) of snow-free surface present or many rocks protruding through the snow. A perennial patch of snow appeared smooth and white, hiding underlying surface. Thin snow covering glacial ice was typically greyish in color, often with banding, much less of a texture than surrounding ice-free landscape.

Often, it seems a number of glaciers are thinning in place with a thin layer of debris on the ice that thickens down valley. The landscape surrounding this relatively smooth appearance is rumpled like the bedrock terrain further away. Interpretation is difficult. These are probably shrinking glaciers that are being covered in the debris. The outline is clear where ice meets bedrock, but in the talus debris area, we digitized along the glacier ice boundary unless some other feature like exposed ice or a crevasse is visible then included that as part. See INV_ID E618081N4774579 (Figure A9) for example.

At Lower Fremont Glacier, a number of sizable ice patches appear down valley as if a deposit of buried ice is present. However, there is no obvious connection to the glacier itself.

The GNIS identified a single glacier as the Sacagawea Glacier, and two separate Fremont Glaciers (Figure A10). By 2017 the single glacier had split into four glaciers. We chose to label the largest glacier and the glacier to the southeast the Sacagawea Glacier. The other two glaciers were labeled the Fremont Glaciers.

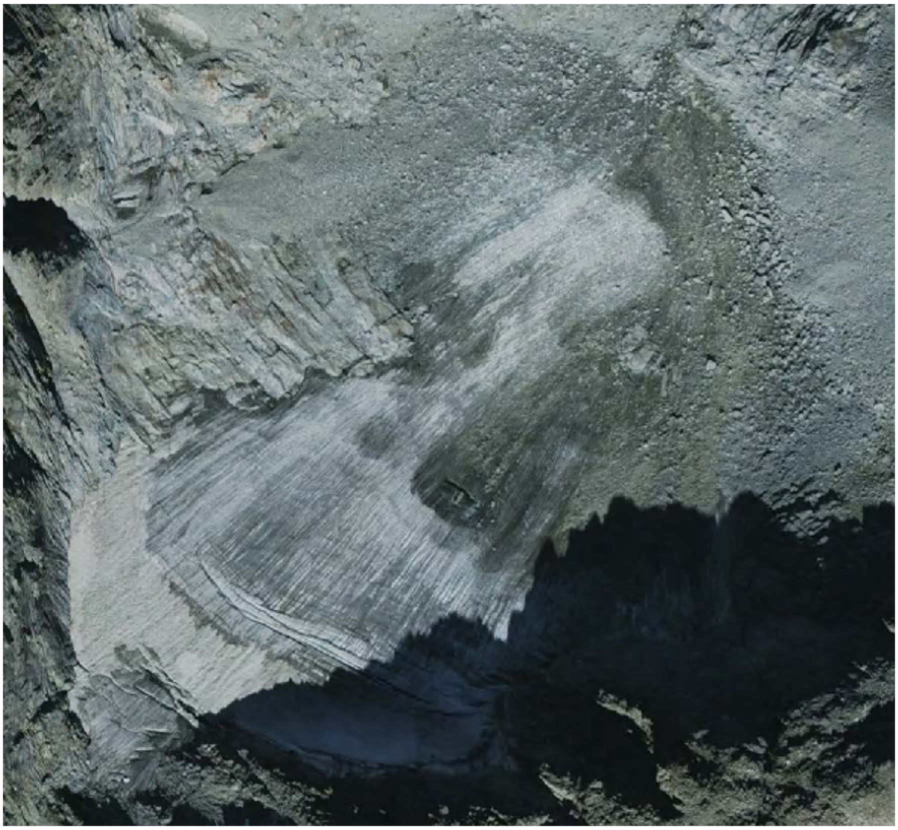

Figure A9. An example of an unnamed glacier in the Wind River Range, WY, INV_ID E618081N4774579 seemingly melting into the talus surrounding the terminus (top of image). The glacier is flowing from the lower left-hand corner to the upper right-hand corner. Base image from the NAIP taken in 2015.

6.8 Glaciers that have split into multiple pieces and current errors in glacier label names

Table A16 compiles the list of glaciers that have split into multiple pieces since the USGS 1:24000 mapping (Fountain et al., 2017). Table A17 lists current map errors in the labeling of glaciers. The purpose of including this table is to facilitate updating the USGS Geographic Names Information System.

Table A16. List of named glaciers that have split into multiple pieces. Names come from the Geographic Names Information System. ‘Count’ refers to the number of pieces in the updated

S Glacier	Label unclear
Snow Creek Glacier	Label unclear
South Glacier	Not labeled
Cascade Range-Southern	

No Name Glacier	Not labeled
Stevens Glacier	Not labeled
Wyoming	
Wind River Range	
Dinwoody Glaciers	Label unclear
Fremont Glaciers	Label unclear

Author Contributions. Andrew G. Fountain was the principal investigator of the project, he wrote the proposal and digitized glacier and snowfield outlines, analyzed the data, and led the writing of this report. Bryce Glenn was the GIS expert responsible for the geographic format (e.g. projection, attributes, database structure) and quality control. He digitized glacier and snowfield outlines, analyzed the data, and helped write the report. Chris McNeil provided some of the imagery.

Competing Interests. The authors declare that they have no conflict of interest.

Acknowledgments. Hassan Basagic and Kristina Dick digitized the glaciers of Mt. Shasta and the North Cascade National Park, respectively. We greatly appreciate their help and expertise. Nathan Walker of the U.S. Forest Service provided a very helpful initial review of this report. We kindly acknowledge the funding from the US. Forest Service. Mazar imagery was accessed through the USGS and NGA NEXTVIEW license. The Maxar imagery has limited availability owing to restrictions (proprietary interest). Contact cmcneil@usgs.gov for more information. Any use of trade, firm or product names is for descriptive purposes only and does not imply endorsement by the U.S. Government.
