25 **Abstract.** Reanalysis data plays a vital role in weather and climate study, as well as
meteorological resource development and application. In this work, the East Asia Reanalysis
System (EARS) was developed using the Weather Research and Forecasting (WRF) model
and the Gridpoint Statistical Interpolations (GSI) data assimilation system. The regional
reanalysis system is forced by the European Centre of Medium-Range Weather Forecasts
30 (ECMWF) global reanalysis EAR-Interim data at 6-h intervals; and hourly surface
observations are assimilated by the Four-Dimension Data Assimilation (FDDA) scheme
during the WRF model integration; upper observations are assimilated in a three-dimensional
variational data assimilation (3D-VAR) mode at analysis moment. It should be highlighted
that many of the assimilated observations have not been used in other reanalysis systems. The
35 reanalysis runs from 1980 to 2018, producing a regional reanalysis dataset covering East Asia
and surrounding areas at 12-km horizontal resolution, 74 sigma levels, and 3-hour intervals.
Finally, an evaluation of EARS has been performed with the respect to the root mean square
error (RMSE), based on the 10-year (2008-2017) observational data. Compared to the global
reanalysis data of the EAR-Interim, the regional reanalysis data of the EARS are closer to the
40 observations in terms of RMSE in both surface and upper-level fields. The present study
provides evidence for substantial improvements seen in EARS compared to the ERA-Interim
reanalysis fields over East Asia. The study also demonstrates the potential use of the EARS
data for applications over East Asia and proposes further plans to provide the latest reanalysis
in real-time operation mode. Simple data and updated information are available on Zenodo at
45 <https://doi.org/10.5281/zenodo.7404918> (Yin et al., 2022), and the full datasets are publicly
accessible on the Data-as-a-Service platform of China Meteorological Administration (CMA)
at <http://data.cma.cn>.

Keywords: Regional reanalysis, East Asia, Data assimilation, Multiple observations

50 **1. Introduction**

The East Asia Reanalysis System (EARS) project was launched by the China Meteorological Administration (CMA) in late 2014. It aimed to build a regional reanalysis system that can assimilate as much as possible multi-source observational datasets, and to establish a long-term high-resolution regional atmospheric reanalysis, which is high quality
55 for mesoscale weather, regional climate, environment studies, and other applications. This paper is to report the progress of the project, including the used numerical model, data assimilation, observations, and preliminary achievements. Thus, the major objectives of the present study are to (i) introduce the work we have already done; (ii) help understand and use the EARS reanalysis products; and (iii) provide guidance for repeating and extending the
60 work in the future.

Atmospheric reanalysis data, which may serve as alternative data to actual observations, play an important role in weather and climate studies, including numerical model validation. In the past several decades, a series of atmospheric reanalysis products were produced with different goals (Wright et al., 2019); some have been widely used in theoretical studies and
65 applied to weather and climate research to improve prediction skills and reduce hazard risks. With the ongoing development of atmospheric sciences, high-resolution atmospheric reanalysis data are much needed. In view of this demand, a large number of high-resolution regional reanalysis products have been produced for various parts of the world (e.g., Mesinger et al., 2006; Jakob et al., 2017; Vidal et al., 2010; Usui et al., 2017; Yang et al., 2022).
70 However, little attention has been paid to East Asia, although China's first generation of global atmospheric reanalysis (CRA40) was released recently. Only low-resolution global reanalysis products have been used for the region, including the National Centers for Environmental Prediction-Department of Energy Reanalysis version 2 (NCEP2) (Kanamitsu et al., 2002), the European Centre of Medium-Range Weather Forecasts (ECMWF)

75 Reanalysis-Interim (ERA-Interim) (Dee et al., 2011), the Japanese 55-year Reanalysis (JRA55)
(Kobayashi et al., 2015), and the Modern-Era Retrospective Analysis for Research and
Applications version 2 (MERRA2) (Gelaro et al., 2017). More recently, the ECMWF released
the fifth generation of its atmospheric reanalysis (ERA5) (Hersbach et al., 2020), replacing
the ERA-Interim; it is a global atmospheric reanalysis with a horizontal resolution of 0.25
80 degrees. Although these global reanalysis systems have achieved great progress, their
products were developed for global coverage. They have limited regional usage due to low
spatial and temporal resolution (Chen et al., 2014). Most importantly, multiple observations
over East Asia were not included in these global reanalysis products. Consequently, the global
reanalysis products are inadequate for studying characteristics of local weather and climate in
85 East Asia, such as strong rainfall in the warm sector in southern China during the period from
April to June (the so-called pre-summer rainy season) (Chen et al., 2014). In view of the
above-mentioned inherent issues, it is highly imperative to develop a high
spatiotemporal-resolution reanalysis product for East Asia.

Several regional atmospheric reanalysis datasets were produced in the past two decades,
90 such as the North American Regional Reanalysis (NARR) (Mesinger et al., 2006), the
High-resolution Regional Reanalysis for the European Coordinated Regional Downscaling
Experiment (CORDEX) (Bollmeyer et al., 2015; Bach et al., 2016), the Arctic System
Reanalysis (ASR) (Bromwich et al., 2017), the Bureau of Meteorology Atmospheric
high-resolution Regional Reanalysis for Australia (BARRA-R) (Jakob et al., 2017),
95 high-resolution regional reanalysis of Japan (NHM-LETKF) (Fukui et al., 2018), and the
regional reanalysis of Indian Monsoon Data Assimilation and Analysis (IMDAA) (Mahmood
et al., 2018). These data have been widely used for regional weather and climate studies.
Recently, Yang et al. (2022) developed 10-year (2010-2019) regional reanalysis, focusing on
the Korean Peninsula and its surrounding areas only. With the same objective, the CMA

100 planned a project, intending to produce a high-resolution regional atmospheric reanalysis dataset for East Asia, with high quality for mesoscale weather system study and regional climate analysis. For this purpose, the EARS was launched in late 2014 and a 39-year (1980-2018) reanalysis dataset is now available to the public.

This is our first open documentation of the project, on the basis of several progress
105 reports (e.g., Liang et al., 2020; Yin et al., 2019), which briefly describes the EARS and documents its performance. It includes the numerical model set, data assimilation method, assimilated observational datasets, and preliminary results. In section 2, we describe the EARS system and the data used. In section 3, we present the preliminary results of a 10-year (2008-2017) reanalysis dataset with validation. Finally, a summary and discussion are
110 provided in section 4, along with future activities and plans.

2. East Asia Reanalysis System and Data Used

2.1 System Setup

The EARS is established based on the Advance Research Weather Research and Forecasting (WRF version 3.9.1) model (Skamarock et al., 2008) and the Gridpoint Statistical
115 Interpolations (GSI) data assimilation system (Hu et al., 2018). To improve the model performance in East Asia, a series of experiments were launched for dynamic and physical options. At present, the GIS runs in a three-dimensional variational data assimilation (3D-VAR) mode, and much attention has been paid to the effect of assimilating each category of observations. To date, the EARS works continuously in a 39-year run, with a cold start at
120 the interval of six hours.

In the EARS (Fig. 1), the WRF-ARW model grid spacing is 12 km, which covers a large domain of an area of 10,800 km × 9,120 km (with 900 × 760 grid points); and it is centered at (100°E, 38°N). A total of 74 sigma levels is used in the vertical, with the model top fixed at

10 hPa. The model terrain is interpolated from the 30-arc-second USGS GMTED2010; and
125 the land use fields are interpolated from 21-class MODIS datasets. The model physics
schemes used include the following: (i) the Kain (2004) cumulus parameterization scheme; (ii)
the new Thompson microphysics scheme (Thompson et al., 2008); (iii) the rapid radiative
transfer model (Iacono et al., 2008) for both shortwave and longwave radiative flux
calculations; (iv) the Yonsei University (YSU) Planetary Boundary Layer (PBL) scheme
130 (Hong et al., 2006); (v) the revised MM5 Monin-Obukhov similarity scheme for the surface
layer (Janjić, 1994), and (vi) the Noah-MP land-surface scheme (Niu et al., 2011). It should be
emphasized that the model set was optimized via a series of experiments covering various
weather phenomena and continuous simulations (e.g., Zhang et al., 2016; Li et al., 2018; Yin
et al., 2014; Yin et al., 2020).

135 A schematic illustrating the flow of analysis steps of the EARS is shown in Fig. 2. The
WRF model integrates for 12 hours in every cold start, starting at 0000, 0600, 1200, and 1800
UTC, with hourly outputs. The ERA-Interim 0.79-degree reanalysis data at 6-h intervals are
utilized as initial and boundary conditions for the cold run. Please refer to Dee et al. (2011)
for detailed information. At the model's initial time, the upper-level (sounding and aircraft)
140 observations are assimilated with the GSI system in 3D-VAR mode. During the model
integration, the Four-Dimension Data Assimilation (FDDA) functions are activated by
performing surface observation nudging (Reen, 2016). The required analysis data for the
FDDA are obtained through the WRF's preprocessing OBSGRID module (Wang et al., 2017),
using the hourly surface observations after performing data quality control, which includes
145 temperature, relative humidity, and horizontal winds. The model outputs in the first six hours
are considered spin-up process, and thus not used for research. The model outputs at the ninth
and twelfth hours are used as the first guess of the GSI; and the upper-level observations are
assimilated in a 3D-VAR mode. The upper-level observations include sounding, aircraft

observation, and cloud-derived wind vector. The composited radar reflectivity is ingested by
150 the way of cloud analysis to produce the final reanalysis data. Note that model hourly outputs
are also available. Unlike a global reanalysis system, the EARS conducts a cold start every six
hours, and the WRF model integrates 12 hours for each run. Accordingly, the model outputs
from the sixth to twelfth hours are used to produce hourly precipitation during the WRF
model integration. Before generating long-term reanalysis, the EARS was validated by
155 continuous simulations of the year 2014. The results indicated that the EARS performed
better in terms of atmospheric variables, and provided more mesoscale details than the
large-scale ERA-Interim reanalysis (used as background in the EARS), and its outputs can be
used for developing a long-term reanalysis product.

2.2 Assimilated Data

160 Various categories of observational data used in the EARS are listed in Table 1. The
National Meteorological Information Center (NMIC) of CMA archives all observational
datasets after performing strict data quality control. The observational data are publicly
accessible at <http://data.cma.cn/> (last access 8 Jan 2023). In particular, the traditional
observational datasets have been greatly improved by merging multiple data sources, which
165 are officially released by the NMIC. Note that many of the datasets were not shared publicly
before. Figure 3 shows spatial distributions of radiosonde and radar observations, surface
observations over land, and surface observations over the ocean. Note that the aircraft and
satellite (cloud-derived wind vector) observations are not presented due to irregular moving
trajectories depending on time and space.

170 Previous studies (e.g., Kawai et al., 2017; Benjamin et al., 2010; Lee et al., 2019; Rabier
et al., 2009; Ingleby et al., 2016) have confirmed that numerical model performances were
enhanced by assimilating radiosonde observations globally. Figure 4 shows the radiosonde
observations assimilated in the EARS, which has been greatly improved by combining

datasets from various databases and employing more observational data sources from China.

175 It can be seen that the counts of radiosonde observations show slight variation from 1980 to 2000, and then increase obviously, almost doubled by 2018. In addition to regular observations shared in the Global Communication System (GTS) of World Meteorological Organization (WMO), another 33 radiosonde stations in China are incorporated. Most importantly, more vertical-level observations are included by merging logs of old records.

180 Taking the radiosonde observations of Beijing station at 0000 UTC 1 July 2016 as an example (Fig. 5), the merged radiosonde observations show more detailed vertical structures, compared to those in the Integrated Global Radiosonde Archive (IGRA) version 2, which is used in the National Center for Atmospheric Research (NCAR) global reanalysis of the Climate Forecast System Reanalysis (CFSR). Besides, radiosonde observations at both 0600

185 and 1800 UTC are used (Fig. 4a,c), although the observations are discontinuous and much fewer than those at 0000 and 1200 UTC (Fig. 4b,d). Moreover, radiosonde observations from field experiments are used, including those from the Third Tibetan Plateau Atmospheric Scientific Experiment (TIPEX-III) (Zhao et al., 2018), the Southern China Monsoon Rainfall Experiment (SCMREX) (Luo et al., 2017), among others. Note that these supplementary

190 radiosonde observations were not utilized in any global reanalysis system outside of China. Overall, the number of radiosonde observations assimilated in the EARS has increased significantly after combining several sources, especially from 2000 to 2018.

Previous studies (e.g., Mirza et al., 2016; James et al., 2020) indicated that assimilating aircraft observations was beneficial for numerical modeling. The aircraft observations used in

195 the EARS are provided by the NMIC after quality control (Liao et al., 2021), which is a new product by integrating nine different data sources into the Integrated Global Meteorological Observation Archive from Aircraft (IGMOAA). Adding the datasets from the Chinese Aircraft Meteorological Data Relay (AMDAR), the observation count has increased

significantly, compared to that of the IGMOAA. The integrated data were officially released
200 by the NMIC and are updated in real-time at the Data-as-a-Service platform
(<http://data.cma.cn/>). Generally speaking, aircraft observations were rare in the early days;
and these observations have increased greatly from 2×10^3 in 2005 to 7×10^3 in 2018 (Fig. 6).
Although the aircraft observations are hourly, there are large differences at different moments
of the day. One can see that the count of aircraft observations in the daytime is much larger
205 than that in the nighttime, though the count of aircraft observations in the nighttime has
slightly increased since 2005.

For surface observations over land (Fig. 3b and Fig. 7a), besides those from the National
Centers for Environmental Prediction (NCEP) Global Data Assimilation System (GDAS) and
the National Climatic Data Center (NCDC) Integrated Surface Database (ISD), more than
210 2440 surface observations from the CMA are added. Detailed processing of the datasets can
be found in Jiang et al. (2021). Note that only a small portion (less than 300 stations in the
early days and nearly 400 stations at present) of the surface observations is shared in the GTS.
The observations over the sea surface are combined with the International Comprehensive
Ocean-Atmosphere Data Set (ICOADS) (Fig. 3c). After the combination, the ocean-based
215 observation count used in the EARS increases by approximately 32% in total, compared to
the ICOADS. As shown in Fig. 7b, the surface observations have increased significantly,
especially since 2000. All the hourly surface observations (over land and ocean) are further
quality controlled by using the modules of OBSPROC and OBSGRID provided by the WRF
Variational Data Assimilation (WRFDA); and the outputs in ASCII format are used for
220 observation nudging during the WRF model integration. we pointed the readers to Skamarock
et al. (2008) for more details. Similarly, all the upper-level traditional observational datasets
are quality controlled by using the OBSPROC module, and then written in the PREPBUFR
format for GSI assimilation in a 3D-VAR mode.

One of the main features of the EARS is its emphasis on radar data assimilation. All
225 weather radar observations over China are used in the EARS (Fig. 3d). Radar observations
have increased rapidly from 80 stations in 2008 to over 190 stations in 2018 (Fig. 8). Note the
radar observations show obvious seasonal variations because most of the radars are out of
service in cold seasons. To obtain high-quality-controlled radar observational data, much
attention has been paid to the preprocessing of raw radar data. A major issue of the radar
230 observations is the non-meteorological echo, which has direct influences on the cloud
hydrometeors in the GSI cloud analysis processes. In view of this issue, much effort has been
devoted to removing isolated non-meteorological echoes and ground clutters from the radar
data (Zou et al., 2018), which makes quality-controlled radar data more accurate (Wu et al.,
2018). After quality control, all radar observations at the same time are utilized to generate
235 mosaic products in BUFR format, which can be inserted into the GSI cloud reanalysis module.
Detailed information about radar data processing and remapping can be found in Zou et al.
(2014). In fact, quality-controlled radar observations are also an important part of the
reanalysis data, which can be used for weather and climate studies, as well as numerical
model validation. Despite considerable effort expended in processing radial wind, the radial
240 wind has been not assimilated at present as more work is required.

Another feature is the application of the cloud-derived wind vector datasets from
Fengyun-2 geostationary meteorological satellites. The cloud-derived wind vector appears
with a count of nearly 6.0×10^4 (Fig. 9). Note that the data have been strictly quality controlled
and widely applied in daily operational numerical weather prediction in China; thus these
245 datasets can be applied directly in the EARS.

Table 1. Observational data used in EARS. Those data are publicly accessible at

250

<http://data.cma.cn/> (last access 8 Jan 2023)

Data	Variable	Starting year
Radiosonde	Pressure, temperature, wind, and moisture	1980
Aircraft	Temperature and wind	1980
Surface ¹	Pressure, temperature, wind, and moisture	1980
Radar	Radar reflectivity	2008
Satellite	Cloud-derived wind vector	2008

2.3 Validation Data and Method

The performance of the EARS is assessed by comparing it with observations and with the large-scale forcing of the ERA-Interim reanalysis (used as the background of the EARS).
255 A 10-year good quality and stable quantity of observations are selected for the assessment. For comparison with station observations, results from the EARS and ERA-Interim are interpolated onto the stations using the nearest neighbor interpolation via the Model Evaluation Tools (MET), which is developed by the Developmental Testbed Center (DTC) of the U.S. (Newman et al., 2022). Following the operational model evaluations of the CMA, we
260 use a total of 2,423 surface observational stations as the reference for the reanalysis data validation. The observations over the Qinghai-Tibet Plateau and its surrounding areas are much sparser, compared to those over the other regions (Fig. 10a). Similarly, a total of 120 radiosonde data over China are used to evaluate high-level variables (Fig. 10b). As has been stated above, the radiosonde observations are mainly obtained at 0000 UTC and 1200 UTC,
265 and the measurements include temperature, (relative) humidity (or dew-temperature), air pressure, horizontal wind speed, and direction.

The quality of the regional reanalysis is also compared to one-month (July 2016) continuous radiosonde observational data, which were obtained from a field experiment in the

¹ Including the surface observations over ocean.

central Taklimakan Desert, Xinjiang Uygur Autonomous Regions, China. The central
270 Taklimakan Desert is far from other observation sites, where the assimilated observations
have little influence on the reanalysis data. Note that these data have not been applied to any
weather forecasting or reanalysis systems (including global and regional systems), which
should be an excellent source of independent observations (Huang et al., 2021). The
radiosonde observational station (marked with a black star in Fig. 10b) is located at (83.63°E,
275 39.04°N), 1,099.3 m above the sea level. The radiosonde observational data were collected
four times at 0000, 0600, 1200, and 1800 local standard time (LST, = UTC + 6) a day in July
2016, using the Global Positioning System (GPS)-based radiosonde. One of the advantages of
the radiosonde observation is its high vertical resolution, which is achieved by high frequency
(at intervals of one second) data acquisition during balloon ascending.

280 To assess the new EARS data, we compare them with surface and radiosonde
observations in terms of root mean square error (RMSE), given by

$$RMSE = \sqrt{\frac{1}{N} \sum_{i=1}^N (F_i - O_i)^2}, \quad (1)$$

where N is the total number of all observations; F_i and O_i denote reanalysis data and
observation, respectively.

285 We use RMSE(EARS) and RMSE(ERA-I) to represent the RMSEs for the regional
EARS and global ERA-Interim, respectively. The fractional percentage improvement (I) of
the RMSE can be defined as follows:

$$I(\%) = \frac{RMSE(ERA-I) - RMSE(EARS)}{RMSE(ERA-I)} \times 100\%. \quad (2)$$

Accuracy is perhaps the most widely used objective validation method for quantitative
290 precipitation forecasts. Following the MET verification measures for categorical
(dichotomous) variables, we employ a table of 2×2 contingency (Table 2). The accuracy of
precipitation forecast is defined by

$$Accuracy = \frac{hits + correct\ negatives}{total}. \quad (3)$$

The accuracy ranges from 0 to 1, and a perfect forecast would have an accuracy of 1.

295

Table 2. Contingency table for categorical (dichotomous) variables.

		observation		
		yes	no	total
reanalysis	yes	hits	false alarms	forecast yes
	no	misses	correct negatives	forecast no
	total	observed yes	observed no	total

3. Results

3.1 Performance of Surface Field

Figure 11 compares 10-year-averaged RMSEs of surface variables from the EARS and
 300 ERA-Interim using box-percentile plots. For the EARS, the averaged RMSEs of surface
 pressure (P), temperature (T), specific humidity (Q), zonal wind (U), meridional wind (V),
 and wind speed (WS) are $14.11(\pm 19.22)$ hPa, $2.05(\pm 1.43)^\circ\text{C}$, $1.18(\pm 0.28)$ g kg⁻¹, $1.76(\pm 0.69)$
 m s⁻¹, $1.95(\pm 0.63)$ m s⁻¹, and $2.06(\pm 0.58)$ m s⁻¹, respectively. The ERA-Interim has larger
 averaged RMSEs of P , T , Q , U , V , and WS , which are $24.34(\pm 27.17)$ hPa, $2.25(\pm 1.43)^\circ\text{C}$,
 305 $1.33(\pm 0.35)$ g kg⁻¹, $1.98(\pm 0.58)$ m s⁻¹, $2.35(\pm 0.70)$ m s⁻¹, and $2.42(\pm 0.51)$ m s⁻¹, respectively.
 In terms of RMSE, the EARS performs much better, with respective improvement
 percentages of 42.01%, 8.82%, 11.28%, 11.37%, 16.96%, and 14.75% for P , T , Q , U , V , and
 WS , respectively. Generally speaking, P has the largest improvement, followed by V , U , and
 Q ; and T has the smallest improvement. Similarly, the 25th, 50th, and 75th percentiles show
 310 obvious improvements.

In terms of RMSE, we have noted that the EARS shows an obvious improvement in the

surface meteorological fields over East Asia, compared to it's the ERA-Interim (Fig. 11). According to the statistical results, P has the largest improvement percentage of the RMSE, followed by V ; and T has the smallest improvement. The smaller RMSE is mainly attributable to the data assimilation of a large number of observations. Note that the optimized WRF model, focusing on East Asia with a high horizontal resolution of 12 km and 74 sigma levels in the vertical, is also beneficial to the smaller RMSE. As has been stated above, the WRF model was tested and verified in various aspects by paying attention to dynamic and physical options, and to observation nudging parameters (Yin et al., 2018). According to our previous tests with the optimized WRF model, the downscaling results performed better than the ERA-Interim, which provides good background conditions for the GSI data assimilation and the subsequent reanalysis data. Previous studies (e.g., Andrys et al., 2015; Gao et al., 2022; Qiu et al., 2017) also indicated that WRF downscaling at a high resolution has significant performance gains in downscaling.

Figure 12 shows spatial distributions of the averaged RMSEs of P for the EARS and ERA-I, and for their differences. Clearly, the spatial distribution for the EARS is similar to that of the ERA-Interim. Given the spatial distribution, there is a smaller RMSE over eastern China, which is beneficial from the ingestion of dense surface observations. Note that the higher resolution of the complex terrain over western China has positive contributions to the model results, except for limited observations over this region. More specifically, both EARS and ERA-Interim show large RMSEs over western China, especially along the east side of the Qinghai-Tibet Plateau. The spatial distributions for other surface variables are also generated, although there are not presented here. Please refer to the supplementary for more results. In general, the EARS has similar improvements to P in T . Concerning Q , both EARS and ERA-Interim have obvious RMSEs over southern China, which may be related to a large amount of available water vapor in this region. The EARS shows a similar spatial distribution

of RMSE of U to that of the ERA-Interim, while obvious differences can be found in the RMSE of V . A large RMSE belt of U is in the northeast toward the Tibet Plateau. The EARS reduces RMSE in V significantly, indicating that the quality of V is improved considerably.

340 The EARS alleviates the RMSE over values 2.5 m s^{-1} at most stations. Note that the EARS has larger RMSEs in the wind field (both U and V) over western China than the ERA-Interim. This may be related to complicated dynamics associated with the Tibet Plateau, land processes, or/and poor quality of observations over this region; and attention is required to understand the shortcoming. For WS , the improvement shows a similar pattern to that in V . In

345 terms of RMSE, the EARS performs better than the ERA-Interim at most stations, although the EARS has poor quality at some stations.

3.2 Upper-Level Fields

Figure 13 shows the mean RMSEs of vertical profiles of U , V , T , and Q , verified against 120 radiosonde observations over China during 2008-2017 (Fig. 10b). Generally speaking, the

350 EARS shows much smaller RMSEs than the ERA-Interim at all levels, although both show similar vertical distributions. The RMSEs for the ERA-Interim are nearly twice as large as those of the EARS, except for the RMSEs of Q at the upper levels. More specifically, the RMSEs of U and V for the EARS are nearly 1 m s^{-1} throughout the vertical column, while those of the ERA-Interim are mostly larger than 2 m s^{-1} . Also, the RMSEs of U and V for the

355 EARS show slight variation in vertical, while the RMSEs of ERA-Interim are large at the lower and upper levels and small at the middle levels. As for the RMSEs of T , the RMSEs of the EARS are within 0.9°C ; and the RMSEs of the ERA-Interim are less than 1.5°C . Both reanalysis products show large RMSEs at the lower level near the ground; and the RMSEs for T decrease first with increasing height, bottomed out near 400 hPa. The second-largest

360 RMSEs for T occur at the higher level of 100 hPa. The large RMSEs for T at the upper levels mainly result from limited radiosonde observations. Besides, the interactions between the

365 troposphere and stratosphere may have some impact on the accuracy of the reanalysis products. The RMSEs for Q decrease rapidly with increasing height and approach zero near 200 hPa, which corresponds to the decrease of moisture content from the bottom to up. It should be pointed out that the small RMSEs at the upper levels result from a very low value of Q , rather than from having a good performance at these levels. In view of the vertical profiles of the EARS verifying against radiosonde observations given in Fig. 13, the EARS is considerably better than the ERA-Interim. The RMSEs for EARS are almost half as small as that of the ERA-Interim. The RMSEs of U , V , and T for the EARS are considerably smaller
370 than those of the ERA-Interim. At upper levels above 500 hPa, the RMSEs of Q for both EARS and ERA-Interim are similar in magnitude, while the former shows a smaller value than the latter. As stated in Mesinger et al. (2006), the reanalysis data are influenced by both the estimate of the background and observation error covariances.

3.3 Rainfall

375 Despite several objective verification methods for modeling quantitative rainfall amounts, systematic assessment of simulated rainfall performance remains difficult. Consequently, a simple comparison between the EARS and ERA-Interim is given here in terms of the accuracy of 3-h accumulated rainfall. Please refers to Yang et al. (2023) for detailed analyses of the simulated rainfall properties of the EARS. Figure 14 shows the accuracy of 3-h rainfall
380 for both EARS and ERA-Interim. Although the accuracy shows slight diurnal variation, both EARS and ERA-Interim have high averaged accuracies of over 0.5 and show good performances from early morning (2100 UTC) to the midday on next day (0300 UTC). The EARS has higher rainfall accuracy than the ERA-Interim at all times. For an overview (i.e., mean), the EARS provides a higher total mean accuracy of 0.61, with 0.56 for the
385 ERA-Interim. Note that the improvements vary from 4.53% to 16.18%, with the averaged improvement percentage of the accuracy being 8.99%. We also calculated the equitable threat

score for 3-h accumulated rainfall (not shown). For rainfalls above 20.0 mm, the EARS is much better than the ERA-Interim, indicating that the EARS has better capability to reproduce heavy rainfall over East Asia, especially for 3-h accumulated rainfall that is over 50
390 mm. Note that the ERA-Interim cannot capture 3-h accumulated rainfall that is over 70 mm, which may be caused by the global model's low resolution of nearly 79 km.

Figure 15 shows the spatial distribution of averaged 3-h accumulated rainfall accuracy for the EARS and ERA-Interim in 2008-2017. Clearly, both EARS and ERA-Interim have high forecast capability for precipitation over central China with rainfall accuracy of over 0.6,
395 followed by southern and eastern China (Figs. 15a, b). The low accuracy (less than 0.4) mainly appears in western China, especially over the Qinghai-Tibet Plateau. The results are consistent with previous studies and with operational predictions. In general, the EARS has better performance on the 3-h scale at most stations than the ERA-Interim (Fig. 15c), although the EARS has less accuracy at some stations. The EARS with more local observations is
400 probably the main reason for its better performance; and the benefit of the optimized WRF model with the high resolution of 12 km may be another reason. The results indicate that the EARS would be more suitable for investigating precipitation over East Asia.

3.4 Features in Lower Levels over Central Taklimakan Desert

Figure 16 shows the diurnal variation of observed and simulated vertical thermal
405 structures in the lower levels (0.6 km above the ground). From the observations, obvious transitions exist in the thermal structure. More specifically, there is an inversion layer near the surface in the nighttime, while a sub-adiabatic or superadiabatic layer occurs in the daytime. The transition, from stable to convective and back to stable condition, is consistent with the diurnal variation of solar radiation (Yin et al., 2021). In general, both the EARS and
410 ERA-Interim are able to reproduce similar diurnal transitions as in the observations. Although there are some differences between the reanalysis products and observations, the transitions,

from stable to convective and back to stable condition, are consistent with the observations. Specifically, the EARS is closer to the observations, compared to the EAR-Interim. For instance, the EARS captures the obvious inversion at 0600 local standard time (LST), while
415 the ERA-Interim underestimates the inversion.

Figure 17 compares the averaged profiles of observed horizontal wind and those of the reanalysis products. An obvious directional shift from northeasterly to westerly appears nearly 2.6 km above the ground on average. In fact, the altitude of the wind directional shift exhibits noticeable diurnal fluctuation, bottomed out at 0600 LST and peaked at 1800 LST with
420 altitudes near 2.0 and 3.4 km, respectively. Note that the horizontal wind speed decreases and then increases with increasing height due to vertical wind shear. Compared to the observations, both EARS and ERA-Interim capture the principal vertical wind profile patterns over the central Taklimakan Desert. However, the diurnal variation of wind profiles is slightly underestimated by the EARS, while the ERA-Interim completely misses the diurnal
425 fluctuation. Besides, the ERA-Interim underestimates wind speed near the surface; it seems that the ERA-Interim reanalysis system cannot well describe the near-surface thermodynamic processes.

4. Conclusions and future outlook

We present a detailed report about the EARS, including 39-year (1980-2018)
430 high-resolution regional reanalysis datasets over East Asia that show major improvements over the global reanalysis in both spatial resolution and accuracy. The qualities of the reanalysis dataset were verified based on surface observations and radiosonde observations from 2008 to 2017, as well as radiosonde observations from field experiments in July 2016. Regarding resolution, the 12-km grid is much higher than those of global models. For
435 accuracy, both near-surface and upper-level fields are closer to the observations than the global reanalysis ERA-Interim.

The EARS is established based on the WRF-ARW model and GSI data assimilation system. To improve the EARS's performance in East Asia, a series of experiments have been conducted for selecting dynamic and physical options. For the GSI, much attention was paid
440 to the improvements of assimilating each category of observations. The EARS started cold runs every day, starting at 0000, 0600, 1200, and 1800 UTC with the ERA-Interim 0.79-degree analysis data at 6-h intervals as initial and boundary conditions. The WRF model was integrated for 12-h each time with hourly outputs; and hourly surface observations were ingested by performing surface observation nudging. The model outputs at the ninth and
445 twelfth hours are used as the first guess of the GSI, and the upper-level observations were assimilated in a 3D-VAR mode and mosaic radar reflectivities were ingested by cloud analysis. To the present, 39-year (1980-2018) reanalysis data have been achieved.

To assess the EARS data, 10-year (2008-2017) data were compared with surface and radiosonde observations in terms of RMSE. The results show substantial improvements in the
450 EARS, compared to the ERA-Interim reanalysis over East Asia. The better performance of the EARS is mainly attributable to the data assimilation of a large number of observations. In addition, the optimized WRF model, focusing on East Asia with a high resolution of 12 km and 74 sigma levels, is also beneficial to the high quality of the EARS. It should be noted that the present validation is based on the observations from CMA. Although the EARS covers a
455 large area, only limited observations were obtained by the Global Communication System (GTS). We welcome more validation from others with observations outside of China as much as possible.

In the future, we will further inspect the regional high-resolution data against the observations from the Second Tibetan Plateau Scientific Expedition and Research (STEP)
460 program, in particular using it in high-resolution studies over the East Asian monsoon region. Besides, radar retrieval horizontal wind, which is retrieved by an improved version of the

Integrating Velocity-Azimuth Process (IVAP) method (Liang et al., 2019), will be ingested by performing upper-level observation nudging. Most importantly, from 2019 onward, we will shift to using the ERA5 products as initial and boundary conditions for the WRF model.

465 Besides, the intensive surface observations (exceeding 80,000) over China after strict quality control will be introduced in the surface observation nudging. The EARS will run in real-time operation mode to provide the latest reanalysis data with approximately a 5-day lag (depending on the availability of the ERA5 data).

470 **Appendix A: Abbreviations**

Table A1 List of abbreviations used in the paper.

Abbr.	Term
3D-VAR	Three-dimensional variational data assimilation
AMDAR	Aircraft Meteorological Data Relay
ASR	Arctic System Reanalysis
BARRA-R	Bureau of Meteorology Atmospheric high-resolution Regional Reanalysis for Australia
CMA	China Meteorological Administration
CFSR	Climate Forecast System Reanalysis
CORDEX	Coordinated Regional Downscaling Experiment
CRA40	China's first generation of global atmospheric reanalysis
EARS	East Asia Reanalysis System
ECMWF	European Centre of Medium-Range Weather Forecasts
ERA5	ECMWF fifth generation of its atmospheric reanalysis
ERA-Interim	ECMWF ERA-Interim reanalysis
FDDA	Four-Dimension Data Assimilation
GDAS	Global Data Assimilation System
GSI	Gridpoint Statistical Interpolations
GTS	Global Communication System
ICOADS	International Comprehensive Ocean-Atmosphere Data Set
IGMOAA	Integrated Global Meteorological Observation Archive from Aircraft
IGRA	Integrated Global Radiosonde Archive
IMDAA	Indian Monsoon Data Assimilation and Analysis
ISD	Integrated Surface Database
JRA55	Japanese 55-year Reanalysis
MERRA2	Modern-Era Retrospective Analysis for Research and Applications version 2
MET	Model Evaluation Tools
NARR	North American Regional Reanalysis
NCAR	National Center for Atmospheric Research
NCDC	National Climatic Data Center

NCEP	National Centers for Environmental Prediction
NCEP2	National Centers for Environmental Prediction-Department of Energy Reanalysis version 2
NHM-LETKF	high-resolution regional reanalysis of Japan
NMIC	National Meteorological Information Center (NMIC) of CMA
RMSE	Root mean square error
WMO	World Meteorological Organization
WRF	Weather Research and Forecasting
WRFDA	WRF Variational Data Assimilation

Data Availability

A Digital Object Unique Identifier (DOI: <https://doi.org/10.5281/zenodo.7404918>) is
475 available for the EARS reanalysis data. The 39-year EARS data reported in this work are
available at 3-h intervals, starting at 00 UTC from 1980 to 2018. The database format is GRIB
version 1 and the total volume of the data files is 54.6 TB. The GRIB files are hosted at the
CMA Data-as-a-Service platform (<http://data.cma.cn/>) as their total volume exceeds the
volume that could be provided by Zenodo (Yin et al., 2022). Simple data and updated
480 information are available on Zenodo at <https://doi.org/10.5281/zenodo.7404918> (Yin et al.,
2022), and the full datasets are publicly accessible on the Data-as-a-Service platform of China
Meteorological Administration (CMA) at <http://data.cma.cn>. The data can be obtained in the
form of a hard disk copy by contacting the authors at present, and will be accessed freely at
this location soon. The EARS 3-h data on pressure levels and hourly precipitation data are
485 available in GRIB format, which can be used as a model (e.g., the WRF) forcings. Owing to
the large amounts of data, more variables, and datasets on the 74 model (sigma) levels can
also be obtained by contacting the authors.

Author contributions. X. Liang proposed the main scientific ideas and contributed to radar
490 data processing. J. Yin contributed supplementary ideas and produced the 39-year regional
reanalysis and validation. F. Chen and J. Yin developed the reanalysis system, J. Yin, X. Liang,

and Y. Xie analyzed the simulations and wrote the manuscript. K. Hu, L. Cao, and F. Li contributed to the preparation of observational datasets and reanalysis management. H. Zou completed the composite radar reflectivity for complex cloud analysis. G. Wang and Y. Zhao
495 launched the simulations for WRF model optimization. J. Liu and J. Xu conducted data assimilation experiments. F. Zhu and X. Sun prepared the programs for validation.

Competing interests. The authors declare that they have no competing interests.

500 **Acknowledgments.** This work was conducted by using the PI-Dawning supercomputer system provided by the China Meteorological Administration (CMA). The authors are grateful to the European Centre of Medium-Range Weather Forecasts (ECMWF) for providing the global reanalysis EAR-Interim data (<https://www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/era-interim>). We thank Dr.
505 Zhiqian Liu at the National Center for Atmospheric Research (NCAR) and Prof. Zijiang Zhou at the National Meteorological Information Center (NMIC) of CMA for their helpful discussions. All the figures are generated by NCAR Command Language (NCL), which is available at <http://dx.doi.org/10.5065/D6WD3XH5> (last accessed on 20 September 2022).

510 **Financial support.** This study is jointly supported by the National Key Research and Development Program of China (2017YFC1501800), Second Tibetan Plateau Scientific Expedition and Research (STEP) Program (2019QZKK010402), National Natural Science Foundation of China (42075083 and 42192554), and National Department Public Benefit Research Foundation (GYHY201506002).

Figures

740

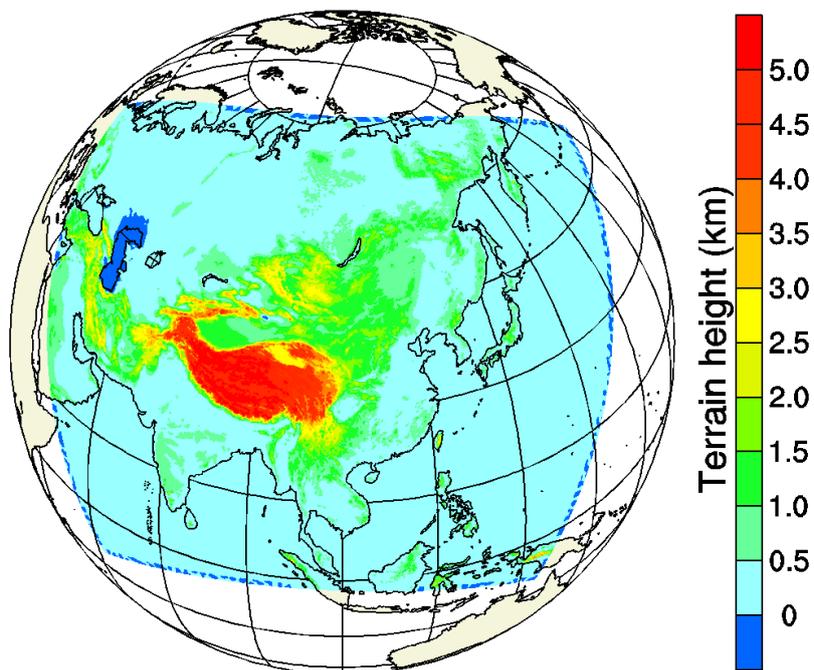

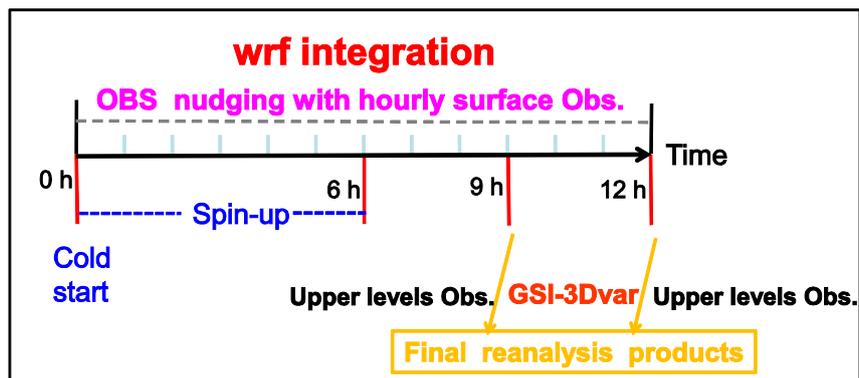

Fig. 1 The East Asia Reanalysis System (EARS) domain in the WRF model, and its 12-km topography. The shading indicates the height of the terrain in the model.

745 **Fig. 2** Schematic illustrating the flow chart of analysis steps of the EARS. See text for details.

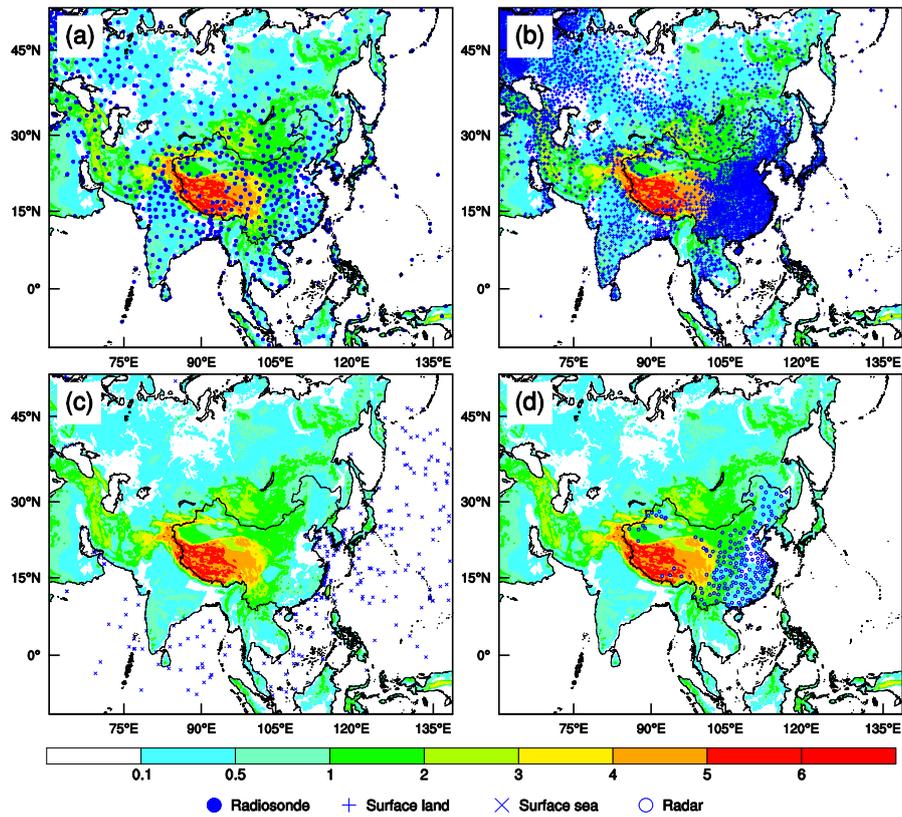

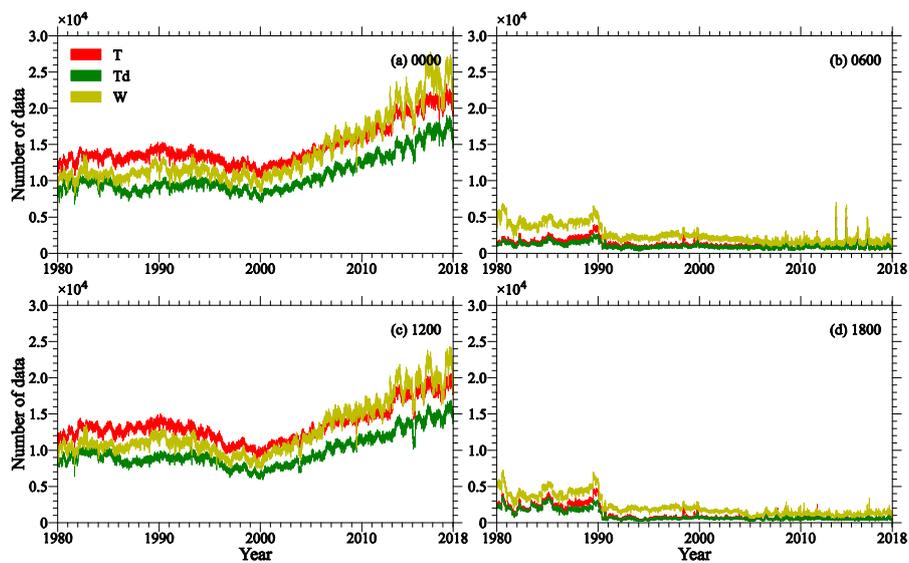

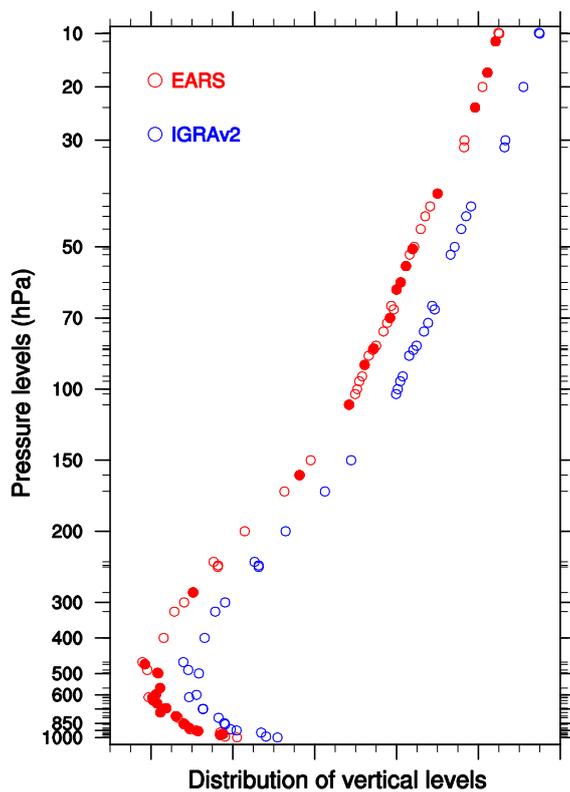

Fig. 3 Spatial distributions of (a) radiosonde, (b) land, (c) sea, and (d) radar observations for EARS.

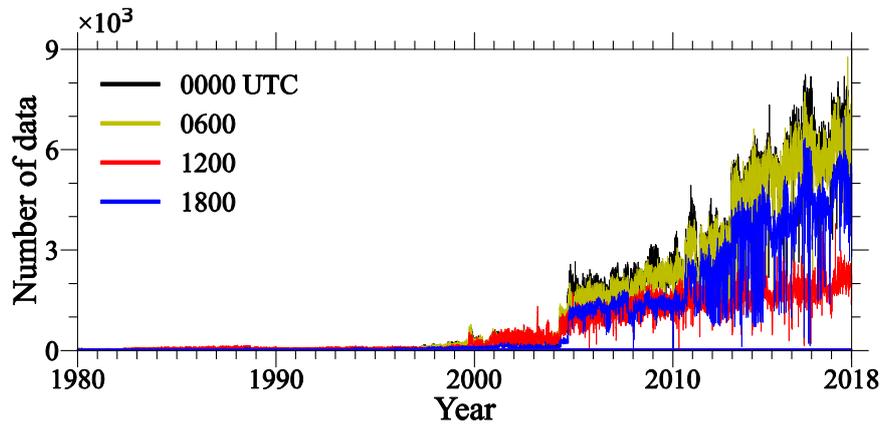

750

Fig. 4 Counts of radiosonde observations assimilated in EARS at (a) 0000, (b) 0600, (c) 1200, and (d) 1800 UTC. T , T_d , and W denote temperature, dew-temperature, and horizontal wind, respectively.

755 **Fig. 5** Comparison of merged radiosonde (red) used in EARS and the Integrated Global Radiosonde Archive version 2 (IGRAv2, blue) at Beijing station (54511) at 0000 UTC 1 July 2016 at Beijing station (54511). The red dots represent the newly-merged from paper-based records that have never been used in any atmospheric reanalysis system outside of China.

760

Fig. 6 Counts of aircraft observations used in EARS at 0000, 0600, 1200, and 1800 UTC.

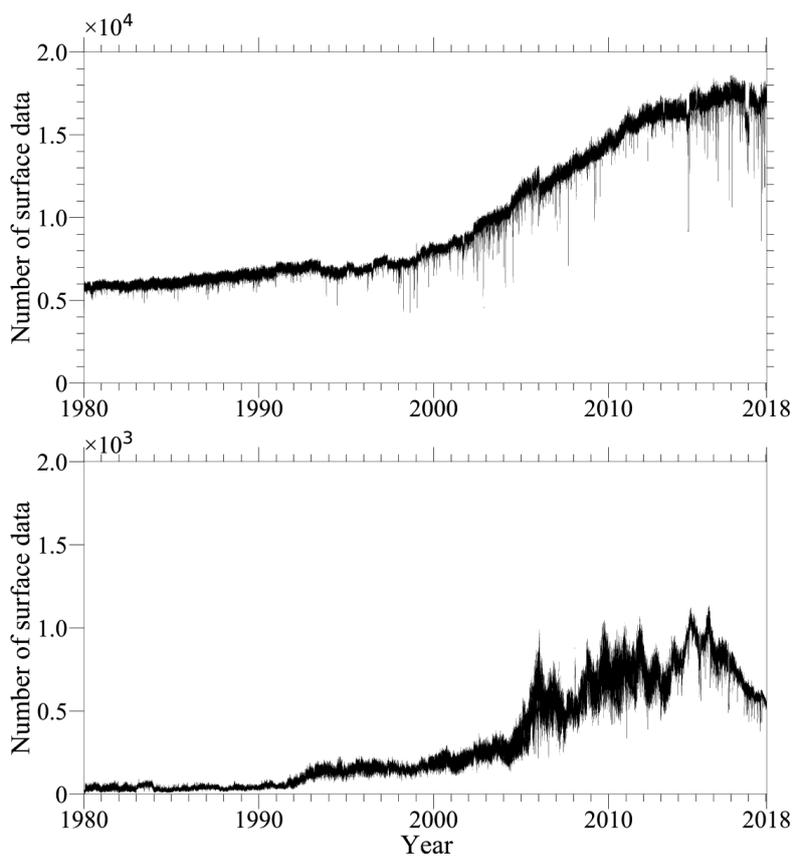

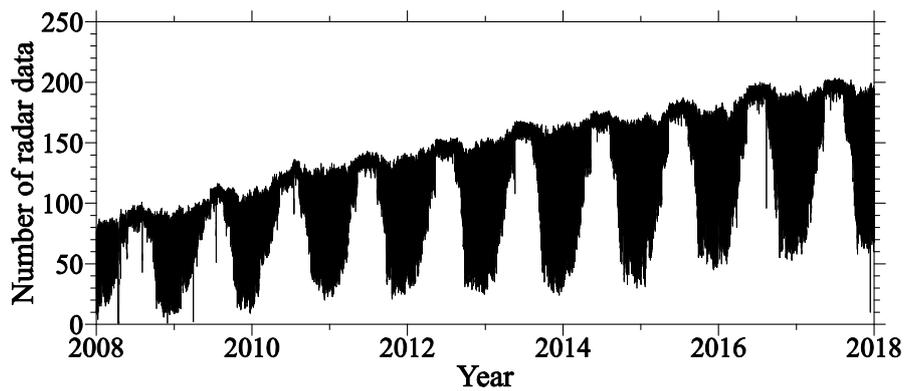

Fig. 7 Counts of the surface observations over (a) land and (b) sea used in EARS.

765

Fig. 8 Counts of the ground-based radar stations used in EARS.

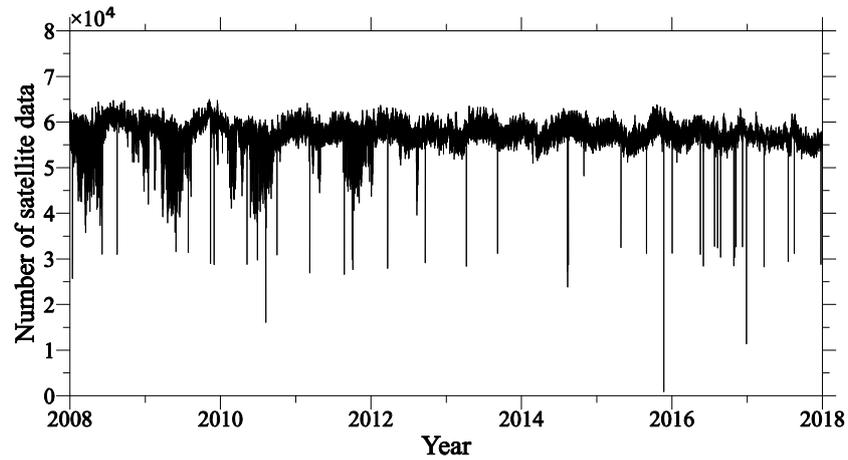

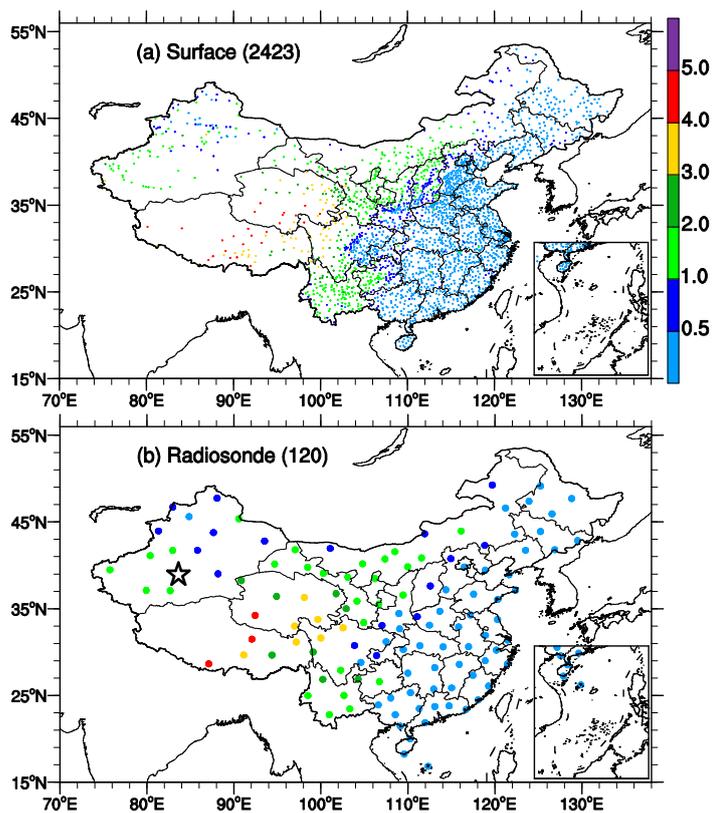

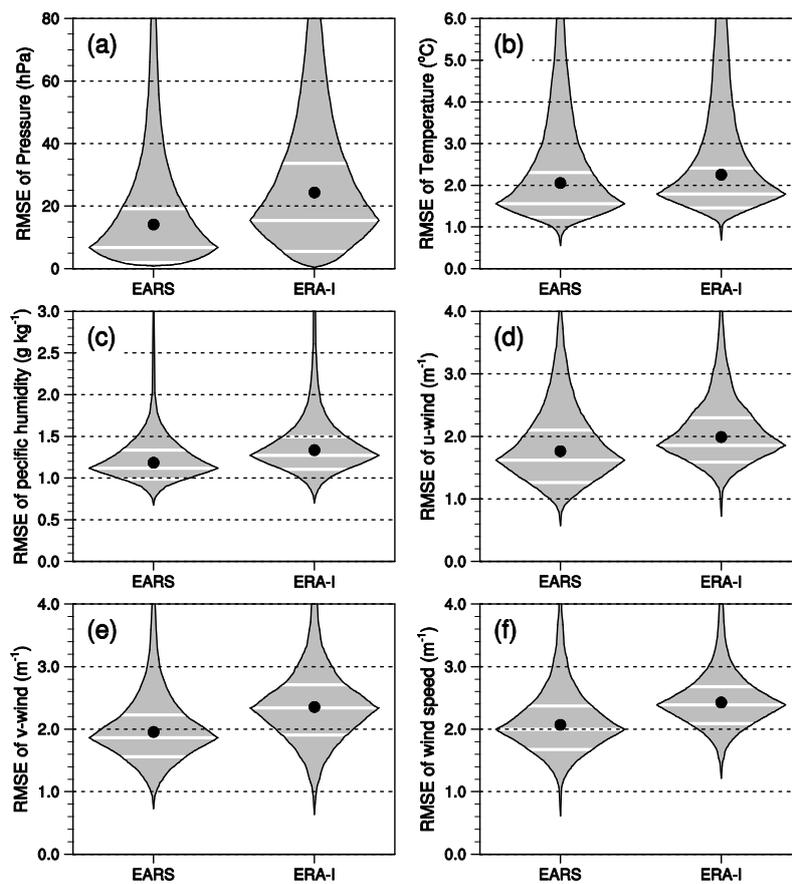

Fig. 9 Counts of cloud-derived wind vectors from the Fengyun-2 (FY-2) geostationary meteorological satellite observations, which are used in the EARS.

770

Fig. 10 Spatial distributions of selected (a) surface and (b) radiosonde stations for verification. The number in parenthesis is the observational count. The color of the dot indicates terrain (km). In (b), the star denotes the location of a radiosonde observational field experiment at the central Taklimakan Desert, China.

775

Fig. 11 Comparison of averaged root mean square error (RMSE) between EARS and ERA-Interim in terms of surface meteorological variables: (a) pressure (P ; hPa), (b) temperature (T ; °C), (c) specific humidity (Q ; g kg⁻¹), (d) zonal wind (U ; m s⁻¹), (e) meridional wind (V ; m s⁻¹), and (f) wind speed (WS ; m s⁻¹). The black dot denotes the averaged value of each category; and the horizontal white lines indicate the 25th, 50th (median), and 75th percentiles. See text for details.

780

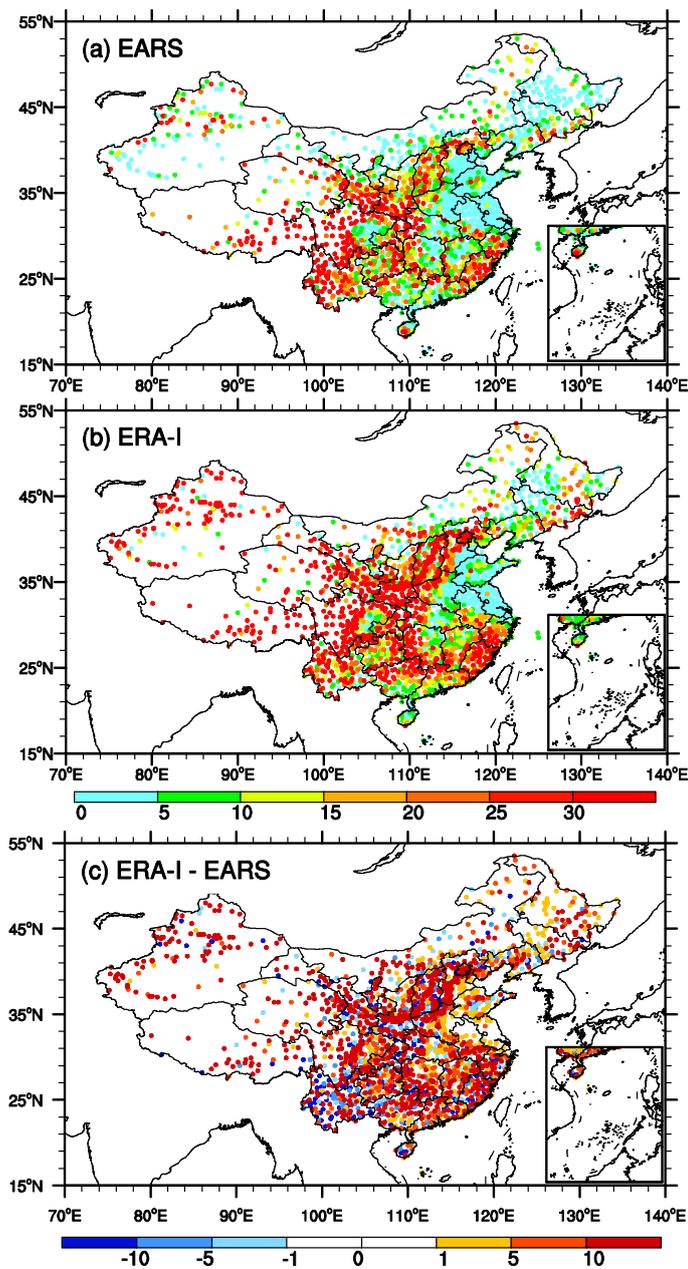

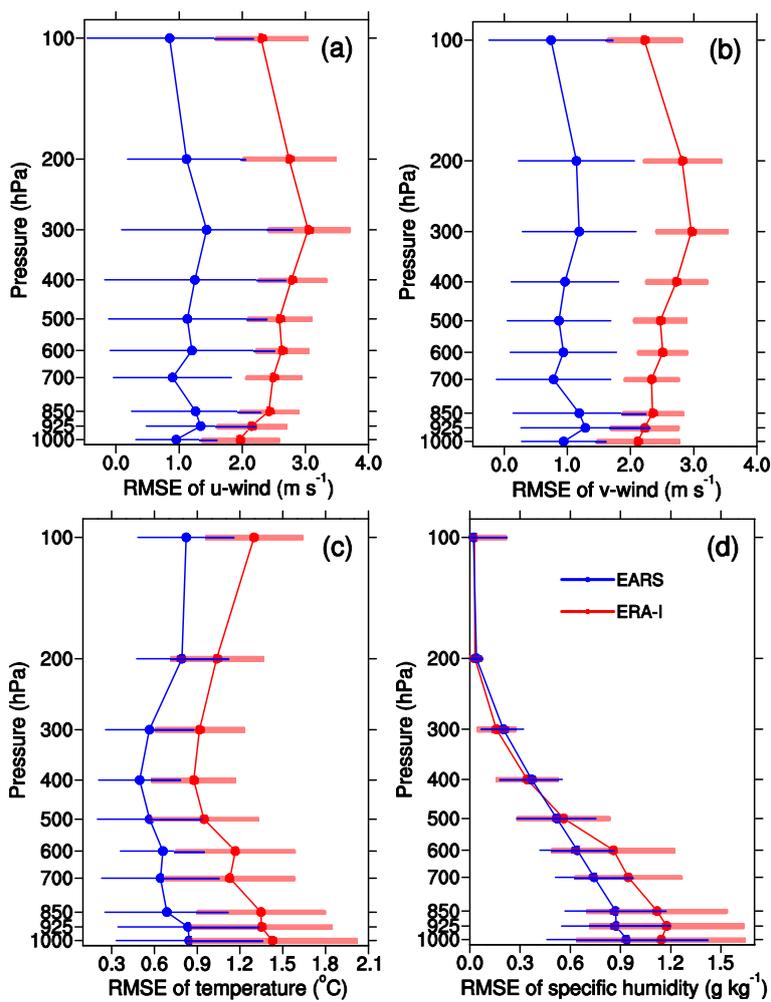

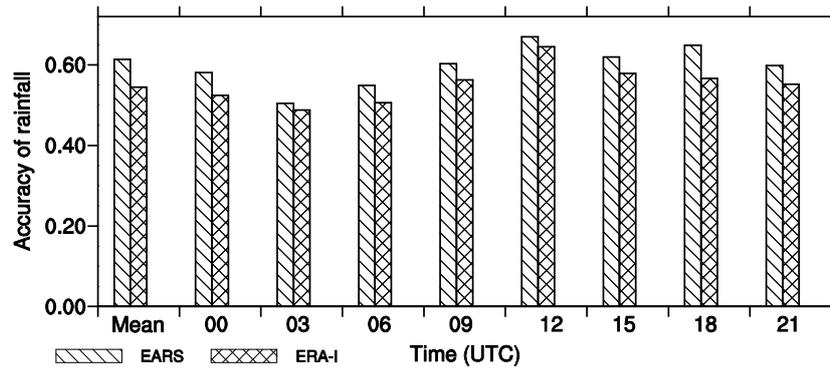

Fig. 12 Spatial distributions of averaged RMSE of surface pressure (P ; hPa) from (a) EARS and (b) ERA-Interim; and (c) their differences (ERA-I minus EARS).

785

Fig. 13 Comparison of averaged RMSEs of EARS and ERA-Interim at different levels for (a) u-wind (U ; m s^{-1}), (b) v-wind (V ; m s^{-1}), (c) temperature (T ; $^{\circ}\text{C}$), and (d) specific humidity (Q ; g kg^{-1}). Standard deviation of RMSE at each level is marked.

790 **Fig. 14** Comparison of the accuracy of 3-h accumulated rainfall between EARS and ERA-Interim in different episodes. Mean denotes the averaged value for all times.

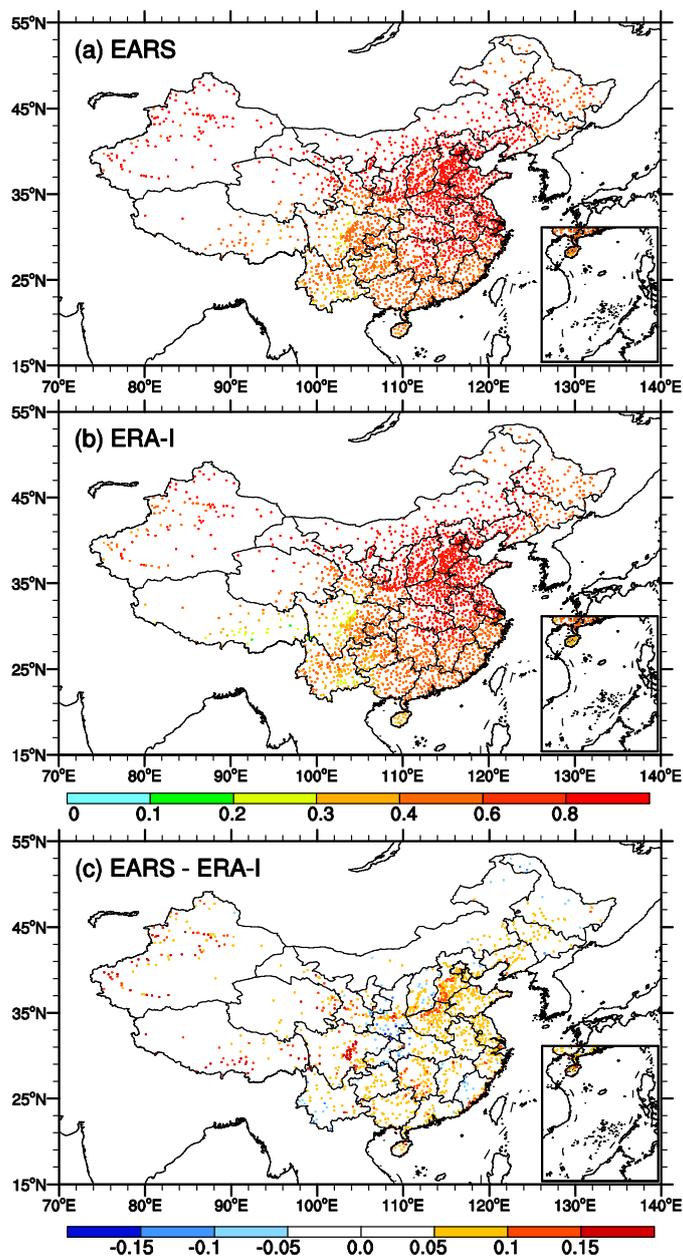

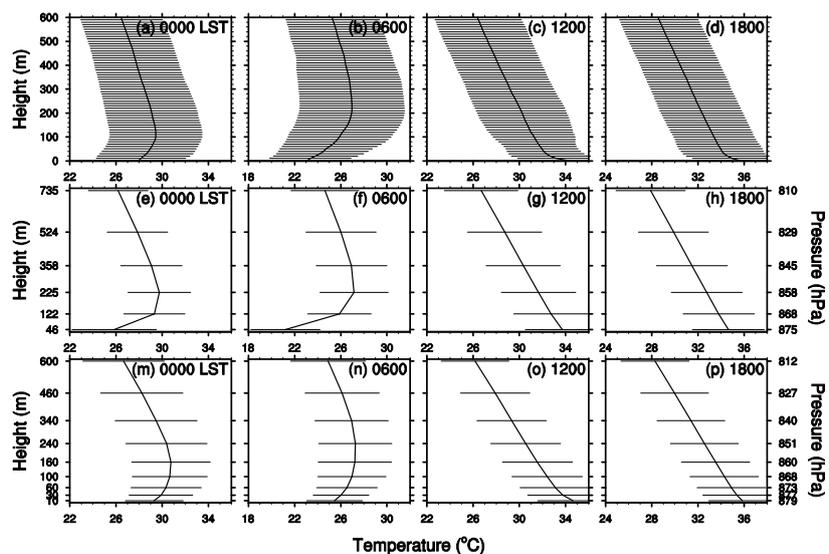

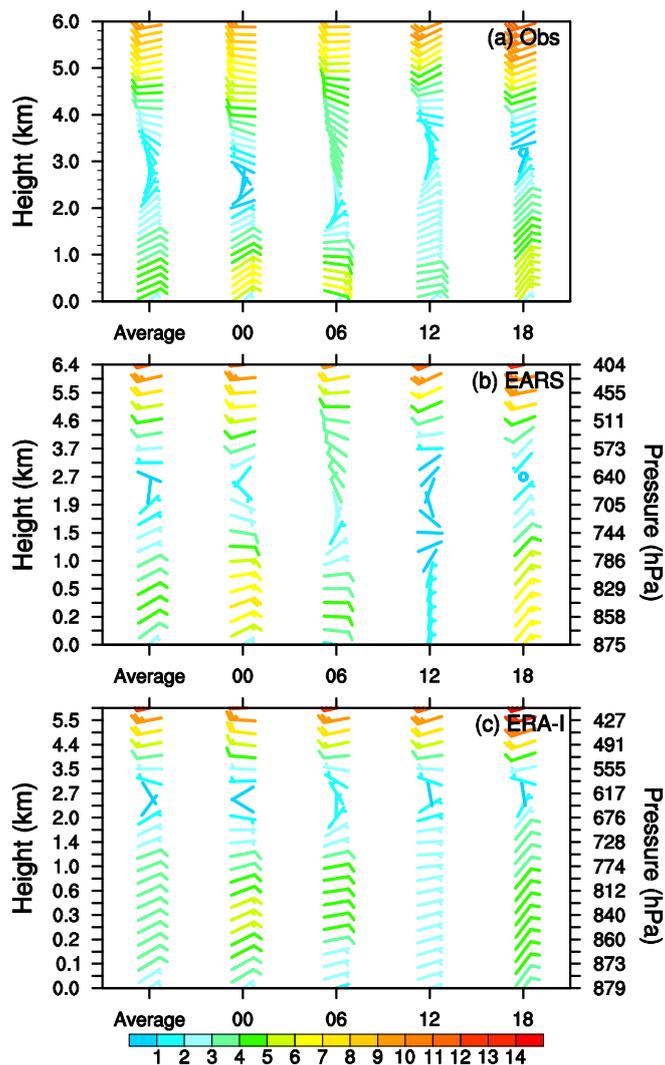

Fig. 15 Spatial distributions of averaged rainfall accuracy of (a) EARS, (b) ERA-Interim, and their difference (EARS minus ERA-I).

795

Fig. 16 Diurnal transitions of the averaged temperature ($^{\circ}\text{C}$) in lower levels from 0000 to 1800 local standard time (LST, = UTC + 6) in July 2016: (a) Observations (Obs), (b) EARS, and (c) EAR-I. Standard deviation at each level is marked.

800 **Fig. 17** Profiles of monthly-averaged horizontal wind barbs in July 2016: (a) observations (Obs), (b) EARS, and (c) ERA-I. A full wind barb denotes 4 m s^{-1} ; and the shading indicates horizontal wind speed (m s^{-1}). Average denotes the total average of all times. Each column corresponds to the average profiles at 0000, 0600, 1200, and 1800 LST.
