### Abstract

Satellite altimetry data are useful for monitoring water surface dynamics, evaluating and calibrating hydrodynamic models, and enhancing river-related variables through optimization or assimilation approaches. However, comparing simulated water surface elevations (WSEs) using satellite altimetry data is challenging due to the difficulty of correctly matching the representative locations of satellite altimetry virtual stations (VSs) to the discrete river grids used in hydrodynamic models. In this study, we introduce an automated altimetry mapping procedure (AltiMaP) that allocates VS locations listed in the HydroWeb database to the Multi-Error Removed Improved Terrain Hydrography (MERIT Hydro) river network. Each VS was flagged according to the land cover of the initial pixel allocation, with 10, 20, 30, and 40 representing river channel, land with the nearest single-channel river, land with the nearest multi-channel river, and ocean pixels, respectively. Then, each VS was assigned to the nearest MERIT Hydro river reach according to geometric distance. Among the approximately 12,000 allocated VSs, most were categorized as flag 10 (71.7%). Flags 10 and 20 were mainly located in upstream and midstream reaches, whereas flags 30 and 40 were mainly located downstream. Approximately 0.8% of VSs showed bias, with considerable elevation differences ( $\geq |15|$ m) between the mean observed WSE and MERIT digital elevation model. These biased VSs were predominantly observed in narrow rivers at high altitudes. Following VS allocation using AltiMaP, the median root mean squared error of simulated WSEs compared to satellite altimetry was 7.86 m. The error rate was much lower (10.6%) than that obtained using a traditional approach, partly due to bias reduction. Thus, allocating VSs to a river network using the proposed AltiMaP framework improved our comparison of WSEs simulated by the global hydrodynamic model to those obtained by satellite altimetry. The AltiMaP source code (<https://doi.org/10.5281/zenodo.7597310>) (Revel et al., 2023a) and data (<https://doi.org/10.4211/hs.632e550deaea46b080bdae986fd19156>) (Revel et al., 2022) are freely accessible online and we anticipate that they will be beneficial to the international hydrological community.

### 1 Introduction

Limited freshwater resources could impede the daily demands of future generations. Monitoring freshwater resources is critical for determining the availability of water for human use. Although continental surface water dynamics can be explored through global-scale hydrodynamic modeling, the effective modeling of freshwater dynamics requires calibration using observed variables such as water surface elevation (WSE), river discharge, and water surface area. Thus, inadequacies of monitoring stream gauges can hinder the performance of hydrodynamic models and fail to accurately represent surface water dynamics (Hannah et al., 2011), such that model evaluation and calibration must depend on remotely sensed data (Meyer Oliveira et al., 2021; Modi et al., 2022; Zhou et al., 2022). Therefore, recent advances in satellite technology have considerably improved our understanding of surface water dynamics.

During the past 30 years, satellite altimetry has provided direct terrestrial water measurements with reasonable accuracy (Papa et al., 2022). Satellite altimeters determine WSEs by considering differences in the travel time of radar or lasers between the satellite and the water surface. Differences between satellite orbit and altimetry range measurements are used to determine the height of the water surface following troposphere, wet troposphere, ionospheric, and/or solid tide correction (Calmant et al., 2008). Several radar altimetry missions have been employed to observe lakes and large rivers, including Topography Experiment (TOPEX)/Poseidon; European Remote Sensing (ERS)-1 and -2; Joint Altimetry Satellite Oceanography Network (Jason)-1, -2, and -3; GEOSTAT Follow On (GFO); Environmental Satellite (ENVISAT); Satellite with ARGOS and ALTIKA (SARAL)-AltiKa; Sentinel-3A, -3B, and -6MF (Calmant et al., 2008; Crétaux et al., 2009, 2011; Santos da Silva et al., 2010; Yang et al., 2022). An updated list of orbit characteristics including temporal resolution, inter-track distance, and frequency for satellite missions that have collected WSE observations is provided in Table 1. In particular, satellite temporal resolution and inter-track distance govern the temporal and spatial resolution of altimetry data and therefore are critical parameters for data analysis.

Any intersection of a satellite track with a water body is considered a virtual station (VS). The allocation of VSs permits a satellite to retrieve successive water levels at each pass (Santos da Silva et al., 2010). The river width and shape, surrounding topography, and land cover are important factors influencing successful water level retrievals, although no single factor is solely predictive of water level accuracy (Maillard et al., 2015). As a result, radar altimetry retrievals of river surface height depend on the high dielectric constant of water, which causes rivers to reflect more radar radiation than land. It is also challenging to identify exact VS locations due to satellite orbit drift. Therefore, the location of a VS is frequently recorded as the center point of the search area for water level retrieval (Coss et al., 2020; Santos da Silva et al., 2010). To facilitate comparative analyses between satellite observations and numerical simulations, caution must be exercised when transforming the latitude and longitude coordinates of VSs to the river network of the hydrodynamic model.

Satellite altimetry observations have been applied in several large-scale studies to monitor natural water resources in rivers and lakes (e.g., Asadzadeh Jarihani et al., 2013; Birkett et al., 2002; Calmant and Seyler, 2006; Dettmering et al., 2020; Schneider et al., 2017; Xiang et al., 2021), calibrate or validate hydrological/hydrodynamic models (e.g., Elmer et al., 2021; Jiang et al., 2019, 2021; Kittel et al., 2021; Meyer Oliveira et al., 2021; Zhou et al., 2022), and for assimilation into hydrological/hydrodynamic models (e.g., Brêda et al., 2019; Michailovsky et al., 2013; Paiva et al., 2013; Revel et al., 2023b). However, incorrect VS allocation can lead to the degradation of post-calibration model performance. Thus, the accurate identification of appropriate VS locations within the relevant river reach in the model space is crucial for the comparison of simulation and observation data, as well as for the effective utilization of satellite altimetry in model calibration and validation.

Large-scale hydrodynamic models typically simulate the water dynamics of discretized river segments (i.e., river grids). The slopes of natural rivers are continuous, whereas elevations are discontinuous among river grids; thus, the digitized VSs can be located between river grids. Physically based hydrodynamic models simulate WSEs with respect to a representative elevation within the river grid which were upscaled from high-resolution hydrography data (i.e., the lowest elevation of high-resolution pixels within the river grid) (Yamazaki et al., 2009, 2011). As a result, the ground elevation of the simulation and observation location can be different, leading to elevation bias between simulated and observed WSEs. Furthermore, river networks are typically delineated using digital elevation models (DEMs), which suffer from inherent errors (Hawker et al., 2019, 2022; Yamazaki et al., 2017). Therefore, river networks used in large-scale models may contain deviations from the courses of actual rivers (Amatulli et al., 2022; Paz et al., 2006; Yamazaki et al., 2009). Apart from other model limitations such as uncertainty in model parameters, simplified physics, and bias in forcing, the discrepancy in the virtual station location in the river network is a considerable contributor to the bias in simulated water surface elevation when compared to satellite altimetry observations.

To understand the ability of large-scale hydrodynamic models to represent actual WSEs, which is critical for comparing and validating the simulated WSE, an understanding relative location of VS within the river grid is needed.

We introduce our automated altimetry mapping procedure (AltiMaP), which was developed to allocate satellite altimetry data into a delineated river network in a manner that improves the representation of observed WSEs for the efficient evaluation of large-scale hydrodynamic model simulations. AltiMaP reduces the incidence of mismatches between VS locations and actual river locations, which are caused by DEM errors, the use of discrete river grids, and the allocation of VSs to the center of the WSE observation search area. We used pre-processed satellite altimetry data obtained from HydroWeb (<https://hydroweb.theia-land.fr>, last access: 2 February 2023) to assign VS locations to the high-resolution DEM-based Multi-Error Removed Improved Terrain Hydrography (MERIT Hydro) flow direction map (Yamazaki et al., 2019). Simulations were conducted using the Catchment-based Macro-scale Floodplain (CaMa-Flood) global river hydrodynamic model (Yamazaki et al., 2011) which uses an upscaled river network of MERIT Hydro flow direction map using Flexible Location of Waterways (FLOW: Yamazaki et al., 2009) algorithm, to evaluate VS allocation accuracy by comparing satellite altimetry WSE observations with simulation results using AltiMaP and a traditional VS allocation method.

## 2 Data and Methods

Satellite altimetry data are increasingly used in observing surface water dynamics as their availability has improved. However, it is essential to develop a framework to deploy altimetry data in the calibration and validation of surface water dynamics

95

simulations. The AltiMaP algorithm was developed for use with the MERIT Hydro flow direction map, although it can be applied to other flow direction maps using the “deterministic eight neighbors” (D8) form, in which the downstream direction is determined by one of the eight neighboring pixels. The CaMa-Flood model discretizes river networks in terms of irregular-shaped unit-catchments and uses the elevation of the unit catchment river mouth (i.e., the lowest elevation of the unit catchment) as the riverbank elevation for that river segment. Therefore, to compare observed WSEs with those simulated by a large-scale hydrodynamic model such as CaMa-Flood, one can allocate VS location to the MERIT Hydro flow direction map and map it into a coarser-resolution river network.

The accurate allocation of each VS to the MERIT Hydro by AltiMaP involves three main steps: conversion of the VS longitude and latitude to the x- and y-coordinates of a 3” pixel (~90 m × 90 m at the equator), flagging the VS according to the land cover of the pixel, and allocation of the flagged VS to the nearest river channel on the MERIT Hydro flow direction map. This study introduces the concepts and an overview of the satellite altimetry allocation algorithm; the source code (<https://doi.org/10.5281/zenodo.7597310>, Revel et al., 2023a) and dataset prepared for HydroWeb using AltiMaP for use with MERIT Hydro (<https://doi.org/10.4211/hs.632e550deaca46b080bdac986fd19156>, Revel et al., 2022) are provided.

## 2.1 Satellite altimetry data

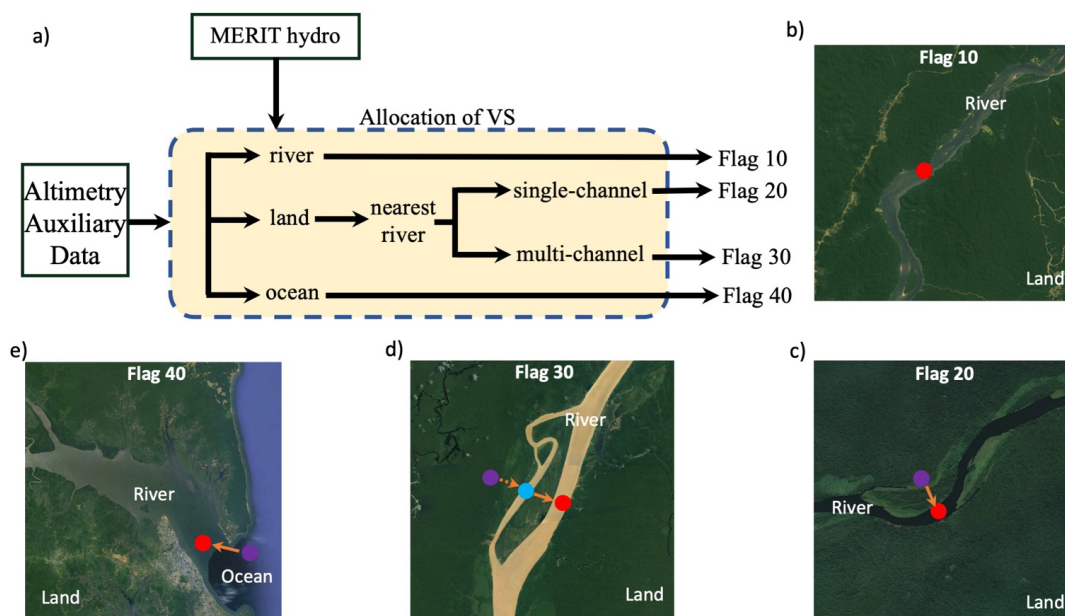

Although satellite altimetry missions were developed for ocean surface observations, they have increasingly been applied to observe lakes and rivers (Abdalla et al., 2021; Calmant et al., 2008; Calmant and Seyler, 2006; Yang et al., 2022). Several agencies have already processed their original satellite altimetry data and produced data archives for studying WSEs, including the HydroWeb (Crétau et al., 2011; Santos da Silva et al., 2010), Hydrosat (Tourian et al., 2016, 2022), Database for Hydrological Time Series of Inland Waters (DAHITTI; Schwatke et al., 2015), Global Reservoirs and Lakes Monitor (G-REALM; Birkett and Beckley, 2010), Copernicus Global Land Service (CGLS; Calmant et al., 2013; Crétau et al., 2011), River & Lake (Birkett et al., 2002), Hydrosat (Santos da Silva et al., 2010; da Silva et al., 2012), and Global River Radar Altimetry Time Series (GRRATS; Coss et al., 2020) archives. In this study, we used satellite altimetry data from HydroWeb for its accessibility and global coverage. We initially identified all VSs listed in HydroWeb as potential VSs in this study, and then removed biased VSs, as explained in Section 2.4.

## 2.2 Hydrography data

An accurate flow direction map is essential for simulating realistic surface water dynamics at the global scale. The river network used in this study is a 3” flow direction map derived from the MERIT DEM (Yamazaki et al., 2017) and water body datasets including the Global 1” Water Body Map (GIWBM; Yamazaki et al., 2015), Global Surface Water Occurrence (GSWO; Pekel et al., 2016), and OpenStreetMap, which are referred to as MERIT Hydro (Yamazaki et al., 2019). The 3” MERIT Hydro flow direction map was used to determine whether VSs were located on land, river, or ocean pixels. The allocation procedure for the higher-resolution flow direction map is described in Section 2.3.

## 2.3 Allocation of VSs to the MERIT Hydro

VSs must be assigned to river network pixels of the hydrodynamic model for accurate comparison of simulated and observed WSEs. The DEM-based river network can deviate from the cause of the actual river due to errors in DEM and low representability of the coarse-resolution of the river network (Amatulli et al., 2022; Paz et al., 2006; Yamazaki et al., 2009). Moreover, the reported location of the VS provided in HydroWeb can be further away from the actual river because HydroWeb provides the center of the search region, within a range of a few kilometers (e.g., 5 km × 5 km). Therefore, an important step

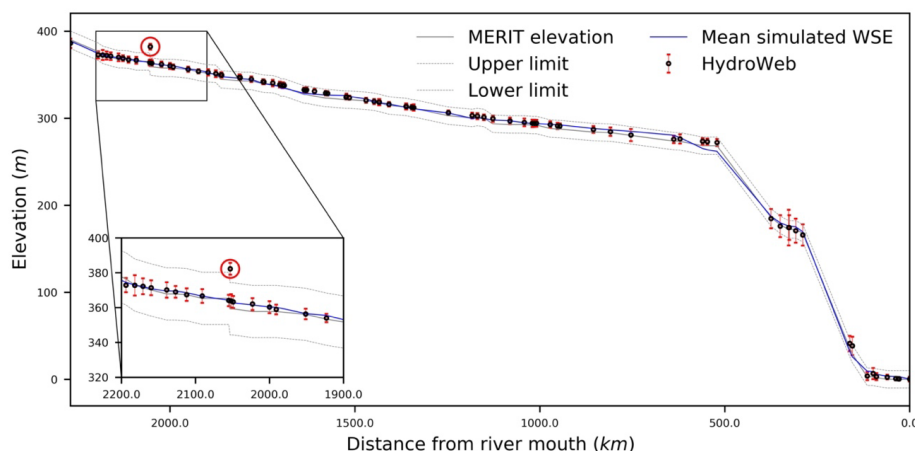

**Figure 1: Schematic diagram of allocating virtual stations (VS) to MERIT-hydro river network. The panels b, c, d, and e present schematics corresponding to Flag 10, Flag 20, Flag 30, and Flag 40, respectively. Red, blue, and purple dots are for final, secondary, and initial locations of VS allocation. (© Google Earth 2022)**

in allocating VSs to large-scale hydrodynamic models is to assign each VS to a river centerline on a higher-resolution flow direction map (e.g., MERIT Hydro, at 3"). A schematic diagram of this allocation process is shown in Figure 1. Initially, the satellite altimetry auxiliary data (e.g., longitude and latitude) for each VS were converted into 3" pixels. Then we flagged each VS according to the land cover of the initial allocation of the pixel, with 10, 20, 30, and 40 representing river channel, land with the nearest single-channel river, land with the nearest multi-channel river, and ocean pixels, respectively (Figure 1). Finally, we searched for the centerline of the nearest river according to geometric distance and allocated the VS to that location. VSs initially located on land pixels with the nearest multi-channel rivers were allocated to the nearest largest channel of the multi-channel river (considering the upstream catchment area) by searching in a direction perpendicular to the river. We assume the observation is from the largest river when there are multiple river channels near the VS location.

#### 2.4 Filtering biased stations

Even when VSs were aligned perfectly with the river network, simulated WSEs obtained using the river network deviated from satellite altimetry observations. These deviations were caused by errors in the parameters (e.g., riverbank height or river bathymetry) and/or the forcings (e.g., surface and subsurface runoff), although satellite altimetry for inland waters can also contain errors (Biancamaria et al., 2017; Frappart et al., 2006; Santos da Silva et al., 2010). The satellite altimetry data should be within a relatively comparable limit with simulated WSE to calibrate or validate the large-scale hydrodynamic models. Since the ground elevations were not recorded at the VS, we compared the mean WSE at the VS with MERIT DEM elevation corresponding to the allocated locations of that particular VSs in the MERIT Hydro flow direction map at 3"-resolution. Then we removed VSs with mean WSEs that were  $\geq 15$  m higher or lower than the MERIT DEM elevation of the corresponding pixel. These limits were selected in consideration of variation in the flow (Coss et al., 2020) and flood wave height of large

**Figure 2:** Example of virtual station (VS) showing unrealistic observations in Congo mainstream. MERIT riverbank elevation, upper limit, lower limit, and mean simulated WSE using CaMa-Flood hydrodynamic model with VIC BC runoff is shown in grey, grey dashed, grey dashed, and blue lines, respectively. Black dot indicates the mean satellite altimetry height, and standard deviation is shown in red error bars.

155 rivers (Trigg *et al.*, 2009). We determined that these constraints would be sufficient to include any river surface measurements within a comparable limit, given the elevation data used in this study; however, this threshold can be changed readily to meet user requirements. An example of the application of these restraints for a main Congo channel is provided in Figure 2, in which an unreasonably high VS allocation was removed as biased.

## 2.5 Comparison with simulated WSEs

160 We used the CaMa-Flood v4.0 model (Yamazaki *et al.*, 2011), which has a spatial resolution of 6' to evaluate the performance of the AltiMaP VS allocation method. CaMa-Flood determines river hydrodynamics using a local inertial flow equation (Bates *et al.*, 2010; Yamazaki *et al.*, 2011). The model is forced by runoff (surface and subsurface water flow per unit area) from a land surface model (LSM) to route the water through a river. CaMa-Flood is a physical model that simulates floodplain dynamics and complex hydrodynamics including the hysteresis (Yamazaki *et al.*, 2011, 2012), and flow bifurcation (Yamazaki *et al.*, 2014b). Incorporating accurate DEMs such as MERIT DEM (Yamazaki *et al.*, 2017, 2019) into the CaMa-Flood has enabled it to represent WSE dynamics more accurately compared to satellite altimetry (Modi *et al.*, 2022). Because CaMa-Flood uses the lowest elevation of the unit-catchment as the elevation of the river segment, and VSs are located where the satellite track crosses the river, which may occur elsewhere within the unit catchment, there may be elevation differences between observed and simulated WSEs (Figure 3). Therefore, evaluating elevation differences between VS locations and unit catchment outlets is important.

170 We forced the CaMa-Flood hydrodynamic model using the runoff simulated by the Variable Infiltration Capacity (VIC) LSM (Liang *et al.*, 1994) with bias correction (VIC BC) (Lin *et al.*, 2019). The standard model parameters were used in this simulation including parameters such as river bathymetry, river width, and Manning's coefficient. For comparison with WSEs simulated by CaMa-Flood, we mapped VSs to a 6'-resolution global river network after allocating VSs to the MERIT Hydro network at 3"-resolution using AltiMaP, because the CaMa-Flood river map was derived by upscaling the MERIT Hydro flow

direction map using FLOW algorithm (Yamazaki et al., 2009). Then we compared the resulting simulated WSEs with observed  
175 WSEs mapped onto the river network based on the MERIT Hydro using the AltiMaP algorithm and the traditional method,  
i.e., converting longitude and latitude to the CaMa-Flood grid.

## 2.6 AltiMaP variable identification

The AltiMaP variables provided for each VS are listed in Table 2; the full dataset is provided  
180 in <https://doi.org/10.4211/hs.632e550deaea46b080bdae986fd19156> (Revel et al., 2022). The data primarily includes variables  
related to VS metadata, VS allocation to the MERIT Hydro, and VS mapping to a coarse-resolution river network (e.g., global  
6'). The VS metadata consists of the VS ID, name, longitude, latitude, and satellite name. Important parameters for VS  
allocation that are related to the MERIT Hydro river network can also be calculated for other river network datasets, by flagging  
and allocating VSs as described in Section 2.3, and then adding 100 to the flag of any VS that is biased (Section 2.4). The  
185 distance from a VS mapped to a river centerline to the unit catchment river mouth is an important parameter for understanding  
differences in water surface dynamics between simulated and satellite altimetry observations. The best and second-best  
candidate locations for VSs on the MERIT Hydro river centerline ( $10^\circ \times 10^\circ$  grid) are also reported, along with their geometric  
distances from the VS location; for single-channel rivers, these data are not available. The river width at each VS location

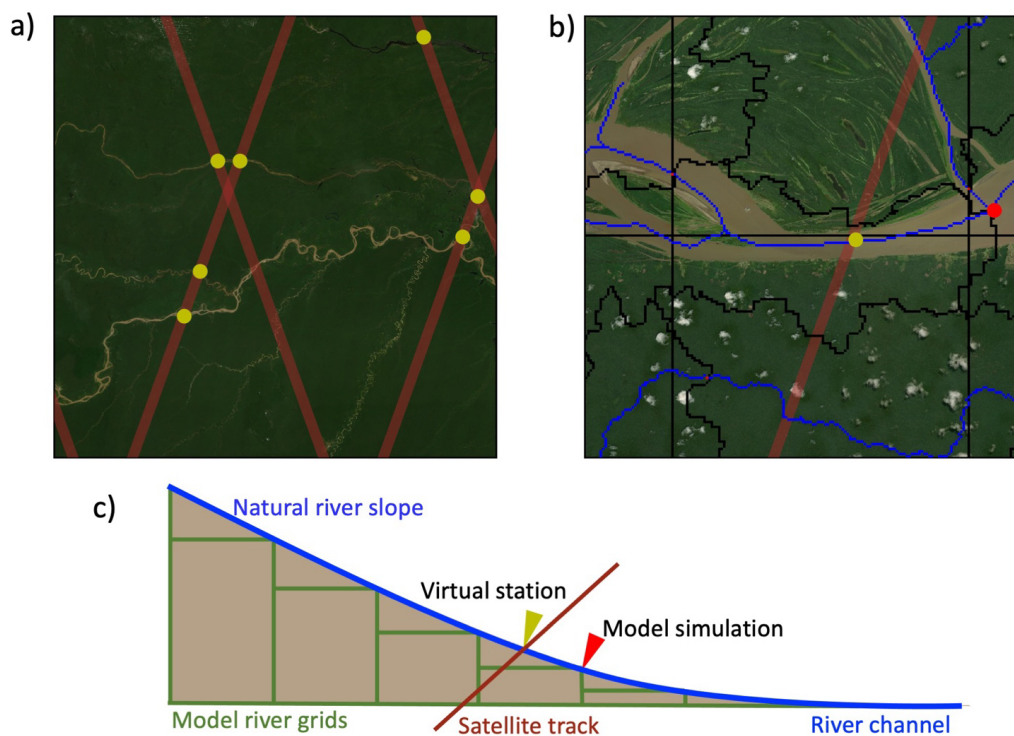

Figure 3: Representation of Virtual Station (VS) in the river network map for large-scale hydrodynamic model. a) Satellite tracks, b) VS representation in unit-catchment, and c) longitudinal section of the river. Yellow and red color points indicate the VS locations and unit-catchment mouth. The model simulation is corresponding to the unit-catchment mouth corresponding to red point. (Aerials are from Esri, DigitalGlobe, GeoEye, i-cubed, USDA FSA, USGS, AEX, Getmapping, Aerogrid, IGN, IGP, swisstopo, and the GIS User Community)

mapped onto the MERIT Hydro river network was calculated using satellite-based water masks and flow direction maps  
 190 (Yamazaki et al., 2014a). The distance from the VS to the best and second option locations on MERIT Hydro is also included.  
 The coarse-resolution river network variables include the x and y coordinates for the global 6' map used in the large-scale  
 hydrodynamic model, as well as the elevations of the Earth Gravitational Model 2008 (EGM08) and Earth Gravitational Model  
 1996 (EGM96).

195 **Table 2: AltiMaP data description. The data can be divided into three basic categories namely, VS metadata, MERIT Hydro-related, and coarser-resolution river network-related.**

Variable	Description	Units
VS metadata		
ID	Identification number of VS	-
station	VS name	-
dataname	dataset name	-
lon	longitude	degrees east
lat	latitude	degrees north
satellite	name of the satellite	-
MERIT Hydro-related		
flag	allocation flag	-
elevation	elevation at VS location on MERIT Hydro	m
dist_to_mouth	distance to the unit-catchment mouth	km
kx1	best x-coordinate with respect to the $10^\circ \times 10^\circ$ higher resolution tile	-
ky1	best y-coordinate with respect to the $10^\circ \times 10^\circ$ higher resolution tile	-
kx2	second-best option of x-coordinate with respect to the $10^\circ \times 10^\circ$ high-resolution tile	-
ky2	second-best option of y-coordinate with respect to the $10^\circ \times 10^\circ$ high-resolution tile	-
dist1	distance from the second-best location to the VS	km
dist2	distance from the second-best location to the VS	km
rivwth	River width of the allocated location	m
Coarse-resolution river network-related		
ix	x-coordinate with respect to coarse resolution	-
iy	y-coordinate with respect to coarse resolution	-
EGM08	EGM 2008 datum elevation	m

EGM96 EGM 1996 datum elevation m

### 3 Results

The AltiMaP dataset produced allocation locations for 12,523 VSs worldwide that are listed in the HydroWeb database. In this section, we discuss the characteristics of VS flags and conditions that can lead to considerable bias in satellite altimetry compared to the MERIT DEM.

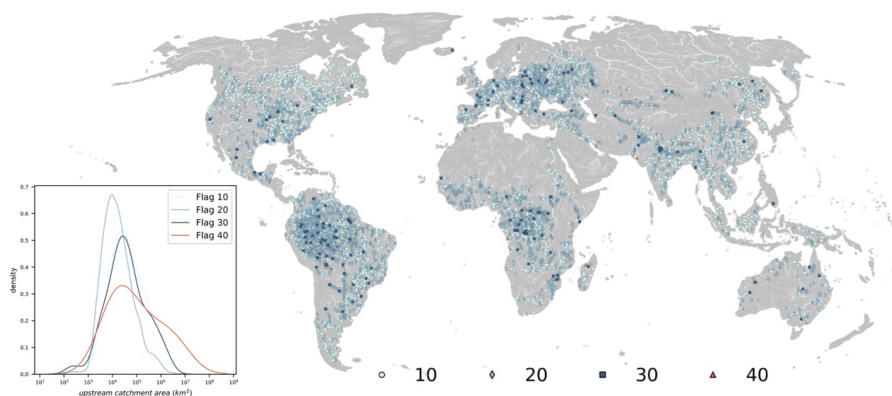

#### 3.1 Allocation of VSs to the river network

Figure 4 shows the global distribution of flags 10, 20, 30, and 40, which VSs initially located on river channel river, land with a single-channel river nearby, land with a multi-channel river nearby, and ocean pixels, respectively. Flag 10 was the most common, accounting for 71.74% of all VSs, followed by flags 20 (26.88%), 30 (1.34%), and 40 (0.04%). Flags 10 and 20 were evenly distributed worldwide.

The log probability distributions of upstream catchment areas for different flag values are also shown. The median upstream catchment areas were  $1.80 \times 10^4$ ,  $2.97 \times 10^4$ ,  $2.56 \times 10^5$ , and  $3.95 \times 10^4$  km<sup>2</sup> for flags 10, 20, 30, and 40, respectively. Flag 30 represented the largest median upstream catchment area because most braided rivers are located in the downstream reaches of large rivers. The distribution of flag 40 was strongly right-skewed, influenced by the larger upstream catchment areas of ocean grids. Flag 10 had the smallest median upstream catchment area, which indicates that most flag 10 VSs were located in upstream reaches.

#### 3.2 Biased VSs

Figure 5 shows the spatial heterogeneity of biased VSs, their distribution of upstream catchment areas in log scale, variation in their elevations, and a histogram of river widths at VS locations, calculated using MERIT Hydro. Biased VSs accounted for 2.6% of all VSs, and were distributed worldwide, with no distinct spatial pattern. A large number of them were allocated to large river basins such as the Amazon, Congo, and Mekong basins. Most were flagged 20, which was the second most common

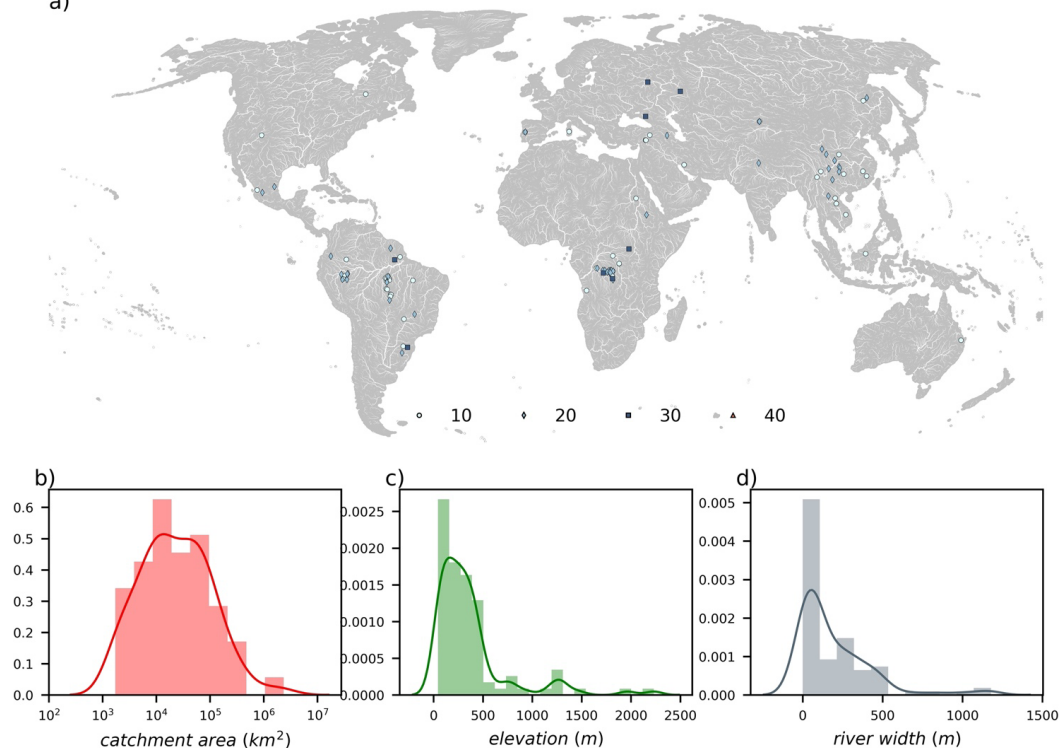

**Figure 4: Global map of allocation flags. Panel at lower left corner shows probability distribution of the upstream catchment area in log scale for different flags. Flags 10, 20, 30, and 40 are indicated by light blue, medium blue, dark blue, and red colors, respectively.**

allocation flag. Many were detected in the Amazon basin of South America. The median upstream catchment area of biased VSs was  $2.98 \times 10^4 \text{ km}^2$ , their median elevation was 199.6 m, and the median river width was 87.5 m, with most values ranging from 0 to 500 m. Thus, most biased VSs were detected in narrow rivers at high altitudes.

a)

**Figure 5:** a) Global distribution, b) histogram of catchment area ( $\text{km}^2$ ), c) histogram of elevation (m), and d) histogram of river width (m) of biased VSs. Light blue circles, medium blue diamonds, dark blue squares, and red triangles for flags 10, 20, 30, and 40, respectively in panel a.

220 VSs with biased WSEs were generally found in narrow, high-elevation river reaches, although some were found in rivers such  
as the main Congo channel. Most biased VSs had WSEs that exceeded the MERIT Hydro feasible elevation range. Large  
biases can be caused by off-nadir measurement of nearby water bodies (Maillard et al., 2015), deviations of the MERIT Hydro  
river network from actual river (Amatulli et al., 2022), and DEM errors such as vegetation bias (Yamazaki et al., 2017). Further  
study is needed to fully understand the causes of errors in river WSEs obtained by satellite altimetry which is beyond the scope  
225 of this data description paper.

## 4 Discussion

### 4.1 Effect of discrete river reaches and DEM errors

As the distance from the VS location to the unit catchment river mouth increased, the RMSE of simulated WSE increased  
(Figure 6), mainly due to the difference in elevation between these points. Thus, large errors may be associated with simulated  
230 WSE when the VS is located far from the unit catchment mouth. Similarly, the RMSE of simulated WSE increased slightly as  
the slope within the unit-catchment increased, with larger slopes ( $> 200 \text{ m/km}$ ) showing an RMSE increase from 2 to 4 m.

**Figure 6: Boxplot of the root mean square error (RMSE) against a) the distance to the unit-catchment mouth and b) unit-catchment slope.**

This variation may have been caused by the non-uniformity of slopes within unit catchments of the CaMa-Flood model; however, it was well within the range of variation within unit-catchment slope bins, which reached up to 8 m.

One of the main reasons for elevation bias between the satellite altimetry and model simulations is elevation differences between the VS locations and the base elevation of the model. This type of bias can be eliminated using the VS location as the unit-catchment mouth. However, this approach is challenging because unit-catchments size may very small when several VSs located close to each other, which may lead to computational instability in CaMa-Flood model because it is optimized for unit-catchments of equal size. In addition, changing unit-catchment sizes can reduce the computational efficiency of the model drastically, which is critical for global-scale hydrodynamic models such as CaMa-Flood. Therefore, we did not consider updating the river network to use the VS locations as unit-catchment mouths in AltiMaP.

The allocation of VSs to a river network is highly dependent on the DEM used to delineate the river network (Schumann and Bates, 2018). Most freely available global-scale DEMs have large vertical errors that are accentuated over complex topography; these are unable to resolve microtopographic variation in relatively flat terrain (Chu and Lindenschmidt, 2017; Gallien et al., 2011). Although global-scale DEMs such as the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) or Shuttle Radar Topography Mission (SRTM) exhibit non-negligible height errors, recent studies have attempted to eliminate these errors (e.g., Hawker et al., 2022; Rizzoli et al., 2017; Yamazaki et al., 2017). In this study, we used the MERIT DEM, which is a highly accurate global-scale DEM that is freely available (Hawker et al., 2019). Thus, AltiMaP can be applied to river networks delineated using any accurate global DEM.

#### 4.2 VS allocation to MERIT Hydro

Mapping the VSs to MERIT Hydro, a high-resolution global river network is a crucial step in leveraging their potential for hydrological modeling. There are several compelling reasons for mapping the VSs to MERIT Hydro, which is a high-resolution global river network at 3". Firstly, the mapping process can be easily adapted to various resolution river networks of the CaMa-Flood hydrodynamic model, such as 0.25° or 0.1°. This flexibility allows for the integration of VSs into a range of hydrological

models, depending on the desired level of detail and accuracy. Secondly, the relative location of the VSs within the CaMa-  
255 Flood unit-catchment can be determined, which is essential for the calculation of important parameters such as elevation  
difference and distance to the unit catchment mouth (`dist_to_mouth`). These parameters are critical for evaluating and  
understanding the dynamics of water in a river network. Finally, the ability to allocate VS to any river network with a similar  
topology is demonstrated by mapping the VSs to MERIT Hydro, which is having D8 connectivity. Therefore, it is crucial to  
assign the VSs to the base map of the river network in the hydrodynamic model to enhance the evaluation of the models and  
260 to identify the causes for the discrepancies between the model and observations.

RMSEs were calculated for WSEs simulated by CaMa-Flood and forced by VIC BC runoff (Lin et al., 2019). The spatial  
distributions of WSE RMSEs for VS allocations obtained using AltiMaP and the traditional method of allocating VSs to the  
CaMa-Flood grid are shown in Figure 7. Traditional VS allocation was performed using directly converting longitude and  
latitude information to coarse-resolution (i.e.,  $0.1^\circ$ ) grids. At the global scale, RMSEs were generally similar between both VS  
265 allocation methods. However, the satellite altimetry was better represented by AltiMaP for 17.52% of VSs (negative  $\Delta$ RMSE)  
and by the traditional method for only 12.85% of VSs (positive  $\Delta$ RMSE).

The AltiMaP and traditional VS allocation methods had median RMSEs of 7.86 and 8.70 m, respectively (Figure 8). The inter-  
quartile range was larger for the traditional method. Thus, AltiMaP reduced the RMSE by 10.6% through more accurate VS  
allocation to the river network map. RMSE was reduced by AltiMaP for all flags, with the largest reduction observed in flag  
270 30 (Table 3) due to VS allocation to more appropriate segments of multi-channel rivers, followed by flags 20, 10. But accuracy  
was slightly degraded in flag 40, in which VSs were allocated inward from the ocean. The remaining error may be attributed  
to elevation differences between VS locations and simulated WSE locations (Figure 3) and limitations of the hydrodynamic  
model.

A flag-wise comparison revealed that errors associated with the allocation method varied among flags in the AltiMaP results.  
275 Almost all AltiMaP flags had lower RMSE than those produced by the traditional method. This difference was due to the  
irregular shape of unit-catchments in the CaMa-Flood hydrodynamic model. In long, narrow unit catchments, slight deviations  
in VS location could lead to the misidentification of adjacent unit catchments as target grid. Thus, simulated WSEs deviated  
by 1–15 m, depending on the slope and river path (e.g., straight vs. meandering river). These results highlight the importance  
of implementing specialized procedures such as AltiMaP to locate optimal river grid matches for each VS prior to WSE  
280 comparisons.

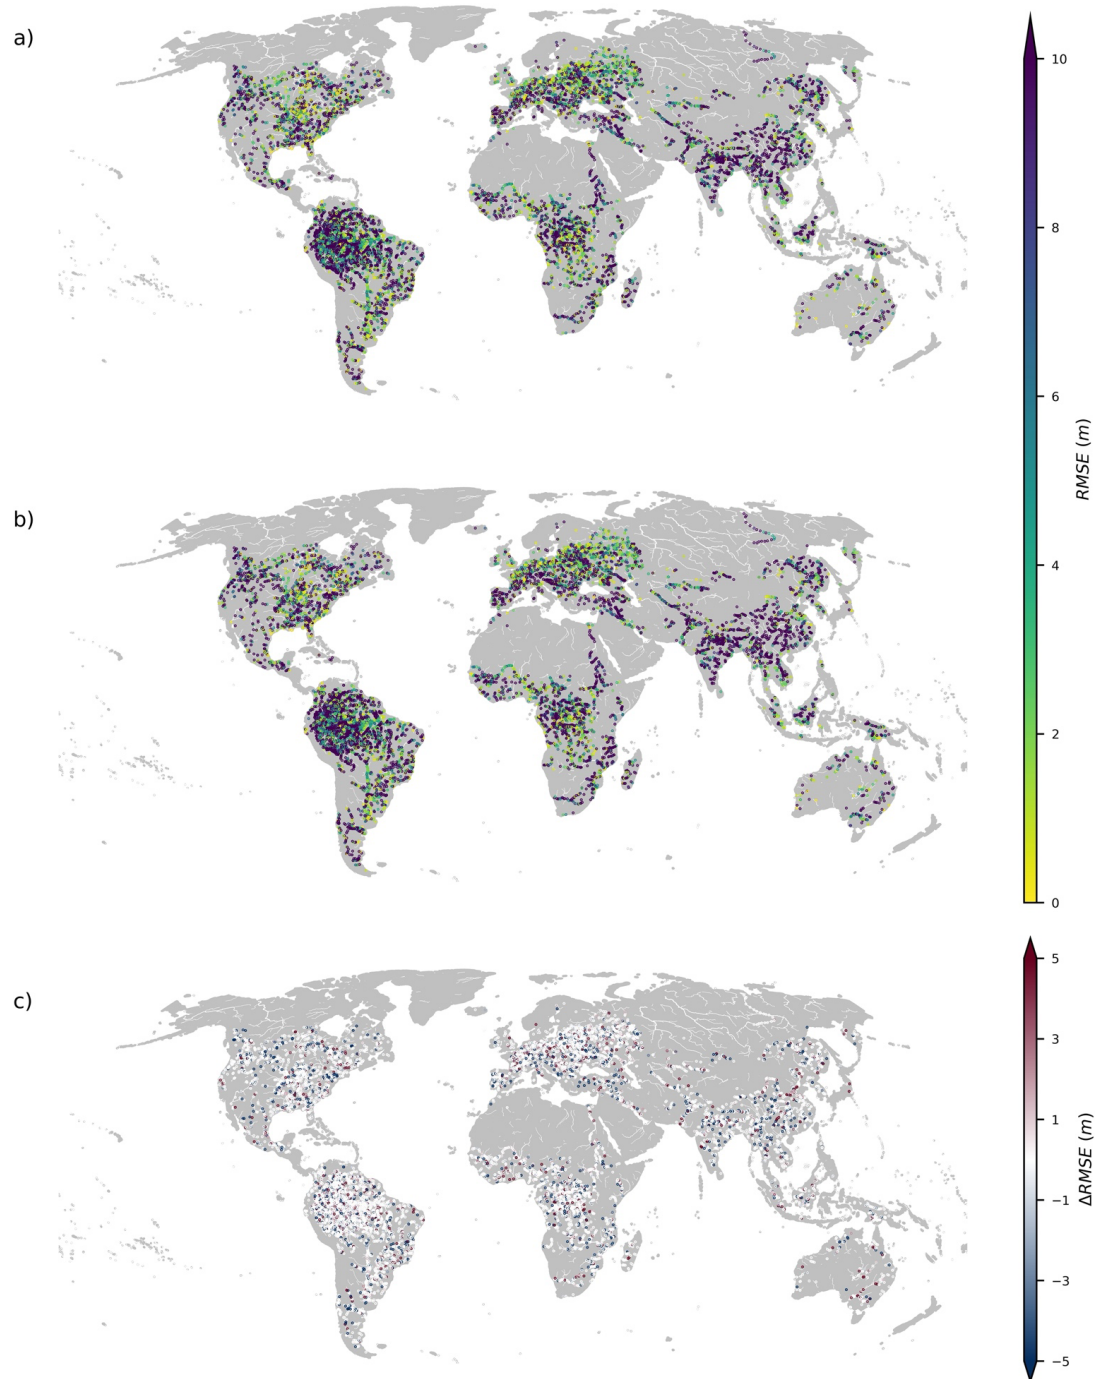

### 4.3 Advantage of mapping VSs

Because we used river network-related variables in the AltiMaP VS allocation algorithm, we were able to calculate distances  
and elevation differences between each VS and the unit-catchment river mouth. These parameters are particularly important  
for comparing WSEs simulated by coarse-resolution, large-scale river routing models such as CaMa-Flood, which are based  
285 on discretized river reaches with a representative elevation for each pixel. Minimizing the distance and elevation difference  
between the VS and unit-catchment river mouth is critical for improving the accuracy of WSE simulations. Thus, this elevation  
difference may be used as a proxy to interpret bias between simulated and observed WSEs (Fassoni-Andrade et al., 2021).  
Satellite altimetry data are also extremely useful for evaluating and calibrating hydrodynamic models and correcting variables  
through data assimilation (e.g., Zhou et al., 2022), which requires correct VS allocation to a river network map.

290 The flags used in AltiMaP to classify VSs provide a unique opportunity for users to identify the VS allocation methods  
used to evaluate hydrodynamic model outputs. Notably, simulated WSEs in first- and second-candidate river pixels for VSs  
that were initially allocated to multi-channel rivers (flag 30) can be used to select optimal VS locations along the river network.  
Most VSs flagged 10 were located in upstream reaches, whereas those flagged 30 and 40 were initially located in multi-channel

rivers and oceans (which are most in need of relocation) and were allocated to downstream reaches. It is important to correctly

**Figure 7:** Global map of root mean square error ( $RMSE$ ) for a) expert method and b) ordinary method; and c)  $RMSE$  difference ( $\Delta RMSE$ ) between expert and ordinary methods.

295 allocate VSs initially located on multi-channel rivers because river networks based on the MERIT Hydro separate each channel  
of a multi-channel river into different unit-catchments. Thus, discrepancies in the allocation of VSs located on smaller channels  
can mistakenly alter the WSE dynamics of the simulation, such that the allocation flags are important indicators of VS usage  
in the context of hydrodynamic modeling.

### 5 Data availability

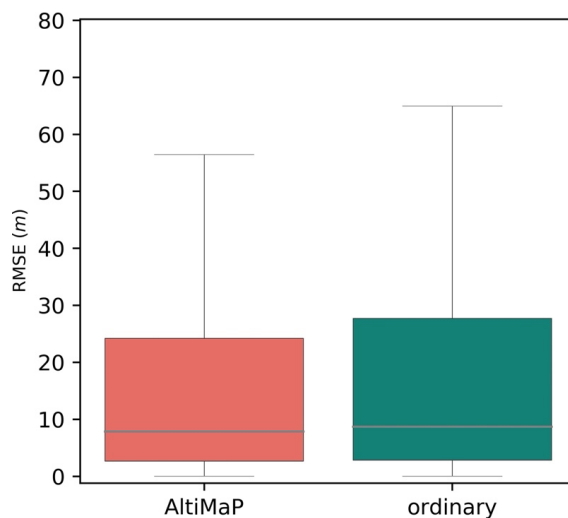

300 Data produced by AltiMaP were published in <https://doi.org/10.4211/hs.632e550deaea46b080bdac986fd19156> (Revel et al.,  
2022). MERIT Hydro river network data are freely available ([http://hydro.iis.u-tokyo.ac.jp/~yamadai/MERIT\\_Hydro/](http://hydro.iis.u-tokyo.ac.jp/~yamadai/MERIT_Hydro/)) under  
a Creative Commons license (CC-BY-NC 4.0).

### 6 Code availability

The AltiMaP algorithm was published in <https://doi.org/10.5281/zenodo.7597310> (Revel et al., 2023a) and is available for  
305 noncommercial use. The CaMa-Flood source codes are also available ([https://github.com/global-hydrodynamics/CaMa-Flood\\_v4](https://github.com/global-hydrodynamics/CaMa-Flood_v4)) under the Apache 2.0 license.

**Table 3: Median root mean squared error of simulated WSE using CaMa-Flood hydrodynamic model. The simulated WSE is compared with HydroWeb satellite altimetry data where the VS s were allocated using AltiMaP or the ordinary allocation method.**

	AltiMaP	Ordinary
All	7.86	8.70
Flag 10	7.88	8.54
Flag 20	7.90	9.28

## 310 7 Summary

We introduce AltiMaP, an effective methodology for comparing satellite altimetry WSE observations with WSEs simulated by large-scale hydrodynamic models such as CaMa-Flood. The procedure involves allocating each VS to a suitable high-resolution (3") pixel, flagging the pixel according to land cover, and filtering out biased VSs according to the local MERIT DEM elevation. The main objective of this study was to improve the accuracy of VS allocation to a river network for a useful comparison of simulated and observed WSEs, among other applications. We compared WSEs simulated by the CaMa-Flood hydrodynamic model based on VIC BC runoff to satellite altimetry WSEs based on VS allocation to the MERIT Hydro river network using AltiMaP.

After mapping the flagged VSs to a 6' river network, biased VSs with values above or below the feasible MERIT Hydro elevation range were filtered out. Most VSs were located on single-channel rivers; VSs initially located on land were distributed worldwide. VSs initially located on multi-channel rivers and oceans were allocated to downstream reaches of large rivers such as the Amazon, Congo, and Mekong Rivers. Biased VSs, incompatible with the river network elevation profile, were mainly found in narrow rivers at high elevations, likely because most altimeters are designed to observe ocean topography. Such VS biases are mainly caused by off-nadir measurements, DEM errors, or errors in the geolocation of river networks.

We also allocated VSs to a coarse-resolution CaMa-Flood river network for comparison with the simulated results. AltiMaP VS allocation represented the satellite altimetry more accurately than a traditional method, reducing the RMSE associated with the simulated WSEs by approximately 10%, representing a difference of approximately 2 m in multi-channel rivers. AltiMaP can be applied to any currently available processed satellite altimetry datasets (e.g., DAHITTI, Hydrosat, and CGLS) and any river network with simple land cover definitions (e.g., river, land, and ocean). We anticipate that the algorithm will contribute to the evaluation and/or calibration of hydrodynamic models using satellite altimetry and the acquisition of accurate hydrodynamic model output through satellite altimetry assimilation.

**8 Author contribution:** MR developed and finalized processing algorithms, performed the exploration of the methods, and finalized the manuscript. MR and DY designed the experiments. XZ provided the simulated data for comparison. All co-authors involved in revising and editing the manuscript.

**9 Competing interests:** The authors declare that they have no conflict of interest.
