Abstract. Plant litter decomposition in terrestrial ecosystems involves the physical and chemical breakdown of organic matter. Development of databases is a promising tool for achieving a predictive understanding of organic matter degradation at regional and global scales. In this paper we present aridec: a comprehensive open database containing littermass loss data from aridlands across the world. We describe in detail the structure of the database and discuss general patterns in the data. Then, we explore what are the most appropriate model structures to integrate with data on litter de-15 composition from the database by conducting a collinearity analysis. The database includes 184 entries from aridlands across the world, representing a wide range of climates. For the majority of the data gathered in aridec it is possible to fit models of litter decomposition that consider initial organic matter as a homogenous reservoir (one pool models), as well as models with two distinct types of organic compounds that decompose at different speeds (two pool models). 20 Moreover, these two carbon pools can either decompose without interaction (parallel models), or with matter transfer from a labile pool to a slow-decomposing pool after transformation (series models). Although most entries in the database can be used to fit these models, we suggest potential users of this database to test identifiability for each individual case as well as the number of degrees of freedom. Other model applications that were not discussed in this publication might also be suitable for use with this database. Lastly, we give some recommendations for future decomposition studies to be potentially added to this database. The extent of the information included in aridec in addition to its open-sci-25 ence approach makes it a great platform for future collaborative efforts in the field of aridland biogeochemistry. The aridec version 1.0.21 is archived and publicly available at https://doi.org/10.5281/zenodo.66003456025969 (Sarquis et al., 2022), and the database is managed under a version-controlled system and centrally stored in GitHub (https:// github.com/AgustinSarquis/aridec, last access: 31 May 9 February 2022).

30 1 Introduction

35

40

45

Plant litter decomposition has a central role in the balance between carbon (C) storage and losses in terrestrial ecosystems. This process involves the physical and chemical breakdown of organic matter. Together with soil organic matter decomposition, this process is the main route of carbon dioxide (CO₂) efflux to the atmosphere in terrestrial ecosystems (Chapin et al., 2011). It also plays a key role in the formation and stabilization of soil organic carbon (SOC; Cotrufo et al., 2013). Therefore, in the context of current global change, a thorough understanding of decomposition is crucial for future C budget and storage predictions (Davidson and Janssens, 2006).

Arid ecosystems (hereafter aridlands) are variously defined as water-limited ecosystems, where the scarcity and unpredictability of precipitation drive most processes (Noy-Meir, 1973). They are also defined as regions where evaporation is higher than precipitation, which in turn limits ecosystem productivity (Jafari et al., 2018). Moreover, aridlands can be classified based on an Aridity Index as hyper arid, arid, semi-arid, and dry subhumid ecosystems (United Nations Environment Programme, 1997). Around 41% of the global land area are considered as aridlands (Safriel and Adeel, 2005) and these systems are expanding due to global change (Feng and Fu, 2013; Reynolds et al., 2007; Yao et al., 2020). Despite their comparatively low productivity, some aridlands can have a potentially large impact on global CO₂ dynamics (Ahlström et al., 2015; Poulter et al., 2014). The wide extent of aridland cover and their influence on regional and global biogeochemical cycles make the study of aridlands a priority.

In particular, plant litter decomposition in aridlands is still not well understood (Austin, 2011). Litter mass loss in the field is mainly studied using the litterbag method or some variant (Harmon et al., 1999). The vast majority of litterbag studies come from temperate forests favored by the ease of litter collection and the concentration of researchers close to these study sites. There are fewer studies in aridlands, and few efforts have been made towards synthesizing aridland decomposition literature (Austin, 2011; Cepeda-Pizarro, 1993) or to examine patterns of decomposition in global aridlands (Zhang and Wang, 2015). Nonetheless, substantive literature has already been produced, which would allow for the compilation of a comprehensive database on plant litter decomposition in aridlands that could help boost our understanding of these ecosystems.

Development of databases is a promising tool for achieving a predictive understanding of organic matter degradation at regional and global scales (Luo et al., 2016). This predictive understanding can be obtained through mathematical models, but there is substantial uncertainty with respect to which models to use. For litter decomposition, some efforts have been made, by fitting models with multiple C pools of different quality that decompose at different rates (Adair et al., 2008), as well as incorporating the effect of abiotic stressors like photodegradation on C dynamics (Adair et al., 2017; Chen et al., 2016; Foereid et al., 2011). Taken together, increased data availability and global representativity of well-constructed databases with our current most complex modeling tools could help us achieve a better understanding of the land C cycle with a higher predictive power.

Once a database of observations has been constructed, there exists the possibility of fitting complex models from these data, although this should be approached with caution. A common issue with mechanistic models used in environmental sciences is that they are poorly identifiable (Brun et al., 2001), meaning that different parameter sets of a model generate similar probability distributions for the observed data (Sierra et al., 2015). In other words, it is impossible to identify a unique set of parameters that explains model behavior. One reason behind this issue is that the information one would like to learn from models is often of a much higher complexity than the information content of the observed data (Brun et al., 2001). It is possible to detect identifiability issues by carrying out collinearity analyses (Sierra et al., 2015; Soetaert and Petzoldt, 2010), among other techniques. Thus, in addition to applying current ecological knowledge about underlying mechanistic processes in model construction, it is important to avoid identifiability problems when fitting these models with real data.

Another important aspect when developing this type of database is to follow an Open Science approach (Hampton et al., 2015). Open Science entails the practice of making all stages of scientific knowledge freely available and presented in a transparent and reproducible way for the whole scientific community to use. Such an approach has the potential to enhance the quality of research products and to speed up scientific progress through collaborative work. Particularly, the development of databases can benefit greatly from an open science perspective by allowing self-motivated reviewers to make comments and by allowing scientists from outside of the core research group to make their own contributions to the database, among other benefits. This latter aspect is key to ensure databases stay updated as new studies get published.

In this paper we present *aridec*: a comprehensive open-science database that comprises time series of litter mass loss (decomposition) data from aridlands across the globe. First, we describe in detail the structure of the database and discuss general patterns in the data. Second, we run a collinearity analysis on the database to explore what might be the most appropriate model structures to fit. We chose a group of models of organic matter loss provided in the R package SoilR as potential models, including models of one, two and three pools with and without matter transfers between them (Sierra et al., 2012). Third, we present an example of applied usage of the database. Lastly, we discuss the scope of the database and give outlines on good field decomposition experimental practices stemming from this work.

2.1 Database description

90 We conducted a Scopus search on February 17th, 2021, for field decomposition studies of all times from aridlands published in peer-reviewed journals. We used the search words 'arid OR "dry season" AND decomposition' and excluded results from unrelated subjects. This search produced a list of 1142 publications. To be included in the database, studies additionally needed to fulfil certain criteria: a) *field* studies in which leaf, shoot or root litter of terrestrial plants was used, and b) minimum of three time points of mass loss data. We did not include wood or dung decomposition studies. We also included publications from our personal libraries. In total, this left us with a list of 184 eligible publications.

We named the database *aridec* and uploaded it to a repository in GitHub (GitHub, 2022; Sarquis et al., 2022). From each selected publication, we created a database entry consisting of three separate files: a file containing time series of mass loss (*timeSeries.csv*), a file containing metadata of the study site and the experimental setup (*metadata.yaml*) and a file with relevant information of the initial characteristics of the litter at the beginning of the experiment (*initConditions.csv*). We saved each entry in an individual folder named after the last name of the first author and the year of publication. If there was more than one paper per author and year, we added lowercase letters to differentiate them (e.g.: Austin2006a and Austin2006b). We included all entries inside the *data* folder. Other folders in the repository include the *Rpkg* folder containing an R package for querying and manipulating the database, a *test* folder with scripts for testing the integrity of the data and the R package, and an additional folder with miscellaneous *scripts* that demonstrate additional functionality. The overall structure of the database is similar to the structure of SIDb (Schädel et al., 2020) a database of soil incubation time series, and contains the following folder structure:

- aridec
 - Rpkg
- 110 test

100

105

- scripts

- data

- single entry
 - metadata.yaml
 - initConditions.csv
 - timeSeries.csv

The *timeSeries.csv* file includes litter mass loss over time as reported in the original publication. It is a csv type file ("comma-separated values") with column names in the first row. The first column name is always the variable Time and the first value in this column is always "0" (zero). Successive time values should be specified according to each sampling date reported in the study. Time units accepted are days, weeks, months, and years. Starting from the second column, column names should be unique variable identifiers. Below these names, mass loss data should be included as a percentage of the initial value, which is always 100. When data in the paper are reported in graph form, it is necessary to extract data point values with software tools such as WebPlotDigitizer (Rohatgi, 2020). Acceptable mass loss units are percentage of remaining dry weight, dry organic matter, dry ash-free mass, or C. For remaining mass data as well as for time, units should be specified in the *metadata.yaml* file described below.

The *metadata.yaml* file includes additional information reported in the original paper. It is a yaml type file ("YAML ain't markup language"), which allows us to write lists of items in a hierarchical form and is both machine and human readable. It includes four main sections: entry identification data, the *siteInfo*, the *experimentInfo* and the *variables* sections. A template for this file with a full description of how to complete it is available inside the *data* folder. The first part includes the *citationKey* which is a unique identifier for the whole entry in the format LastnameYEAR (lowercase letters must be added when there are two or more entries by the same author and year, i.e.: LastnameYEARa and LastnameYEARab). This *citationKey* name should be the exact same as the folder name. Next is the *doi*, which stands for the Digital Object Identifier where data is published. *entryAuthor* and *contactName* are both first and last name of the person who wrote the entry file and their supervisor (only if applicable), respectively. If the entry author works independently of a supervisor, both fields should be filled with the same name. *contactEmail* should be filled with the supervisor's e-mail address. *entryCreationDate* stands for the date when the file was created, following the format: YYYY-MM-DD. *entryNote* should include any notes or comments related to this entry, such as missing data or additional data sources used to complete this file. Lastly, *study* requires a short study description in not more than one sentence.

The second part of the metadata.yaml file is the siteInfo section, which includes environmental information of ecological interest from the study site. First is the site field that requires an identification name for the site (not necessarily the site's real name). If the study includes more than one site, an array format should be used in this field and the rest of the items in this section should be arrays of equal length. The coordinates field should be completed using decimal units, checking for the negative sign that denotes southern and western hemispheres. If absent from the publication, coordinates can be approximately obtained from Google Earth (Google LLC, 2020). The country field should be completed avoiding full names (e.g.: "China" instead of "People's Republic of China" or "USA" instead of "United States of America"). Mean annual temperature (°-C) and mean annual precipitation (mm) should be entered in the fields MAT and MAP, respectively. When climatologic data are absent from the paper, they can be retrieved from other databases like the POWER database [NASA Langley Research Center (LaRC)]. The rainySeason field should be filled with either one of five options: whole year, spring, summer, autumn, winter; if precipitation does not follow a unimodal pattern, this item is left blank. Elevation of the study site in m a.s.l. should be entered under the elevation field, which if absent from the publication can be retrieved from other sources such as Google Earth. The type of vegetation cover of the site should be specified in landCover, with possible options: marsh, greenbelt, farmland, mangrove forest, subalpine, shrubland, urban, sandland, forest, steppe, desert, grassland, and savanna. The item *veqNote* should include a short description of not more than one sentence of the species or functional type composition at the site, if available. The *cover* item should be completed with percentage values of total plant cover or with cover values for specific plant functional types, as available. Lastly, the soilTaxonomy item must be completed using the taxonomic classification of the soil at the site. If the classification system used in the paper is unknown, it is better to leave this section blank, for exact equivalences between soil classification systems are unlikely.

The third part of the *metadata.yaml* file is the *experimentInfo* section which includes information regarding the experimental design of the study. *incDesc* stands for incubation description and must include a short list of treatments and sampling points in time. The number of replicates should be specified, paying attention to occasional pseudoreplication in decomposition studies. Experiment *duration* in days should be completed with the maximum time length that samples stayed in the field. The month in which the experiment started should be specified under *startingMonth*. The name of the litter used for the experiment should be specified under *litter*, and it should match the name used in the *initConditions.csv* file (see below). Under the *litterbag* field, many sub-fields for different characteristics of interest should be completed, such as mesh material, mesh size (one side of a square in mm), dimensions (in cm), mesh transmittance (as a percentage of full sunlight) and litterbag position (full list of options available in the template file). A general rule for the *experimentInfo* section is that when there is more than one option for a field they should be considered as different levels of a treatment. In this case that field should be left blank in this section, and a new field should be created in the *variables* section by replacing the *experimentalTreatment* placeholder in each variable (see below)

The last section of the *metadata.yaml* file is the *variables* section, which serves as a link between columns in the *timeSeries.csv* file and metadata. Thus, this section should have as many variables as columns in the *timeSeries.csv* file. The first variable (V1) must always be called "Time" and only time units should be modified accordingly. The rest of the variables (V2 to Vn) must be adequately edited to represent treatment application as described in the original publication. Variable names should match column names in the *timeSeries.csv* file. Litter mass loss *units* should be expressed either in (dry) mass remaining, organic matter remaining. Organic matter remaining is in our database a synonym of (or ash-free dry mass remaining. This is because the ash-free dry mass correction assumes that ash is inorganic matter and thus ash-free mass is equivalent to organic matter for the purpose of this database (Harmon et al., 1999)) remaining, or G remaining. Under varDesc (as in variable description) one should write a brief sentence indicating specific treatment levels applied to this variable. The *site* field should be completed using the same site name entered in the *siteInfo* section. The *experimentalTreatment* item is a place holder for treatments with multiple levels. It should be replaced by any of the listed variables in *experimentInfo* and completed with an appropriate treatment level. In *compTreat* complementary treatments not included in the rest of the metadata items should be indicated using key words (e.g.: grazed/ungrazed, water addition, control, etc.). Finally,

Figure 1: A guiding flowchart of the entry-submitting process for potential contributors of aridec.

transmittance and wavelength threshold (nm) data for radiation filters should be indicated under *filter*. This sub-section should be completed only for photodegradation studies.

The last file in the *data* folder is the *initConditions.csv* file which contains details on the plant litter substrate used for each experiment. The first row contains column names. The first column name is *species* and is the only mandatory item, nonetheless we strongly recommend completing all items if possible. We suggest checking for the correctness of scientific names in the Global Biodiversity Information Facility database (GBIF.org, 2022). Names in the *species* column should be used to complete the *litter* item in the *metadata.yaml* file. Four options are valid for the *type* column: deciduous or evergreen (for woody plants) and forb or graminoid (for herbaceous plants). For the *N-fixer* item we recommend consulting the *NodDB* database (Tedersoo et al., 2018). Units for the sample *amount* column are in g, for the nutrients and fibers in percentage and for *SLA* (specific leaf area) in mm² mg¹. When litter quality traits are not provided in the original paper, they can be obtained upon request from the *TRY* database (Kattge et al., 2020). We created a template for the *initConditions.csv* and a *README.md* file with further instructions in the *data* folder. Special attention should be made to the *material* section of the *README.md* file, for litter substrates are highly variable among studies and this is key for database consistency. In Fig. 1, we present a flowchart with the full process of entry submitting for potential contributors.

We generated a Global Aridity Index (GAI) map with the study sites from the database. We retrieved GAI data from the Consortium for Spatial Information global climate data sets (CGIAR-CSI; Trabucco & Zomer 2018). This index is calculated after dividing mean annual precipitation by mean annual reference evapotranspiration. The raster data set we used is based on WorldClim2 database (Fick & Hijmans, 2017). We chose this dataset because it encompasses a relatively long period of time (from 1970 to 2000) and it has a high spatial resolution (~1 km at the Equator). We then classified each study site by its GAI value as hyper-arid (0 - 0.05), arid (0.05 - 0.2), semi-arid (0.2 - 0.5), dry sub-humid (0.5 - 0.65) and humid (0.65<; United Nations Environment Programme, 1997). Complementarily, to explore how representative our sites in *aridec* are of the whole climatic range of aridlands, we first made a random point-sampling of 6793 pixel units separated at least 1 km away from each other within the range of aridlands (GAI: 0 - 0.65). For each sample, we averaged mean monthly temperatures from WorldClim2 to obtain mean annual temperature values. We did the same for our *aridec* coordinates and plotted both sets of data together to evaluate how well aridlands are represented in our database. We used the QGIS software to process data and create a map (QGIS Development Team, 2021).

2.2 Model fitting and collinearity analysis

A central application of this database is the development of models of litter decomposition for aridlands. In an attempt to explore what are the most appropriate model structures to integrate with data from the database, we selected different structures of decomposition models based on recent theory of models of organic matter decomposition (Sierra and Müller, 2015). These model structures are already implemented in the *SoilR* package (Sierra et al., 2012), and we provide here an interface between our database and this R package. *SoilR* is a modelling framework that contains a wide set of functions and tools to model soil organic matter decomposition within the R computing platform (R Core Team, 2020).

Organic matter decomposition in *SoilR* is represented by systems of linear differential equations that generalize most compartment-based models. A simple general structure to represent litter decay with no inputs follows Equation 1:

$$\begin{vmatrix} \frac{dC(t)}{dt} = AC(t) \\ (1) \end{vmatrix}$$

235

240

195

200

$$C(t) = \stackrel{\cdot}{\iota}_{C_{pool 1}}, ..., C_{pool m}]^{\mathrm{T}}$$

$$A = \begin{bmatrix} -k_1 & \cdots & a_{1i} \\ \vdots & \ddots & \vdots \\ a_{j1} & \cdots & -k_m \end{bmatrix}$$

Where C(t) is a $m \times 1$ vector with m pools of litter mass observed at time t, and A is a square $m \times m$ matrix that contains decomposition rates (k_m) for each pool and transfer rates (a_{ij}) between them. These different pools may correspond to different ways in which the quality of the litter is expressed in different studies. For example, they may correspond to different compounds obtained from a specific extraction method (e.g., water soluble sugars, or acid detergent lignin), or they can be defined by general decay classes such as fast and slow decay compounds. These pools have different decomposition rates, pool 1 being the fastest decomposing pool and pool m being the slowest. The linear dynamical system represented by Eq. (1), has many different solutions, but we are only interested in the solution that satisfies

$$C(t = 0) = C_0 = total \ C_0 \cdot p_1, ..., total \ C_0 \cdot p_m]^T$$
 —(2)

where C_0 is a $m \times 1$ vector with the value of initial litter mass content in the different compartments m. Total C_0 is set to be 100% in *SoilR* for our database and resulting parameters p_m are the initial proportions of litter in m pools. Using this framework, we chose to fit a total of five different models with an increasing number of parameters (Table 1).

Model structure	m	Parameters
Two-pool parallel	2	k_1 , k_2 , and p_1
Two-pool series	2	k_1, k_2, p_1 , and a_{21}
Two-pool with feedback	2	k_1 , k_2 , p_1 , a_{21} , and a_{12}
Three-pool parallel	3	k_1, k_2, k_3, p_1 , and p_2
Three-pool series	3	$k_1, k_2, k_3, p_1, p_2, a_{21}, $ and a_{32}

Table 1: fitted model structures and parameters. m: number of C pools. k₁, k₂, k₃: decomposition rates of pools 1, 2 and 3, respectively. p₁, p₂: initial proportions of C in pools 1 and 2, respectively. a₂₁: transfer rate from pool 1 to pool 2. a₁₂: transfer rate from pool 2 to pool 1. a₃₂: transfer rate from pool 2 to pool 3.

For this set of models, we performed an identifiability analysis following the procedure described by Soetaert & Petzoldt (2010). Non-identifiability is a common issue with inverse-modelling approaches. It is a type of model overparameterization that makes precisely determining parameter values virtually impossible, thus parameters are "non-identifiable". When parameters are functionally related, changes in one parameter can be compensated by changes in others. This produces different parameter sets that have similar probability distributions, thus the inability to determine a single parameter set for the model (Sierra et al., 2015). Analyzing for parameter identifiability in models fitted with aridec data allowed us to assess which model structures are the most appropriate to use in this context.

This identifiability analysis is based on the calculation of the collinearity index (Brun et al., 2001). This index is a measure of the degree to which changes in one parameter are compensated by changes in other parameters for a certain model structure and data set. We used the *modCost* function from the *FME* R package to first adjust a model cost function (Soetaert and Petzoldt, 2010). This function estimates weighted residuals of the model output versus the observed data and calculates sums of squared residuals, according to the formula:

$$res_{k,l} = \frac{Mod_{k,l} - Obs_{k,l}}{error_{k,l} \cdot n_l}$$
(3)

where $Mod_{k,l}$ and $Obs_{k,l}$ are the modeled and observed values for any data point, k, of a variable l, respectively. $error_{k,l}$ is a weighing factor that makes the term non-dimensional.

The model cost function, together with a set of pre-set initial parameter values, is then used as an input to calculate a matrix of sensitivity functions using the *sensFun* function from *FME*. This function estimates the sensitivity of the model output to the parameter values using the expression:

$$275 \quad S_{ij} = \frac{\partial r_i}{\partial \Theta_j} \cdot \frac{w_{\Theta_j}}{w_{r_i}}$$

245

255

265

where $S_{i,j}$ represents each entry of the matrix, r_i are model residuals calculated from the cost function, Θ_j is a model parameter, w_{ri} is the scaling of r_i , and $w_{\Theta i}$ is the scaling of parameter Θ_i (Soetaert and Petzoldt, 2010).

The final step in this analysis is calculating the collinearity index *γ*. The *collin* function from *FME* uses the sensitivity matrix as an input to calculate *γ* for every combination of parameters. *γ* is defined as

$$\gamma = \frac{1}{\sqrt{\min\left(EV\left[\hat{S}^T\hat{S}\right]\right)}}$$
(5)

where

$$\hat{S}_{ij} = \frac{S_{ij}}{\sqrt{\Sigma_j S_{ij}^2}}$$
(6)

290

where \hat{S}_{ij} contains the columns of the sensitivity matrix that correspond to the parameters included in the set and EV estimates the eigenvalues. The collinearity index equals 1 if the columns are orthogonal, and the set is identifiable. The index equals infinity if columns in the sensitivity matrix are linearly dependent (Soetaert and Petzoldt, 2010). The interpretation of the collinearity index is thus: a change in the residuals caused by a change in one of the parameters can be compensated by a proportional change $1/\gamma$ in another parameter. For practical purposes, if $\gamma > 20$ the parameter combination is considered non-identifiable (Sierra et al., 2015).

For the identifiability analysis, we first selected a representative group of 30 entries from the database ranging from 3 to 19 time points (Table 2). The number of data points in time limits the number of parameters that can be fitted because it affects the number of degrees of freedom. Thus, models with more parameters require longer data sets. This meant that, a priori, not all entries could be used to fit all model structures. On the other hand, it is possible to test identifiability for restricted model versions, that is models with some of their parameters fixed to a known value. This implies there are less parameters to be determined, thus it allows to use shorter time series. The details of all the models tested are reported in Table 3. From this first analysis, we noticed that two pool parallel and series structure models with a restricted initial proportion of litter in pool 1 (p_1) were the two models more likely to meet identifiability with our data. Because of this, we tested collinearity for all the 184 entries in the database, but only for these two models and for the respective models with the full set of parameters, for comparison. R code for this analysis can be found in the *collinearity.R* script inside the *scripts* folder of *aridec*.

Feedback 6 5 15 390 - - - -

Table 3: Minimum number of time points in data sets fitted to each model structure T, number of parameters for each model structure P, number of data sets used for each model structure D, and possible number of combinations of parameters to identify with specific combinations of available data C.

2.3 Applied Example

Our collinearity analysis (see below) showed that although most entries could be used to fit two-pool parallel and series models with a fixed p_1 parameter (i.e., the initial proportion of litter in pool 1), this was dependent on each data set. Restricting the p_1 parameter is a sensible way of achieving identifiability because it is common to find information on litter lignin content in decomposition publications, and this can be used as an initial proportion value for the slow-decomposing litter pool (i.e.: p_2). Since

$$p_1 + p_2 = 1,$$
 (7)

then it is possible to estimate the p_1 as the complementary value of p_2 .

To give a practical example of what can be done with this database, we chose to fit these models using one of the entries where both the models were identifiable, and the initial proportion of litter lignin was available. Together with these models, we fit a simple one pool model for comparison. We used variable 2 (V2) from the Day2018 entry which corresponds to $Simmondsia\ chinensis\ (Link)\ C.\ K.\ Schneid.\ leaf\ litter\ decomposed\ under\ full\ sunlight\ treatment\ in the field\ (Day\ et\ al.,\ 2018). The initial proportion of lignin <math>(p_2)$ was 0.09. We used the Bias Corrected Akaike Information Criteria (AICc) to assess model fit (Shumway and Stoffer, 2017).

3.1 Data overview

Figure 2: GAI map generated using data from WorldClim 2 database. Hyper-arid: 0 - 0.03. Arid: 0.03 - 0.2. Semi-arid: 0.2 - 0.5. Dry sub-humid: 0.5 - 0.65. Humid: 0.65<. Points Green points represent study sites in the aridec database. Colors represent different ecosystems as reported in the original publications.

The 184 studies in the database included data for 212 unique study sites around the world. Twenty-four of these sites were repeated in two or more studies. According to the GAI , ~3.6% of sites were classified as hyper-arid (0 - 0.05), ~35.9% as arid (0.05 - 0.2), ~43% as semi-arid (0.2 - 0.5), ~6% as dry sub-humid (0.5 - 0.65), and ~12% as humid (0.65<). We recognize humid sites do not classify as aridlands, but we included them nonetheless because these sites had marked dry seasons according to the original publications. A total of 33 countries were represented in our database. Top-five countries with the biggest amount of study sites were China (58 sites), USA (49 sites), Argentina (32 sites), Israel (22 sites) and Brazil (12 sites). Most sites in the database correspond to arid regions were mean annual temperatures are above zero degrees Celsius, with a very low representativity of colder regions (Fig. 3)

Out of the 184 database entries, we retrieved 1752 series of litter mass loss over time. The oldest publication in the database is from 1975 and the newest from 2021, and there has been a considerable growth in the number of publications per year (Fig. 4a). Study duration in the database ranged from 18 days to 10 years, with a median of 365 and a mean of 430 days (Fig. 4b). The number of sample harvests from the field went from 2 to 23, with a mean of ~6 and a median of 5 (Fig. 4c). Sampling frequency ranged from 0.08 to 11.1 samples per month, with a median of 0.4 and a mean of 0.8 samples per month (Fig 3d). Elevation at the study sites varied from -375 to 4000 m a.s.l., with median and mean values of 557 and ~811 m a.s.l., respectively (Fig. 4e). Mean annual temperature ranged from -0.45 to 29.5 °C at the study sites with a mean value of 14.9 °C and median of 15.6 °C (Fig. 4f). Mean annual precipitation in *aridec* ranged from 2 to 1700 mm, with median and mean values of ~375 and ~494 mm, respectively (Fig. 4g). Out of all sites, 23 % were reported by the authors to be deserts, 17 % forests, 16 % agroecosystems, 12% grasslands, 10 % shrublands, 10 % steppes, 8 % savannas, 2 % coastal ecosystems, and 2 % urban sites (Fig. 4h).

Figure 3: Climate representativity of the aridec database. GAI plotted against Mean annual temperature (°C). WorldClim2 points were generated via a random sampling of 6793 pixels in QGIS. All data comes from WorldClim2 database. Horizontal dashed lines represent the breaks in GAI between aridland categories: hyper-arid, 0 - 0.03; arid, 0.03 - 0.2; semi-arid, 0.2 - 0.5; dry sub-humid, 0.5 - 0.65; humid, 0.65<.

3.2 Identifiability analysis

Figure 5 shows results from the first identifiability analysis carried out on a subset of 30 entries. Here we can compare how entries with equal number of time points behave under each model structure. For the two-pool parallel model structure four parameter combinations were compared: a full three parameter model and three alternative models with one restricted parameter each. There were 30 points for the full model with 62.1 % of values below the collinearity index γ = 20 threshold, i.e.: almost 40 % of the models were not identifiable. For the models restricted to two parameters, 95.6 % out of the 90 models compared were identifiable. When specifically looking at the model with a restricted p_I value, 100 % of the models were identifiable. This was expected because usually the fewer the parameters to be estimated, the lower the collinearity in models.

360

The two-pool series model structure analysis included: a full four parameter model and ten alternative models with one or two restricted parameters each. From a total of 25 full parameter models, 48 % were identifiable according to their γ values. Out of 150 models with two restricted parameters, 94.7 % of models were identifiable, while for models with only one restricted parameter, 68.3 % of models were identifiable. When specifically checking for the collinearity index in models with a restricted p_1 parameter, 84.6 % of them were identifiable. The non-identifiable values in this last case

Figure 4: aridec data overview including number of publications per year (a), study duration in days (b), number of sample harvests (c), study sampling frequency as number of samplings per month (d), study site altitude in m a.s.l. (e), mean annual temperature in $^{\circ}$ C (f), mean annual precipitation in mm (g), and number of studies per type of land cover (h). Dashed lines represent the mean and dotted lines represent the median in each panel.

370

375

380

corresponded to four entries with four time points each. That means that 100% of models with >5 time points were identifiable for the restricted p_1 model version. This highlights the importance of having longer time series available for modelling.

The case of the two-pool model structure with feedback included: a full parameter model and 24 other model variants with one, two and three restricted parameters each. The analysis of 15 models with all five parameters showed 100 % of non-identifiable results. The results for the restricted model version with four parameters showed 100 % of non-identifiable models out of 75 data points, while only 4.7 % of the 150 data points with three parameters gave γ values

Figure 5: Collinearity index (γ comparison for different model structures using entries from aridec. γ values were \log_{10} transformed and horizontal lines at \log_{10} (20) denote the maximum value of γ for a model to be considered identifiable. Infinite γ values were not plotted. Each panel shows data for a different model structure. The number of entries from the database used for each model structure is reported in Table 3. Each point represents γ for a model structure fitted for a specific data set with different parameter combinations. The color scale for data points shows the number of data points in each data set (i.e.: the number of sampling dates plus the initial date). Values with >8 time points were grouped for easier interpretation. The number of model variants fitted for each model structure and database entry were: n=30 for the two pool parallel model with all three parameters and n=90 with one restricted parameter (a); n=25 for the two pool series model with all four parameters, n=150 with two restricted parameters, and n=75 with one restricted parameter (c); n=15 for the three pool parallel model with all five parameters, n=150 with two and three restricted parameters, n=250 with five restricted parameters, n=300 with four restricted parameters, n=230 with three restricted parameters, n=115 with two restricted parameters, and n=35 with one restricted parameter (e).

lower than 20. The analysis of the restricted model version with 2 estimated parameters generated 57.3 % of identifiable results out of 150 models.

385

When testing for the three-pool parallel model structure, we used one full model with five parameters and 24 model variations comprising from two to four parameters each. None of the full model data points showed collinearity index values lower than 20. Out of the restricted four parameter models only 34.7 % of them could be identifiable. When we specifically looked at the models where either p_1 or p_2 were fixed, none of them were identifiable. Restricted models

with three parameters produced a 68 % of identifiable results. Further, restricted models that only had *k* values were not identifiable. Finally, 89.3 % of models restricted to two parameters were identifiable according to our analysis.

The last model structure analyzed was the three-pool series structure which produced comparisons for models with all seven parameters, plus 118 other model variants with different restricted parameters. None of the models with all seven parameters were identifiable. Only 5.7 % of the models with six parameters were identifiable, none of which corresponded to the models were either p_1 or p_2 were fixed. Models restricted to five parameters produced 10.5% of identifiable results. Specifically looking at models with both fixed p_1 and p_2 , 100 % of those were not identifiable. Restricting models to four parameters generated 28 % of results with γ > 20. Models with three estimated parameters produced 54.9 % of identifiable results. Lastly, 84.8 % of models restricted to only two parameters were identifiable. Because two-pool parallel and series models with a fixed p_1 parameter showed the highest percentage of identifiable cases in this first analysis, we did a second test with the whole database for these models and for their respective full-parameter versions for comparison (Fig. 6). For the two-pool parallel model with the full set of parameters 58.7 % of entries were identifiable, whereas restricting the p_1 parameter yielded 99.5 % of identifiable entries. For the more complex series models the percentages of identifiable entries were much lower, with only 20.1 % for the restricted version and none identifiable cases for the version with a full set of parameters. Clearly, restricting the number of parameters to be estimated decreases collinearity, but the results are highly variable and dependent on each particular data set.

Figure 6: Collinearity index (γ) comparison for four different model structures using the entire database. The full parameter combination includes k_1 , k_2 , p_1 and a_{12} (the latter only for the series model). The restricted parameter combination excludes p_1 . γ values were \log_{10} transformed and horizontal lines at \log_{10} (20) denote the maximum value of γ for a model to be considered identifiable. Infinite γ values were not plotted. Each panel shows data for a different model structure. Each point represents γ for a model structure fitted for a specific data set with different parameter combinations (n = 184, for each model structure). The color scale for data points shows the number of data points in each data set (i.e.: the number of sampling dates plus the initial date). Values with >8 time points were grouped for easier interpretation.

400

405

The previous analysis of collinearity index (Fig. 6) shows that from the proposed model structures to be fitted, our data in most cases can be fitted to two pool parallel and series structure models with a restricted initial proportion of litter in pool 1, aside from single pool models. Figure 7 shows the results from the simulation of the dynamics of organic matter loss from leaf litter fitted from the Day2018 entry. The one-pool model showed how a single reservoir of organic matter from leaf litter decomposed at a k rate of 0.0142 month⁻¹ (Fig. 7a). At the end of the almost three-year period the remaining percentage of total organic matter was 61.02 %. The two-pool parallel model showed a fast-decomposing organic matter pool with a k_1 of 0.0158 month⁻¹ (Fig. 7b). This pool went from representing 91 % of total organic matter to 52.4 % after almost three years. On the other hand, the slow-decomposing pool, which we defined as the initial lignin content of litter, had a value of k_2 of 1.5 x 10^{-16} month⁻¹. We defined this pool as 9 %, and it remained unchanged after two years, which was expected from a k_2 of nearly zero. Lastly, the two-pool series model showed a fast-decomposing

pool with a k_1 of 0.11 month⁻¹ (Fig. 7c). This pool went from 91 % of total organic matter to 1.7 % at the end of the experiment. The slow-decomposing pool in this case had a k_2 of 0.02 month⁻¹. This model also had a transfer coefficient from the fast-decomposing pool to the slow pool of 1 (i.e.: 100 % of organic matter in the fast pool that decomposed in a month transformed into more recalcitrant forms, adding to the slow-decomposing pool). Then, the slow decomposing pool went from 9 % at the start of the simulation to 54.08 % after almost three years. Judging by their AICc values, the three models were similarly supported by the data.

Figure 7: Comparison of three different decomposition model structures fitted with time series of organic matter loss from the Day2018 entry: one pool model (a), two pool model with a parallel structure (b), two pool model with a series structure (c). 435

4.1 The aridec database

The *aridec* database is a comprehensive database with a wide range of information on decomposition studies from aridlands worldwide, which includes litter mass loss data, litter traits and experimental design information. Our exhaustive bibliographic search gave us close to two hundred papers that fulfilled our criteria. Notably, we did not limit

our work to studies published in English: *aridec* includes also papers in Spanish, Portuguese, and Mandarin. This widens the scope of our work to achieve a more inclusive database.

From a geographic perspective, study sites included in *aridec* cover most of the main aridlands of the world (Fig. 2). As expected, countries like China, USA, and Argentina, had the largest number of studies, which might be related to the extension of aridlands in these countries, since China has 6.07 x 10⁶ km² of drylands (Huang et al., 2019), and around 40% and 69% of USA and Argentina territories are considered as drylands, respectively (Verbist et al., 2010; White and Nackoney, 2003). In contrast, some of the biggest deserts in the world, such as the Sahara, the Kalahari, the Australian Outback, and the Arabian desert are underrepresented, if not absent, in our database. Future efforts should focus on this information void, and the *aridec* database will be available to include these coming studies in our framework.

Study sites in the database represent a big part of the climate range where aridlands occur, from hyper arid deserts to dry sub-humid ecosystems (Fig. 2). Some of the study sites (~12%) were classified as humid according to the GAI. We chose to include them because those studies reported marked dry seasons at the study sites and focused on seasonal patterns of litter decomposition. The range of climatic variables such as mean annual temperature and precipitation, physical variables like altitude, along with land cover types are also very well represented in this database (Fig. 4). This wide representativity of climates in *aridec* is a crucial asset if the database is to be used to answer global-scale questions. Nonetheless, dry sub-humid lands but mainly hyper-arid deserts are the least represented in the database, suggesting more studies should be developed in these areas. Moreover, there is a void in the colder end of the climatic range of aridlands (Fig. 3). This might be related to the lack in *aridec* of sites of ecosystems like tundra where the GAI is mostly low, but a bibliographical search like ours could not retrieve the studies in those areas. There is clearly big room for expanding our database and increasing its potential applications.

One of the advantages of the *aridec* database is that its files are compatible with R and, specifically, with the *SoilR* library (Sierra et al., 2012). In addition to the fact that this database is an open-source and open-code project, there is huge potential for broadening the extent of the information in *aridec* and for developing code to work with it. Nonetheless we should mention that the formats included in the database are not R-exclusive and can be used with most commonly available software. YAML files can be read and edited from any text processor and CSV files can also be opened with any spreadsheet software. Although statistical analysis on R scripts cannot be used elsewhere, raw data itself can be freely processed with any statistical software.

The *aridec* database can be used on its own, but we recommend complementing our information with other publicly available databases to expand the application possibilities. Metadata are not always fully reported in publications, so it is possible to fill these gaps with climate and altitude data from databases like NASA Prediction of Worldwide Energy Resources (POWER; NASA Langley Research Center (LaRC)). Leaf litter traits are a big part of the database that are sometimes poorly reported in publications. A general source of litter traits data can be obtained upon request from the TRY database (Kattge et al., 2020). Another more specific source of information is the NODdb where nodulating-N-fixing plant genera are detailed (Tedersoo et al., 2018).

4.2 Model fitting within aridec

440

470

475

480

485

490

Based on our collinearity analyses (Fig. 5 and 6), we suggest that before fitting any models to our data it is crucial to check the identifiability of the parameters with each database entry. We assume that all entries can be fitted to a onepool model since there is only one parameter to estimate. As for the more complex models, the situation is highly dependent on which data entry is being used. For instance, although most entries could be used to fit two-pool models with parallel and series structures, there are some exceptions. Another example can be seen in Figure 5b, where one dataset of more than eight points was not identifiable for a model with all four parameters. Besides collinearity, the number of degrees of freedom will restrict which models can be fitted to the data so these two aspects should be considered together. As models get more complex, we had to progressively exclude entries with less time points because they did not have enough degrees of freedom. As a concluding remark, the results in Figures 5 and 6 are not to be interpreted as how those models perform in general, but how they perform with the specific data in aridec. That is why weMoreover, in most cases fitting these models is only possible by restricting the parameters estimated to only decomposition constants and transfer coefficients. We suggest restricting models to these parameters because it is more likely to find data on initial proportion of lignin or cellulose to be used as proxies for parameters p_{\pm} or p_{2} . Not only might they be more difficult to find in the literature but estimating values for decomposition constants and transfer coefficients might be altogether a better use of this database. Further, we recognize that for some specific combinations of parameters and data sets the more complex models might be identifiable (data points below the log₁₀ (y=20); Fig. 5). Besides collinearity, the number of degrees of freedom will restrict which models can be fitted to the data so these two aspects should be considered together. We provide an R script in the database to test collinearity for individual data sets. Moreover, in most cases fitting these models is only possible by restricting the parameters estimated to only decomposition constants and transfer coefficients. We suggest restricting models to these parameters because it is more likely to find data on initial proportion of lignin or cellulose to be used as proxies for parameters p_1 or p_2 . Not only might they be more difficult to find in the literature but estimating values for decomposition constants and transfer coefficients might be altogether a better use of this database. Further, we recognize that for some specific combinations of parameters and data sets the more complex models might be identifiable (data points below the log_{10} (γ =20); Fig. 5).

Again, interconnection between datasets like *aridec* and others like TRY (Kattge et al., 2020) is a key workaround to the collinearity problem by providing data for parameter restriction (Sierra et al., 2015). We recognize limitations in data available from field studies ultimately restrictlimits our capability to fitmodel more complex models (Brun et al., 2001). This limitation can have further implications if we consider the proportion of identifiable data sets per ecosystem type or level of aridity. For example, semi-arid and dry sub-humid ecosystems show the lowest proportion of identifiable data sets for a two-pool parallel model with all parameters (data not shown). This would lead to an under-representation of some aridlands because of a lack of suitable data available. Moving forward, new decomposition studies should consider making more measurements and including data on litter initial chemical quality, as well as expanding studies to less represented climates and ecosystems. This will allow for the detection and modeling of finer-scaled dynamics of organic matter (see Appendix A).

The applied example in Fig. 7 serves as a glimpse of the potential of this database. Choosing which model to fit with decomposition data is not a minor question. For instance, none of the three models was supported as the best model from their AICc, which suggests they all must be considered when making conclusions from this simulation (Anderson and Burnham, 2004). Whether a time series has a better fit with one model or another depends mostly on mass loss dynamics that were captured by the experimental design. While longer datasets can generally be fitted with more complex models, if the overall mass loss dynamics fit better for a one-pool model, higher model complexity will not be chosen using AIC. To be considered also Depending on our input data one could end up choosing different model structures from their AICc values. Nonetheless, ecological theory may come into play here instead of applying purely statistical reasoning. As has been pointed out recently, litter decomposition is not as much a process of "what is lost" but more of "what is left" (Prescott and Vesterdal, 2021). A balance between statistical fit and theoretical support should be found when choosing which model is best for each study case.

The *aridec* database is available for open access and download at github.com/AgustinSarquis/aridec (Sarquis et al., 2022). Our hope is that newer studies on dryland litter decomposition will be added to the database by new collaborators (see Appendix A). It is important to follow our user guidelines to ensure consistency, all of which are available in the database itself. File templates for uploading new entries to the database are given and further details can be found in them. Additionally, users will find in the database a *README* file, scripts to test file consistency and many examples on how to apply functions and to fit models using R code.

To our knowledge, the *aridec* database is unique. Other databases that focus on land C studies include the Soil Incubation Database (SIDb; Schädel et al., 2020); a peatland productivity and decomposition parameter database compiled by Natural Resources Canada (Bona et al., 2018); and the Chilean Soil Organic Carbon Database (CHLSOC; Pfeiffer et al., 2020). Although they all intend to assess questions related to C budgets in terrestrial ecosystems to some extent, not all of them present decomposition data (i.e.: Pfeiffer et al., 2020). Moreover, only SIDb (Schädel et al., 2020) and *aridec* contain time series of organic matter loss. This is a unique asset that allows for future studies to make new assessments of decomposition without having to worry about inconsistencies in the calculation of *k* parameters. Finally, none of these other databases is centered around plant litter decomposition in aridlands like *aridec*.

The extent of the information included in *aridec* in addition to its open-science approach makes it a great platform for future collaborative efforts in the field of aridland biogeochemistry. In this sense, the main purpose of this database is to further our understanding of C dynamics at the earth system level. Complete datasets like *aridec* are necessary to test which model structures and parameters best explain decomposition processes and to help develop more realistic representations of the global C cycle in drylands (Luo et al., 2016). Further, additional parameters could be used to test the importance of mechanisms that are relevant in arid lands but are underrepresented in the literature. Studies on processes like photodegradation (Adair et al., 2017) could be expanded to a wider geographical range and to soil processes thanks to the representation of sites in *aridec* using the *SoilR* framework (Sierra et al., 2012). Another potential application of our database is to combine ecological data with climatic data in Earth System Models, which is a promising framework to assess future global change stresses and their effects on the biosphere (Bonan and Doney, 2018).

Recommendations for future decomposition field studies

Compiling published studies for the database led us to come up with a set of recommendations that scientists working on field decomposition studies may take into consideration if order to incorporate future entries in *aridec*.

- Coordinates: From the database, 7.6 % of entries had errors in their site coordinates and 8.7 % had no coordinates at all. That means that for 16.3 % of entries we had to either look for coordinates in other publications or search for the approximate location on Google Earth. Exact coordinates are a must for a study to be incorporated in geospatially explicit databases. Since nearly half of the problematic entries corresponded to typographic errors, we recommend

authors and reviewers to check for the correctness of coordinates. Further, we suggest providing coordinates as exact as possible and to avoid using vaguely broad coordinates (e.g., reporting coordinates of the closest town to the study site).

- Soil classification: Out of all entries only 29.3 % reported soil taxonomy from the study site correctly. An additional 7.1 % of entries provided a classification for the soil, but they did not specify the classification system they used (i.e. FAO, WRB, or USDA). This is important because names of soil taxa are not always exclusive to a single classification system and their definitions are most unlikely interchangeable (Hughes et al., 2017). For the most part of studies this information might not be available, but for those where it is we suggest reporting it. Otherwise, making inference from soil types would be impossible.
- Mesh transmittance: Only 13.6 % of entries in *aridec* had measured the light transmittance of the mesh they used to construct litter bags. Light interception by mesh can be very high: as much as 50% of total radiation, photosynthetically active radiation, or ultra-violet radiation, as seen in our database. Considering the established importance of sunlight as a decomposition driver in aridland ecosystems (Austin et al., 2016), studies with mesh materials that block a significant proportion of light might be inducing unwanted effects, and underestimating effects of photodegradation. We recommend, if possible, choosing high-transmittance materials (the highest in our database has a 95 % transmittance of total radiation), measuring mesh transmittance and reporting these values in the manuscript.
- Sampling dates: The matter of choosing when to pick up samples from the field is complex. Ideally, the total amount of sampling dates and the amount of time between those dates should only depend on the hypothesis. The reality is that 565 logistics has a huge impact on what scientists do, especially for field ecological studies. How researchers chose to set their sampling dates will determine the scale of the patterns that they will be able to detect from their experiments. For example, in some aridlands where decomposition is very slow, litter might take years to fully decompose, and short experiments are not able to capture this part of the process. Most of the studies in *aridec* lasted around a year, with only a few studies lasting longer (Fig. 4b). Further, in some systems leaching can have a big impact during the first days to 570 weeks of decomposition, and more frequent sampling at the beginning of the experiment may allow to detect this. In our database, most studies made measurements less than once a month (Fig. 4d), meaning that only monthly to yearly processes could be detected. These limitations extrapolate to modelling challenges: it is not possible to fit data to models that represent patterns that went undetected due to the study design. To accurately estimate decomposition rates (k), it is thought that litter at the last sampling date needs to have lost at least 50% of mass. As such, this suggests that 575 the number of samplings and extension in time of the study should reflect these goals. We suggest that researchers are aware of all these issues, and that also they have enough pickups to actually be able to calculate slopes of the relationships, which increases enormously the power of inference.
- Corrections of mass loss measurements: After collection from the field, samples in most cases carry with them moisture and inorganic matter from the site. This of course can underestimate measurements of litter mass loss. Once in the laboratory, samples should be cleaned of any extraneous material and their moisture content measured. After this, a portion of each sample should be used for quantifying the proportion of ashes (Harmon et al., 1999). This should be done as well for samples that were not taken to the field and are used for measurements of initial litter traits. All mass loss analysis should be done on an oven-dried ash-free basis.
- Time series: A large number of studies could not be included in *aridec* because they only published decomposition rates. As much as this is a common practice, it limits the possibilities for incorporation into databases like ours and for further analysis that might need temporal dynamics data as input. We suggest not only providing averaged values of mass loss over time, but also raw data as supplemental material. This helps bridge the reproducibility gap in ecological studies and represents a step forward to an Open Science approach (Hampton et al., 2015).
- Initial litter quality: The characterization of litter chemical and physical traits at the beginning of experiments is an important tool for answering research-specific questions of decomposition studies. However, from our results it was evident that these initial litter traits are also useful to decrease model collinearity (Fig. 6). Particularly, the initial content of litter components that constitute a big part of total mass like cellulose, acid detergent lignin or water-soluble sugars can be used as proxies for the initial proportion of litter mass in pools of different decomposition rates. Unfortunately, not even half of the studies in *aridec* reported initial lignin content for each litter type. We managed to complete up to 48 % of lignin content data by averaging across database entries of the same species and by requesting data from TRY database. To our surprise, we only found lignin values for 3 out of 236 litter types that we searched in TRY database. This leads us to suggest that not only should authors measure and report these characteristics of interest, but they should also contribute their data to open access databases from which other scientists can benefit.

Data availability

All scripts necessary to obtain figures in this publication are included in the database inside the "scripts" folder.

Conclusions

- The *aridec* database is a comprehensive database with a wide range of information on decomposition studies from aridlands worldwide. Study sites included in *aridec* cover most of the main aridlands of the world and represent well the range of climatic conditions that characterize aridlands. We found that although many studies have been conducted in arid lands, there is low representativity in cold arid regions, where new studies should be performed to obtain a more comprehensive understanding of decomposition in arid lands worldwide.
- Our identifiability analysis showed that the information content in litter decomposition studies can only inform simple models with one or two pools. More complex models can be obtained for datasets with multiple data points, and a well characterized initial litter mass quality (such as lignin or cellulose content), which will result in low collinearity index values and will allow for enough degrees of freedom.
- One of the best assets of the *aridec* database is that its files are compatible with R and the SoilR package, making collaborative work more direct and approachable. Although our application suggestions are based on the use of the SoilR package, we recognize that other approaches might be suitable for the use of this database.
 - To our knowledge, the *aridec* database is unique and the extent of the information included here in addition to its open-science approach makes it a great platform for future collaborative efforts in the field of aridland biogeochemistry.

Authors contributions:

ATA and CS conceptualized this project. AS and IS curated the data. AS and CS created the methodology. AS analyzed the data. ATA and CS acquired funding for this project. CS supervised this project. AS wrote the original draft of this manuscript. CS, ATA, and IS reviewed and edited the manuscript.

Competing interests

The authors declare that they have no conflict of interest.

630 Acknowledgments

C. Casas, M. Jardón and N. Moreno for making a revision of an early version of the manuscript. We also thank two anonymous reviewers who helped upgrade the quality of this manuscript.

Financial support

Financial support for the project came from the University of Buenos Aires (UBACyT 2020), the Agencia Nacional de Promoción Científica y Tecnológica (ANPCyT; projects PICT 2015-1231, PICT 2016-1780, and PICT 2019-02645). AS was funded by the University of Buenos Aires (UBACyT 2018; Res. N° 1245/18) and the German Academic Exchange Service (DAAD; Research Grants - Short-Term Grants program 2021, ID: 57552337).
