Abstract. Snow depth is a key parameter in climatic and hydrological systems. Passive microwave remote sensing, snow process model and data assimilation are the main methods to estimate snow depth in large scale. The estimation accuracies strongly depend on input of snow parameters or characteristics. Because the evolving processes of snow parameters vary spatiotemporally, and are difficult to accurately simulate or observe, large uncertainties and inconsistency exist among existing snow depth products. Therefore, a comprehensive experiment is needed to understand the evolution processes of snow characteristics and their influence on microwave radiation of snowpack, to evaluate and improve the snow depth and SWE retrieval and simulation methods. An Integrated Microwave Radiometry Campaign for snow (IMCS) was conducted at the Altay National Reference Meteorological station (ANRMS) in Xinjiang, China, during snow season of 2015/2016. The campaign hosted a dual polarized microwave radiometer operating at L, K and Ka bands to provide minutely passive microwave observations of snow cover at a fixed site, daily manual snow pit measurements, ten-minute automatic 4-component radiation and layered snow temperatures, covering a full snow season of 2015/2016. The measurements of meteorological and underlying soil parameters were requested from the ANRMS. This study provides a summary of the obtained data, detailing measurement protocols for microwave radiometry, in situ snow pit and station observation data. A brief analysis of the microwave signatures against snow parameters is presented. A consolidated dataset of observations, comprising the ground passive microwave brightness temperatures, in situ snow characteristics, 4-component radiation and weather parameters, was achieved at the National Tibetan Plateau Data Center, China. The dataset is unique in providing continuous daily snow pits data and coincident microwave brightness temperatures, radiation and meteorological data, at a fixed site over a full season. The dataset is expected to serve the evaluation and development of microwave radiative transfer models and snow process models. The consolidated data are available at

41 <http://data.tpdc.ac.cn/zh-hans/data/df1b5edb-daf7-421f-b326-cdb278547eb5/> (doi:
42 10.11888/Snow.tpdc.270886) (Dai, 2020).

44 **Key words:** Snow, Microwave radiometry, Snow pit, Experiment

45 **1 Introduction**

46 Seasonal snow cover plays a critical role in climate and hydrological systems (Cohen, 1994; Ding
47 et al., 2020; Barnett et al., 2005; Immerzeel et al., 2010) by its high albedo, thermal insulation, fresh
48 water reserves and its phase change processes. Snow cover can be accurately identified by optical remote
49 sensing. However, the snow surface albedo is controlled by snow characteristics (Aoki et al., 2003 and
50 2000), and variations in snow characteristics cause uncertainties in albedo estimation. Snow depth and
51 snow water equivalent (SWE) are currently estimated using passive microwave at global and regional
52 scales (Pullianen et al., 2020; Tedesco and Narvekar, 2010; Jiang et al., 2014; Che et al., 2008). Although
53 several global and regional snow depth and SWE products have been released, large uncertainties exist
54 in these products because of the spatio-temporal variations in snow characteristics (Xiao et al., 2020;
55 Mortimer et al., 2020; Che et al., 2016; Dai et al., 2012; Dai and Che, 2022). Therefore, the observation
56 of electromagnetic and physical parameters of snowpack are necessary to improve understanding of the
57 electromagnetic radiation process of snowpack to enhance the estimation accuracy of snow surface
58 albedo and snow depth.

59 To evaluate and improve snow depth and SWE retrieval methods from passive microwave remote
60 sensing observations and to combine remote sensing technologies with modeling and data assimilation
61 methods to produce the most accurate products, a few large or systematic experiments or campaigns have
62 been conducted on electromagnetic and physical characteristics measurement of snow cover. **These**
63 **experiments are summarized in table 1.** The Cold Land Processes Field Experiment (CLPX)
64 (<https://nsidc.org/data/clpx/index.html>), one of the most well-known experiments, was carried out from
65 winter of 2002 to spring of 2003 in Colorado, USA (Cline et al., 2003). During the campaign, snow pits
66 were collected in February and March of 2002 and 2003 to coincide with airborne and ground remote
67 sensing observations. NASA SnowEx campaign (<https://nsidc.org/data/snowex>) was conducted in 2017
68 in Colorado to test and develop algorithms for measurement of SWE in forested and non-forested areas
69 by providing multi-sensor observations of seasonally snow-covered landscapes (Brucker et al., 2017).
70 The campaign is still ongoing and will be conducted in other areas with different snow conditions. In
71 northern Canada, mobile sled-mounted microwave radiometers were deployed in forest, open and lake
72 environments from November 2009 to April 2010 and snow characteristics within the footprints of
73 radiometers were measured to improve understanding the influence of snow characteristics on brightness
74 temperatures (Derksen et al., 2012; Roy et al., 2013). These microwave experiments were of mobile
75 observation. In these experiments, there were multiple observation sites for different land cover, but
76 relative short temporal range. The snow pit observations were used to evaluate snow microwave emission
77 model in different land cover (Tedesco and Kim, 2006; Royer et al., 2017), but they did not exhibit the
78 evolution of snow parameters.

79 In the Arctic region, the Nordic Snow Radar Experiment (NoSREx) campaign was conducted at a
80 fixed field in Sodankylä, Finland, during 2009 ~ 2013 (Lemmetyinen et al., 2016). This experiment
81 provided a continuous time series of active and passive microwave observations of snow cover at a
82 representative location of the Arctic boreal forest area spanning an entire winter season and matched

83 snow pit observations were made weekly. In Asia, snow pit work at 3 or 4 day intervals was conducted
 84 simultaneously with radiation budget observations during winter of 1999/2000 and 2000/2001 to analyze
 85 the effects of snow physical parameters on albedo (Aoki et al., 2003). The NoSREx and Japan radiation
 86 experiments were fixed field observation, which provided longer time series of data than CLPX and
 87 SnowEx. These experiments were conducted in deep snow areas, and the weekly observation could
 88 reflect general evolution process of snow characteristics but might miss some key details that occur at
 89 sub-weekly scales. In the Tibetan plateau with shallow snow cover, multiple years of microwave
 90 radiometry observation at L band were conducted to study passive microwave remote sensing of frozen
 91 soil (Zheng et al., 2019, 2021a and 2021b). However, in the long term series of experiment, no snow pit
 92 was measured and the microwave radiometry observation was performed at L band which is insensitive
 93 to snowpack.

94 **Table 1 Summary of existing experiments for microwave and optical radiation and physical features of**
 95 **snowpack**

Campaign	Location	Temporal range	Observation content
CLPX	Different sites in Colorado,	February and March of 2002 and 2003	Inconsecutive multiple sensor observation, including microwave radiometry over snow, and matched snow pit measurements were conducted at different sites with short temporal range.
SnowEx-year 1	Grand Mesa, and Senator Beck Basin, Colorado	February of 2017	Inconsecutive multiple sensor observation, including microwave radiometry over snow, and matched snow pit measurements were conducted at different sites with short temporal range.
CMRES ¹	Mobile observation at Forest, open and lake in the northern Canadian region	November of 2009-April of 2010	Mobile microwave radiometry and snow pit observation within footprint of radiometer. Short temporal range and inconsecutive observation
NoSREx	Fixed site in Sodankylä, Finland	Snow season during 2009-2013	Consecutive microwave radiometry and SAR observation over snow, and weekly snow pit measurement
JERBS ²	Fixed site in Japan	Snow season during 1999-2000	Consecutive optical radiation observation over snow and consecutive snow pit measurement at 3 or 4-day interval.
IMCS	Fixed site in China	November of 2015-March of 2016	Consecutive microwave radiometry and optical radiation observation, and consecutive daily snow pit measurements.

96 Note: ¹CMRES: Microwave radiometry experiment on snow cover conducted in northern Canada

97 ²JERBS: Experiment of radiation budget over snow cover in Japan

98

99 To understand the evolution of snow characteristics and their influence on passive microwave
 100 brightness temperatures and radiation budget, an integrated experiment on snow was conducted during a

101 full snow season, in Altay, China. The experiment was designed to cover periods from snow-free
102 conditions to eventual snow melt-off during 2015/2016. The microwave radiometry measurements at L,
103 K and Ka bands for multiple angles were complemented by a dual-polarized microwave radiometer with
104 4-component radiation and daily in situ observations of snow, soil and atmospheric properties, using both
105 manual and automated methods. The data of electromagnetic and physical parameters were further
106 consolidated and organized to be easily read and utilized.

107 The dataset is unique in providing continuous daily snow pits data over a snow season at a fixed
108 site and matched microwave brightness temperatures, radiation and meteorological data. In the next
109 section, the experiment location, parameters, and parameter measurement protocols are described;
110 section 3 introduces the consolidated data which was released at the National Tibetan Plateau Data Center,
111 China; section 4 presents content of brightness temperature, 4-component radiation, snow pit data, soil
112 temperature and moisture, and meteorological data; section 5 discusses the possible applications and
113 uncertainties; and finally the conclusions are summarized in section 6.

114 **2 Description of experiment setup**

115 **2.1 Measurement location**

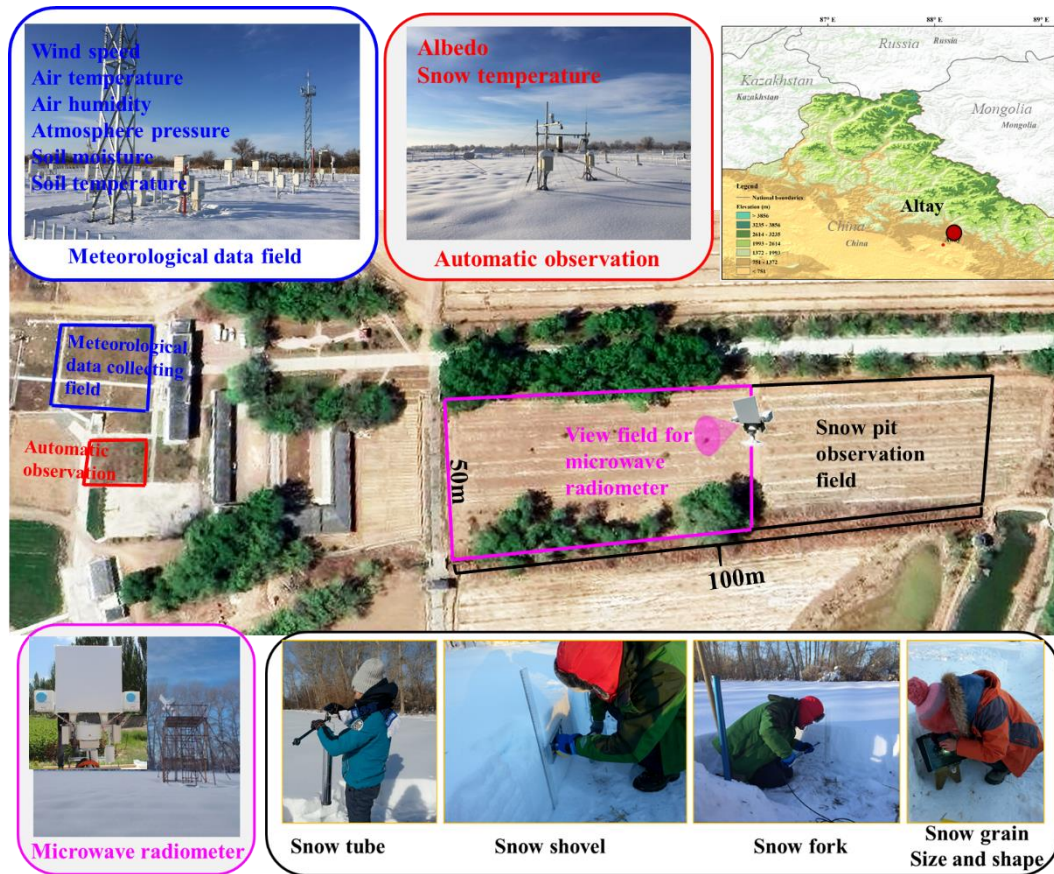

116 The Integrated Microwave Radiometry Campaign for snow (IMCS) was performed during the
117 2015/2016 snow season (from November 27, 2015 to March 25, 2016) at the Altay National Reference
118 Meteorological station (ANRMS) (N47°44'26.58", E 88°4'21.55") which is approximately 6 km from
119 the foot of Altay mountain in the northwest China (Figure 1). Altay mountain with elevation up to 3000
120 m, running northwest and southeast, is at the junction of China, Russia, Mongolia and Kazakhstan, and
121 provides snow water resources for these four countries. The average annual maximum snow depth
122 measured in this station is approximately 40 cm, with a maximum over 70 cm. In the southwest of Altay
123 mountain, crop land and desert with flat terrain are the dominant land covers. Snow cover is critical fresh
124 water for the irrigation in this area. In this experiment, measurements included microwave radiometry,
125 4-component radiation, snow pit and soil parameters. The test site of this experiment was four
126 neighboring bare rectangle fields in the ANRMS with areas of 2500m² (black rectangle field in Figure
127 1), 2500m² (pink rectangle field in Figure 1), 200m² (red rectangle field in Figure 1) and 400 m² (blue
128 rectangle field in Figure 1), respectively.

129 In the pink field, the ground-based microwave radiometer was set up in the middle of the field,
130 facing south to collect brightness temperatures of snow cover. The black field behind the microwave
131 radiometers (north of the radiometers) was for manual snow pit data collection. The microwave
132 radiometer observations and snow pit data collection were conducted by Northwest Institute of Eco-
133 Environment and Resources, Chinese Academy of Science (NIEER) from November 27, 2015 to March
134 25, 2016 (After March 25, 2016, snow melted out).

135 The blue field was for meteorological measurements including wind speed, wind direction, air
136 temperature, air wetness, air pressure, precipitation, soil temperature, soil moisture among others. These
137 parameters were automatically obtained from instruments, and the instruments setup and data collection
138 were operated by ANRMS. This station also has daily manual observation of snow depth and SWE. In
139 this experiment, we requested the wind, air pressure, air wetness, air pressure, soil temperature and
140 moisture data during this experiment from ANRMS. The red field was designed for automatic

141 measurement of layered snow temperatures, snow density, SWE, snow depth, and albedo. These
 142 automatic measurement instruments were installed and maintained by NIEER, and started working from
 143 2013. However, during the experiment, the instruments for snow density and SWE did not work, and we
 144 only collected layered snow temperatures and 4-component radiation.

145 Because the four observation fields are located within the domain of the station and the distance
 146 between them are less than 100m, the snow characteristics and soil and weather conditions are thought
 147 to be the same. Overall, the experiment performed a systematic observation covering electromagnetic
 148 and physical features of snow pack, providing data for studies on snow remote sensing and models.

149
 150 **Figure 1: Location of the Altay National Reference Meteorological station (ANRMS) in Asia and the**
 151 **distribution of three experiment fields in the ANRMS. The black rectangle represents the field used for snow**
 152 **characteristics (approximately 40 m × 50 m) including snow layering, layer thickness, snow density, snow**
 153 **grain size and shape of each layer, and microwave radiometers (approximately 60 m × 50 m) observations.**
 154 **The blue rectangle is the field for meteorological and soil data collection operated by the ANRMS. The red**
 155 **rectangle field is for the automatically observation of the snow temperature, and 4-component radiation,**
 156 **designed by Northwest Institute of Eco-Environment and Resources, Chinese Academy of Science (NIEER).**

157 **2.2 Measurement methods**

158 The microwave signatures from snowpack vary with snow characteristics, soil and weather
 159 conditions. In this experiment, the measurements include microwave radiometry observation to collect
 160 brightness temperature, manual snow pit observation to collect snow physical parameters, automatic
 161 observation to collect 4-component radiation and snow temperatures, and meteorological observation

162 which contains weather data and soil data.

163 2.2.1. Microwave radiometry

164 The brightness temperatures at 1.4, 18.6, 36.5 GHz for both polarization (Tb1h, Tb1v, Tb18h, Tb18v,
165 Tb36h, Tb36v) were automatically collected using a six-channel dual polarized microwave radiometer
166 RPG-6CH-DP (Radiometer Physics GmbH, Germany,
167 <https://www.radiometerphysics.de/products/microwave-remote-sensing-instruments/radiometers/>). The
168 technical specifications of the RPG-6CH-DP are described in Table 2. The RPG-6CH-DP contains a
169 built-in temperature sensor which can measure air temperature. The automated data collection frequency
170 was set to 1 minute.

171

172 **Table 2. Technical Specifications of the RPG-6CH -DP Microwave Radiometer.**

Parameter	Value
Manufacturer	Radiometer Physics GmbH
System noise temperatures	<900 K
Bandwidth	400MHz (20MHz for 1.4 GHz)
System stability	0.5 K
Dynamic range	0~400 K
Frequencies (GHz)	1.4, 18.7, 36.5
Polarizations	V, H
Internal calibration	Internal Dicke switch and software control for automatic sky tilt calibration
Receiver and antenna thermal stabilization	< 0.015 K
Antenna sidelobe level	< -30 dBc
Optical resolution (HPBW)	6.1° (11° for 1.4 GHz)
Incidence angle	0~90°
Azimuth angle	360°

173

174 Before the snow season, a platform with height of 5 m, length of 4 m and width of 2 m was
175 constructed in the experiment field (Figure 2). A 4-m orbit was fixed on the platform. The RPG-6CH-DP
176 was set up on the orbit and could be moved along the orbit. The microwave radiometers at K and Ka
177 bands began working from November 27, 2015, but the L band radiometer did not work until January 30,
178 2016. These radiometers were sky tipping calibrated, and the calibration accuracy is 1 K. In clear sky
179 conditions, the sky brightness temperatures were approximately 29.7 ± 0.3 K at 18.7 GHz for both
180 polarizations and 29.3 ± 0.9 K at 36.5 GHz for both polarizations. But the sky brightness temperature at
181 L band showed large fluctuation. They ranged from -1 to 8 K for horizontal polarization, and 1 to 16 K
182 for vertical polarization.

183

184 Generally, the radiometers were fixed in the middle of the orbit to observe snow cover with incidence
185 angle of 50°. Multi-angle observations were conducted after every big snowfall, and every 5 days in the
186 stable period. In the melt period, observation frequency increased. There are total seventeen multi-angle
187 observation (December 3, 19, and 30; January 3, 8, 13, 18, 3, and 28; February 3; March 3, 10, 15, 22,
188 26, 28, and 31) when the radiometer was set to scan the ground at different incidence angles at two ends
189 of the orbit and the middle place of the orbit. Although the view fields of the antennas for 1.4 GHz, 18
190 GHz and 36 GHz did not completely overlap, the measured results showed that the brightness
temperatures observed by radiometers at the left, middle and right of the orbit varied less than 1 K.

191 Therefore, the snow and soil characteristics were considered homogeneous within the view fields of the
 192 three antennas.

193
 194 **Figure 2 Ground-based microwave radiometer observation.**

195
 196 **2.2.2 Snow pit measurement**

197 The snow characteristics were obtained by manual snow pit measurements in the black field,
 198 including snow layering, snow layer thickness, grain size, snow density, and snow temperatures. These
 199 data were daily collected during 8:00-10:00 am local time, from November 27, 2015 to March 25, 2016,
 200 except 7 days (please see Table 3). Although the snow temperatures were manually measured at snow
 201 pits, the automatically collected snow temperatures in the red field were utilized in this study, because
 202 the temperature measured at snow pits could not reflect the natural temperature profile when the snow
 203 pits exposed to air.

204
 205 **Table 3. Variables collected by manual daily snow pit measurement in black field in figure 1, and their**
 206 **observation instruments, observation time and frequencies.**

Parameter	Instruments	Precision	Layering style	Observation time or frequency	Absent date
Layer thickness (cm)	Ruler	0.1cm	Natural layering	local time	no
Snow density (g/cm ³)	Snow tube (Chinese Meteorological Administration)	pressure: 0.1g/cm ² , snow depth: 0.1 cm	Whole snowpack	8:00-10:00 am	no
Snow density (g/cm ³)	Snow shovel (NIEER)	weight: 0.01g, volume: 1cm ³	Every 10 cm		January 2-3, 2016;

Snow density (g/cm ³) and	Snow fork (Toikka Enginnering Ltd.)	0.0001g/cm ³	Every 5 cm	February 20, 2016
Liquid water content (%)	Snow fork	0.001%	Every 5 cm	
Snow grain size (mm)	Anyty V500IR/UV	0.001mm	Natural layering	December 24, 31, 2015;
Snow grain shape	Shape card	N/A	Natural layering	January 1-3, 23, 2016, February 20, 2016

207

208 The first step of snow pit measurement is making a snow pit. In the black field, a new snow pit was
 209 dug each day. A spade was used to excavate snow pit. The length of the snow pit profile was
 210 approximately 2m to make sure all parameters were measured from unbroken snowpack. The width of
 211 the snow pit was approximately 1m. The snow pit section was made as flat as possible using a flat shovel
 212 or ruler. When the snow profile is exposed to air for a long time, the snow characteristics will be
 213 influenced by environment and will be different from the natural snow characteristics. In order to make
 214 sure every observation conducted on natural snow pit, the snow pit was backfilled with the shoveled
 215 snow after finishing all observations, and the new snow pit in the following day was made at least 1-m
 216 distance from the last snow pit. After finishing a snow pit, the natural snowpack stratification was then
 217 visually determined, and the thickness of each layer was measured using a ruler.

218 The third step was measuring grain size and shape type in each layer. The grain size and type within
 219 each natural layer were estimated visually from a microscope with an “Anyty V500IR/UV” camera
 220 (Figure 3a). A software “VIEWTER Plus” matched the microscope was used to measure grain size. The
 221 grain type was determined based on Fierz et al. (2009). In this experiment, we utilized the length of
 222 longest axes and the length of shortest axes to describe grain size (Figure 3b). When using the software
 223 to measure the grain size, a reference must be needed. In this experiment, a ruler with 0.5 mm marking
 224 was used as a reference (Figure 3c). We adjusted the focus of the camera to make sure the grains at the
 225 clearest status in camera to take photos, and the photo of ruler scale was taken at the same focus. If the
 226 thickness of one layer was less than 10 cm, measurements were performed at the top and bottom of the
 227 layer. If the thickness was greater than 10 cm, measurements were performed at the top, middle, and
 228 bottom of the layer. For each layer, at least 5 photos were taken, and at least 10 typical grains were chosen
 229 to measure the longest axes length and the shortest axes length in the photos of each layer. Each layer
 230 had at least 10 groups of longest and shortest axes length; the final grain size was the average of these
 231 values. Figure A1 presents an example of the original photos of grains in each layer, and Table A1 shows
 232 the matched record of longest and shortest axis length.

233

234
235
236 **Figure 3: Picture of microscope “Anyty V500IR/UV” (a), the measured longest axes lengths and shortest**
237 **axes length of particles (b), and the reference ruler scale (c).**

238
239 Snow density was measured using three instruments: snow tube, snow shovel and Snow Fork
240 (Figure 4). The snow tube instrument, designed by Chinese Meteorological administration, contains a
241 metal tube with the base area of 100 cm² and the length of 60 cm, and a balance (figure 4a). It was utilized
242 to measure the snow density of a whole snowpack by weighing the snow sample. The snow shovel is a
243 1500 cm³ wedge-type sampler, and its length, width and height are 20 cm, 15 cm, and 10 cm, respectively
244 (figure 4b). It was utilized to measure snow density every 10 cm (0-10 cm, 10-20 cm, 20-30 cm...). The
245 Snow Fork is a microwave resonator that measures the complex dielectric constant of snow, and adopts
246 a semi-empirical equation to estimate snow density and liquid water content based on the complex
247 dielectric. The Snow Fork (figure 4c) was utilized to measure snow density and liquid water content at
248 5-cm intervals starting 5 cm above the snow/soil interface (5cm, 10cm, 15 cm, 20cm...). **In order to**
249 **decrease the observation error, every measurement was conducted three times. If there is an abnormal**
250 **value, the fourth measurement would be performed to make sure the accuracy.** Table A2 is an example
251 record table for snow density. **The average value of the three-time observation was the final value.**

253
254
255 **Figure 4: Three instruments for snow density: Snow tube (a), Snow shovel (b), and Snow Fork (c).**

257 2.2.3 Automatic radiation and temperature measurement

258 **In the red field, the 4-component radiation was automatically measured by Component Net**
259 **Radiometer (NR01) manufactured by Hukseflux, and layered snow temperatures was measured by**
260 **Campbell 109S temperature sensors, respectively. The temperature sensors were set up on a vertical pole**
261 **which was vertically inserted in the soil (Figure 5).** The heights of the sensors are 0 cm, 5 cm, 10 cm, 15
262 cm, 25 cm, 35 cm, 45 cm, and 55 cm above soil/snow interface. The snow temperatures at these heights

263 were collected every ten minute.

264 The NR01 net radiometer was set up to measure the energy balance between incoming short-wave
 265 and long-wave far infrared radiation versus surface-reflected short-wave and outgoing long-wave
 266 radiation. The range of short wave is 285~3000nm, and the range of long wave is 4.5~40um. The 4-
 267 component radiation was automatically recorded every ten minutes. In addition, the sensor is equipped
 268 with a Pt100 temperature sensor for parallel recording of the sensor temperature.

269
 270 **Figure 5: Set up of temperature sensors and CNR01 in the red field.**

271

272 **2.2.4 Meteorological observation**

273 The meteorological data include air temperature, air pressure and humidity, wind speed, soil
 274 temperature at -5cm, -10 cm, -15cm and -20 cm and soil moisture at -10 cm and -20 cm. These parameters
 275 are routine observations conducted at ANRMS, and were obtained through request from ANRMS. The
 276 instruments used for soil and weather parameters observations are produced by China Huayun
 277 Meteorological Technology Group corporation. The measurement parameters and their measurement
 278 instruments are listed in table 4.

279 **Table 4. Automatically observed variables and the observation instruments, observation time and**
 280 **frequencies.**

Parameter	Instruments	Precision	Layering style	Observation time or frequency
Snow temperature(°C)	Temperature sensors (Campbell 109S)	0.001 °C	0 cm, 5 cm, 10 cm, 15 cm, 25 cm, 35 cm, 45 cm, and 55 cm	Ten-minute
4-component radiation (W/m ²)	Component Net Radiometer NR01 (Hukseflux)	0.001 W/m ²	6 feet above ground	Ten-minute

Soil temperature (°C)	Soil temperature sensor (China Huayun)	0.1 °C	-5cm, -10 cm, -15cm and -20 cm	Hourly
Soil moisture (%)	Soil moisture sensor (DZN3, China Huayun)	0.1%	-10 cm and -20 cm	Hourly
Air temperature (°C)	Thermometer screen (China Huayun)	0.1 °C	6 feet above ground	Hourly
Air pressure (hPa)	Thermometer screen (China Huayun)	0.1 hPa	6 feet above ground	Hourly
Air humidity (%)	Thermometer screen(China Huayun)	1%	6 feet above ground	Hourly
Wind speed (m/s)	Wind sensor(China Huayun)	0.1m/s	10 m above ground	Hourly

281

282 The air temperature, pressure and humidity were collected using temperature and wetness sensor in
 283 thermometer screen, the wind speed and direction were measured using wind sensor set up at 10 m on a
 284 tower. Soil moisture and temperature were automatically measured using moisture sensor and
 285 temperature sensor. Figure 6 depicts the instruments for these observations.

290 3 Description of consolidated IMCS dataset

291 The microwave brightness temperature, snow parameters, meteorological data were recorded in
 292 different formats, and the observation frequencies and times were different. These data must be
 293 reorganized and consolidated for ease of use. The values from the three-time measurements for snow
 294 density in each layer were averaged to obtain the final snow density. The length of the longest and shortest
 295 axes of particles in each photo were measured using the software. The average lengths of longest and
 296 shortest axes from all photos in each layer were obtained as the final grain size. The daily snow pit data
 297 were finally consolidated into a NetCDF file "snow pit data.nc".

298 The time series of automated layered snow temperature and 4-component radiation data were firstly
 299 processed with removal of abnormal values and gap fill, and then were consolidated into a NetCDF file
 300 "ten-minute 4 component radiation and snow temperature.nc". The ground-based brightness

301 temperatures and the formatted weather and soil data requested from ANRMS were provided ‘as is’.
 302 Brightness temperature data were divided into time series of brightness temperature and multi-angle
 303 brightness temperatures, and separately stored in two NetCDF files, and the weather and soil data were
 304 consolidated into a NetCDF file “hourly meteorological and soil data.nc”. Table 3 describes the contents
 305 of the provided dataset.

306 **1) Brightness temperatures data:**

307 1 Minutely brightness temperature at 1.4 GHz, 18 GHz and 36 GHz for both polarizations at incidence
 308 angle of 50°. This data include date, time, incidence angle, azimuth angle, and brightness temperatures
 309 at the three bands for both polarizations.

310 2 Seventeen groups of calibrated brightness temperature at 1.4 GHz, 18 GHz and 36 GHz for both
 311 polarizations at different incidence angles (30, 35, 40, 45, 50, 55, 60°). This data include date, incidence
 312 angles, azimuth angle, brightness temperatures at the three bands for both polarizations.

313 **2) Manual snow pit data:**

314 Daily snow pit data include date, snow depth, layered snow thickness, average longest axis, average
 315 shortest axis, grain shapes of each layer; layered snow density using snow fork (snow density at different
 316 heights, such as SF_5cm, SF_10cm, SF_15cm), snow density using snow tube, layered snow density
 317 using snow shovel (such as SS_0-10cm, SS_10-20cm, SS_20-30cm, SS_30-40cm).

318 **3) Automated snow temperature and radiation data**

319 Ten-minute 4-component radiation and snow temperature data include date, time, short-wave incident
 320 radiation, short-wave reflected radiation, long-wave infrared incident radiation, long-wave infrared
 321 reflected radiation, sensor temperature, and snow temperatures at different heights (such as ST_0cm,
 322 ST_5cm)

323 **4) Meteorological and soil data:**

324 Hourly weather data include date, hour, air temperature, pressure, humidity, wind speed, soil temperature
 325 at 5 cm, 10 cm, 15 cm and 20 cm, and soil moisture at 10 cm and 20 cm.

326

327 **Table 3 Description of consolidated data**

Data	Content	File name	Variables
Brightness temperature	Brightness temperature	TBdata.nc	Year, month, day, hour, minute, second, Tb1h, Tb1v, Tb18h, Tb18v, Tb36h, Tb36v, incidence angle, azimuth angle

333 4 Overview and preliminary analysis of collected data from IMCS

334 4.1 Snow characteristics

335 4.1.1 Layering grain size and grain shape

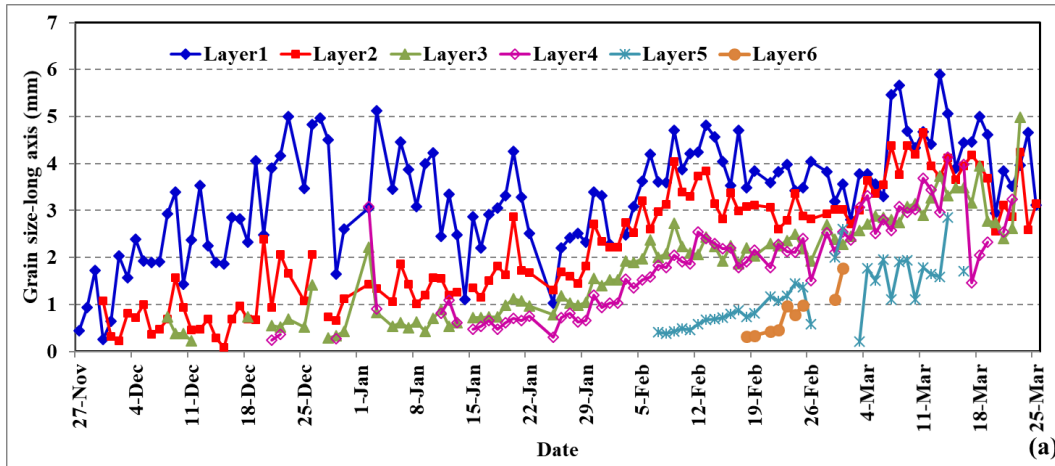

336 During 2015/2016, snow cover began on 25 November of 2015, and ended on March 25 of 2016.
337 During this snow season, there were seven snowfall events and each formed a distinct snow layer except
338 for the third event whose layering became indistinguishable from the second layer (Figure 7 gray). The
339 fourth event was the biggest, after which time snow depth started to decrease and snow density increased.
340 Snow cover began melting on March 14 and snow depth declined to zero within 10 days.

341 Grain sizes within all layers increased during the snow season, except in the bottom layer where
342 grain size experienced a decrease from December 28 to January 20 (Figure 8). In the vertical profile,
343 grain size increased from top to bottom with the snow age. The grain size of the fresh snow was
344 approximately 0.3 mm during the experiment. The biggest long and short axis were up to 6 cm and 4 cm,
345 respectively, and occurred in Layer 1 in during the melt period. The length of short axes is approximately
346 0.7 of the length of long axes. The grain shape generally developed from rounded grains to facet crystals,
347 and then to depth hoar. After March 13, 2016, the minimum air temperature increased to above 0°C,
348 snowpack melt accelerated, and the grain shape developed to melted forms (Figure 7).

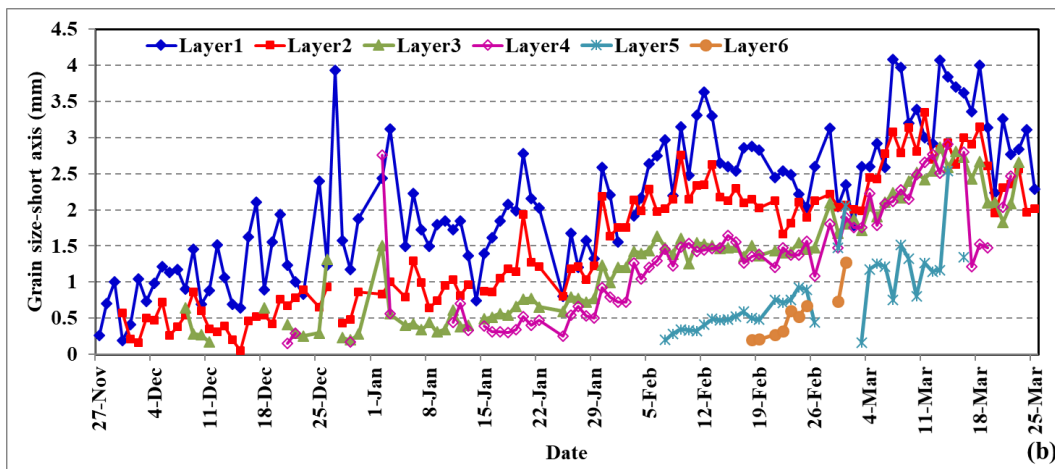

349
350 **Figure 7: Daily variation in snow layers and grain shape in each layer from November 27, 2015 to March 25,**

351 2016.

352

353

354 Figure 8: Daily variation in grain size within each layer from November 27, 2015 to March 25, 2016. The
355 thickness of each layer is presented in figure 9.

356

357 4.1.2 Snow density

358 Snow densities measured by three different instruments shows that the density of fresh snow ranged
359 between 0.05~1.0 g/cm³ (Figure 9). The snow densities increased with snow age, and remained stable
360 after reaching ~0.2-0.25g/cm³. From March 14 on, snow densities abruptly increased, and the maximum
361 value reached was over 0.45g/cm³. In the vertical profile, snow density increased from top to bottom in
362 the accumulation phase, but after January 3, 2016, snow densities in the middle layers were larger than
363 those in the bottom and upper layers due to the well-developed depth hoar of bottom layer. In the melting
364 phase, snow densities in all layers showed little difference. Snow fork provided most detail snow density
365 profile, but it systematically underestimated snow density compared with snow tube and snow shovel by
366 24% (Dai et al., 2022).

367

Figure 9: Daily variation in snow densities measured using three different measurement methods from November 27, 2015 to March 25, 2016. (a) overall snow density measured using snow tube, (b) snow density at 10-cm interval using snow shovel, and (c) snow density at 5-cm interval using snow fork.

374 **4.1.3 Snow temperature**

375 Snow temperature at 0 cm (snow/soil interface temperature) showed little diurnal variation,
376 remaining at approximately -2.0 to 0.7°C. Snow temperature in the top layer had the largest diurnal
377 variation. The diurnal range decreased from top to bottom layers and as the snow depth increased there
378 were more layers with small diurnal variations (Figure 10). After March 17, 2016, the snow temperature
379 of all layers were over 0°C which means snow cover did not refreeze anymore.

380
381 **Figure 10: Minutely variation in layered snow temperatures at 0 cm (snow/soil interface), 5 cm, 15 cm, 25**
382 **cm, 35 cm, 45 cm and 55 cm above ground during experiment time.**

383 **4.2 Soil temperature and moisture**

384 The soil temperature at 5 and 10 cm remained stable and below 0 °C during the snow season but
385 presented large fluctuation before (after) snow on (off) (Figure 11). The temperature difference between
386 5 cm and 10 cm was much larger before snow cover onset than during snow cover period. The soil
387 moistures at 10 cm were above 10% before snow cover onset and after snow off, and there were two soil
388 moisture peaks, one from December 12-14 and another from January 1- 20, within the snow cover period.

389

390 **Figure 11: Hourly soil temperature at 5 cm, 10 cm, 15 cm and 20 cm below the snow/soil interface (a), and soil**
 391 **moisture at 10 cm and 20 cm below the snow/soil interface (b).**

392 **4.3 Brightness temperature**

393 The microwave brightness temperatures varied with snow and soil characteristics, and weather
 394 conditions. Figure 12 shows the daily brightness temperatures, brightness temperature difference
 395 between 18 and 36 GHz, and snow depth at 1:00 am local time. Figure 13 shows the hourly variation in
 396 brightness temperatures at 1.4, 18 and 36 GHz and air temperature after February 1. Data show that
 397 Tb36h and Tb36v decreased during the full snow season, Tb18h shows an obvious decline after February
 398 18, and Tb18v after March 3 (Figure 12). After January 4, snow depth stopped increasing, but the
 399 brightness temperature continued to decrease and brightness temperature difference increased. Based on
 400 Figure 8, snow density became stable on January 15. Therefore, after January 4, the decreasing brightness
 401 temperatures was mainly caused by growing grain size.

402 After February 25, brightness temperature exhibited a distinct cycle of daytime increase and
 403 nighttime decrease (Figure 13), resulting from large liquid water content caused by high daytime air
 404 temperature (above 0°C) and the melted snowpack refreezing at nighttime. After March 14, there was
 405 another big rise in air temperature and even the nighttime air temperatures were above 0°C. During this
 406 period of accelerated snowmelt, the liquid water within the snowpack did not refreeze completely at night
 407 and both the brightness temperature and brightness temperature difference exhibited irregular behavior.

408 The variation of L band was mainly influenced by soil moisture and soil temperature. We have soil
 409 temperatures at 0 cm, 5 cm and 10 cm and soil moisture at 10 cm. However, the L band reflects the soil
 410 moisture within 5 cm which was absent in this experiment. Actually, we did not find the variation of
 411 brightness temperature at L band had relationship with soil moisture at 10 cm and soil temperature.

412

413 **Figure 12: Daily variations in brightness temperatures at 1.4 GHz, 18 GHz and 36 GHz, for horizontal**
 414 **(Tb1h, Tb18h, Tb36h) and vertical polarizations (Tb1v, Tb18v, Tb36v), and the differences between Tb18h**

433

434

Figure 13 Hourly variation in Tb1h, Tb18h, Tb36h, Tb1v, Tb18v, and Tb36v (a), air temperature, soil moisture at 10 cm and soil temperature at 5 cm, and daily variation in snow depth (b), from February 1 to March 28, 2016.

The brightness temperatures at 18.6 and 36.5 GHz from AMSR-2 and at 1.4 GHz from SMAP were compared with the ground-based observation at the overpass time (Figure 14). Although there were large differences between satellite and ground-based observations, the general temporal patterns are the same, even the abrupt change between March 3 and March 4 is captured by both satellite and ground-based sensors. The correlation coefficients at both polarizations were approximately 0.96, 0.7 and 0.88 for 36 GHz, 18.6 GHz and 1.4 GHz, respectively. Satellite observed brightness temperature presented less decrease trend than ground-based observation, and the difference at 36.5 GHz is larger than at 18.6 and 1.4 GHz. Brightness temperatures at 1.4 GHz from both SMAP and ground microwave radiometer kept stable before March 16, after when, brightness temperature rapidly decreased because of the increase of liquid water content. The difference between ground-based and satellite observation might be attributed to the different viewing area.

435

436

438

4.4 4-component Radiation

439

440

441

442

The land surface albedo is strongly related to the land cover. In this experiment, the downward short-wave radiation presented general increase after January, and the trend became distinctive after February (Figure 15). The upward short-wave radiation abruptly increased when the ground was covered by snow (after November 21), and sharply declined on the snow off day (March 25). From the first

443 snowfall by the end of January, the ratios between upward and downward short-wave radiation were
 444 approximately 95%. The ratio decreased with snow age, and in the end of snow season the ratios
 445 decreased to below 50% because of increasing melted water.

446 **Figure 15: Minutely variation in 4-component radiation and daily variation in snow depth at Altay station**
 447 **from November 3, 2015 to April 15, 2016.**
 448

449 5 Discussion

450 5.1 Applications

451 Although the dataset is just for one season observation, the daily snow pit observation with
 452 coincident microwave and optical radiation data in a full snow season provide the most detailed variation
 453 of snow parameters which allow researchers to find more details in snow characteristics and their
 454 relationship with remote sensing signatures. The dataset also fills the snow observation gap in mid-low
 455 snow depth area with relative short snow cover duration.

456 The snow pit data and microwave brightness temperatures have proven useful for evaluating and
 457 updating a microwave emission transfer model of snowpack (Dai et al., 2022). This dataset reflected the
 458 general fact that brightness temperature at higher frequencies presented stronger volume scattering of
 459 snow grains, and were more sensitive to snow characteristics. This experiment revealed that the dominant
 460 control for the variation of brightness temperature was the variation of grain size but not the snow depth.
 461 The largest snow depth or SWE did not correspond to the largest brightness temperature difference
 462 between 18 and 36 GHz in the condition of dry snowpack. Due to the growth of grain size, the maximum
 463 difference occurred before melting for stable snow cover. Therefore, the daily snow depth variations
 464 curve derived from passive microwave remote sensing datasets tend to exhibit a temporal offset from
 465 those of in situ observation.

466 During the snow season, brightness temperatures for both polarizations presented similar variations,
 467 but they behaved different in some time periods. The horizontal polarization was more sensitive to
 468 environment and was less stable than vertical polarization. Besides, the polarization difference at 18 GHz
 469 and 36 GHz showed increase and decrease trends, respectively during the experimental period. The
 470 results for 18 GHz were opposite to the simulation results (Dai et al., 2022). The different polarization
 471 behavior at 18 and 36 GHz might be related to the environmental conditions, snow characteristics and
 472 soil conditions. However, the subsurface soil moisture was not observed, the dynamic ground emissivity
 473 could not be estimated. L band has strong penetrability, and the brightness temperature variations were

474 predominantly related to subsurface soil conditions, except when the liquid water content within
475 snowpack was high. Therefore, in the condition of soil moisture data absence, L band brightness
476 temperatures were expected to reflect soil moisture variation which influence the soil transmissivity
477 (Babaeian et al., 2019; Naderpour et al., 2017; Hirahara et al., 2020).

478 Snow surface albedo significantly influences the incoming solar radiation, playing an important role
479 in the climate system. The factors altering snow surface albedo contains the snow characteristics (grain
480 size, SWE, liquid water content, impurities, surface temperature etc), external atmospheric condition and
481 solar zenith angle (Aoki et al., 2003). Snow albedo was estimated based on snow surface temperatures
482 in some models (Roesch et al., 1999), while others considered snow surface albedo to depend mainly on
483 snow aging (Mabuchi et al., 1997). In this experiment, we obtained the 4-component radiation, snow pit
484 and meteorological data. These data provide nearly all observations of possible influence factors, and
485 could be utilized to discuss and analyze shortwave radiation process of snowpack, and validate or
486 improve multiple-snow-layer albedo models.

487 Snow grain sizes and snow densities within different layers presented different growth rates during
488 different time periods. Generally, the growth rates are related to the air temperature, pressure and snow
489 depth (Chen et al., 2020; Essery, 2015; Vionnet et al., 2012; Lehning et al., 2002); therefore, this dataset
490 can be used to analyze the evolution process of snow characteristics, as well as validation data for snow
491 models.

492 5.2 Uncertainties

493 During the experiment, some uncertainties were produced due to irresistible factors. It is reported
494 that the sampling depth of the L-band microwave emission under frozen and thawed soil conditions is
495 determined at 2.5 cm (Zheng et al., 2019). We did not collect subsurface soil moisture, and the L band
496 radiometer observation began on January 30, 2016. Therefore, it is difficult to obtain the ground
497 emissivity in the full snow season based on the data. The soil moisture data at 10 and 20 cm under
498 soil/snow interface cannot be directly used to validate and develop soil moisture retrieval from L band
499 brightness temperature. We hope detailed soil moisture profile will be observed to estimate the subsurface
500 soil moisture to fill the gap.

501 The grain size data were collected through taking photos. When measuring the length of grains, the
502 grain selection has subjectivity, and the released data are average values. Although the general variation
503 trend can be reflected by the time series of average grain size, some details might be missed. Therefore,
504 the original grain photos could be provided through requesting for authors. In snow melt period, large
505 liquid water content would influence the measurement results of snow fork. So, it is suggested to use
506 small-size snow shovel or cutter to observe layered snow density in future experiments.

507 One season observation is quite valuable for developing and validate remote sensing method or
508 snow model, although the representativeness of this observation remains unknown. We need more years
509 of observation to endorse or confirm the evolution of snow characteristics.

510 6 Conclusions

511 In a summary, the IMCS campaign provides a time series of snow pits observation, meteorological
512 parameters, optical radiation and passive microwave brightness temperatures in the snow season of
513 2015/2016. The dataset is unique in providing microwave brightness temperatures and coincident daily
514 snow pits data over a full snow season at a fix site.

515 The daily snow pit data which provide a detail description of snow grain size, grain shape, snow

516 density and snow temperature profiles. Generally, grain size grew with snow age, and increased from top
517 to bottom. Snow grains are rounded shape with small grain size in the top layer, and depth hoar with
518 large grain size in the bottom layer. Snow density experienced increase-stable-increase variation, and the
519 densities of the middle layers were greater than the bottom layer due to the well-developed depth hoar in
520 the stable period. The data can be used to analyzes the evolution process of snow characteristics
521 combining with weather data, validate and improve the snow process models, such as SNOWPACK
522 (Lehning et al., 2002), SNTHERM (Chen et al., 2020). The improvement of these models can further
523 enhance the prediction accuracy of land surface process and hydrology models, and the simulation
524 accuracy of snow microwave emission models.

525 Microwave radiometer data and snow pit data have been utilized to analyze the volume scattering
526 features of snow pack at different frequencies (Dai et al., 2022). Results showed that grain size is the
527 most important factor to influence snow volume scattering. The data can also be used to further analyze
528 polarization characteristics of snow pack combining with soil and weather data, and be used to validate
529 different microwave emission models of snowpack.

530 The microwave and optical radiations were simultaneously observed. Existing studies reported that
531 the optical equivalent diameter must be used in microwave emission model with caution (Lowe and
532 Picard, 2015; Roy et al., 2013). These data provide a good opportunity to analyze the difference between
533 the influence of grain size on microwave and optical radiation, establishing the bridge between effective
534 optical grain size and microwave grain size.

535 **7 Data availability**

536 The IMCS consolidated datasets are available after registration on the National Tibetan Plateau Data
537 Center and available online at [http://data.tpdc.ac.cn/zh-hans/data/df1b5edb-daf7-421f-b326-](http://data.tpdc.ac.cn/zh-hans/data/df1b5edb-daf7-421f-b326-cdb278547eb5/)
538 [cdb278547eb5/](http://data.tpdc.ac.cn/zh-hans/data/df1b5edb-daf7-421f-b326-cdb278547eb5/) (doi: 10.11888/Snow.tpdc.270886). Microwave radiometry raw Data are available for
539 scientific use on request from Northwest Institute of Eco-Environment and Resources, Chinese Academy
540 of Sciences.

541

542

543 **Author contributions:** LD and TC designed the experiment. LD, YZ, JT, MA, LX, SZ, YY YH and LX
544 collected the passive microwave and snow pit data. HL provided the 4-component radiation and snow
545 temperature data. LW provided meteorological data. LD write the manuscript, and TC made revision. All
546 authors contributed to the data consolidation.

547

548 **Competing interests:** The authors declare that they have no conflict of interest.

549

550 **Acknowledgment:** The authors would like to thank the Altay meteorological station for providing
551 logistics service and meteorological data.

552

553 **Financial support:** This research was funded by the National Science Fund for Distinguished Young
554 Scholars (grant nos: 42125604), National Natural Science Foundation of China (grant nos: 42171143),
555 and CAS 'Light of West China' Program.
