Abstract. Long-time series and large-scale rice calendar datasets provide valuable information for agricultural planning and field management in rice-based cropping systems. However, current regional-level rice calendar datasets do not accurately distinguish between rice seasons in China, causing uncertainty in crop model simulation and climate change impact analysis. Based on satellite remote sensing data and an improved PhenoRice algorithm, we extracted the crop areas and phenology of early-, middle-, and late-season rice across China from 2003 to 2020, and established a multi-season rice calendar dataset named ChinaRiceCalendar. Overall, the ChinaRiceCalendar dataset shows a good agreement not only with field-observed rice calendars in Agricultural Meteorological Stations (AMSs), but also with statistical rice areas in various growing seasons. According to the calendar data from 2003 to 2020, the transplanting dates for early, middle, and late rice shifted by +5.4, +2.6, and -5.7 DOY/decade, respectively; the flowering date for early, middle, and late rice shifted by +5.5, -2.8, and -2.7 DOY/decade, respectively; the maturity date for early, middle, and late rice shifted by +3.2, -3.6, and -5.1 DOY/decade, respectively. The ChinaRiceCalendar can be utilized to investigate and optimize the spatio-temporal structure of rice cultivation in China under climate and land-use change.

1 Introduction

As one of the major food crops, rice feeds nearly half of the world's population (Nelson and Gumma, 2015; Fahad et al., 2019). In the context of climate change, continued warming is projected to result in shorter crop growth periods, lower rice productivity, and food insecurity in the Asian monsoon region (Carleton, 2017; Zhao et al., 2017; IPCC, 2022). Revealing changes in rice phenology will facilitate

36 timely adjustment of planting time, rice cultivars, and cropping systems under global warming (Waha
37 et al., 2013; Wang et al., 2022; Wang et al., 2024). Moreover, a dynamic rice calendar with key
38 phenological dates is integral to agricultural monitoring and farmer support systems (Laborte et al.,
39 2017; Fritz et al., 2019; Mishra et al., 2021). Large-scale rice calendars can contribute to more reliable
40 simulations of crop growth and yield at regional and global scales (Franke et al., 2020).

41
42 Satellite remote sensing is an effective tool for detecting long-term trends in crop phenology at the
43 regional scale (Xiao et al., 2006; Kotsuki and Tanaka, 2015; Luo et al., 2020; Gao and Zhang, 2021;
44 Mishra et al., 2021). Crop phenology detection methods based on remote sensing vegetation indices
45 (VIs) can be categorized into threshold, inflection point, and shape model approaches. The threshold
46 approaches assume that a development stage begins when the VI value exceeds a predefined threshold
47 (Jönsson et al., 2004; Boschetti et al., 2009; Pan et al., 2015; Guo et al., 2016). The inflection point
48 approaches reconstruct the VI time-series curve by filter smoothing or function fitting, and then
49 corresponds the maxima, minima, and inflection points on the curve to the key phenological events
50 (Zhang et al., 2003; Sakamoto et al., 2005; Sun et al., 2009; Wang et al., 2019). The shape model
51 approaches fit observed VI time-series curves by geometric scaling a robust standard VI time-series
52 curve for the specific crop to identify development stages (Sakamoto et al., 2010; More et al., 2016;
53 Zeng et al., 2016; Sakamoto et al., 2018). In addition to the methods based on time series of VIs, there
54 are also rule-based algorithms that integrate multiple approaches and indicators to detect crop
55 phenology, such as the PhenoRice algorithm proposed by Boschetti et al. (2017). The PhenoRice
56 algorithm, which combines the advantages of threshold and inflection point approaches, utilizes the
57 Enhanced Vegetation Index (EVI), the Normalized Difference Flood Index (NDFI), and the land
58 surface temperature (LST) to estimate rice planting dates. The PhenoRice algorithm excels at
59 extracting rice phenology in multiple cropping systems and has been widely used in East Asia, South
60 Asia, Southeast Asia, and Europe (Busetto et al., 2019; Liu et al., 2020; Mishra et al., 2021). However,
61 the performance of the PhenoRice algorithm depends on the division of rice seasons, which requires
62 expert knowledge about rice-based cropping systems in different regions (Mishra et al., 2021).

63
64 In China, there are at least three rice-growing seasons (early, middle, and late seasons) in diverse
65 rice-based cropping systems (e.g., single-rice, double-rice, rice-wheat, rice-rapeseed, and
66 rice-vegetable systems) (Frolking et al., 2002; Qiu et al., 2003; Cao et al., 2021; He et al., 2021).
67 Generally, early-, middle-, and late-season rice are transplanted at Day Of Year (DOY) 30-130, DOY
68 110-180, and DOY 150-230, respectively. The growth periods after transplanting for early, middle, and
69 late rice are 70-100 days, 100-130 days, and more than 130 days, respectively. Although field
70 observations are important data sources for studying rice calendars in different growing seasons, they
71 are usually limited by spatial and temporal discontinuities (Zhao et al., 2016; Wang et al., 2017).
72 Therefore, previous studies have typically utilized satellite remote sensing products to establish rice
73 calendar datasets at the regional scale (Shihua et al., 2014; Liu et al., 2019; Bai and Xiao, 2020; Luo et
74 al., 2020; Mishra et al., 2021). Nevertheless, these calendar datasets based on satellite remote sensing
75 do not rationally classify rice growing seasons across China. For example, the dataset
76 ChinaCropPhen1km only distinguishes between early and late rice in double-rice systems (Luo et al.,
77 2020); the assumptions of the dataset RICA about rice flowering dates in different seasons do not
78 correspond to the realities in China (Mishra et al., 2021); Shen et al. (2023) produced high-resolution
79 distribution maps of single-season rice but did not explore multiple rice cropping systems. Early-,

80 middle- and late-season rice in China are not only planted at different times, but also have
81 distinguishing varietal characteristics, such as different temperature and photoperiod sensitivities (Zong
82 et al., 2021). Thus, a crop calendar that accurately classifies rice seasons will provide reliable data for
83 agricultural models to calibrate crop parameters at the variety level. Moreover, effective identification
84 of different rice seasons will help analyze the response and adaptation of rice phenology to climate
85 change.

86
87 Therefore, to address the shortcomings of the existing rice calendar datasets in China, we attempted to
88 improve the PhenoRice algorithm and use satellite remote sensing data to (1) establish crop calendars
89 for early, middle, and late rice in China; (2) validate the extracted rice areas and calendars in different
90 growing seasons; and (3) explore the spatio-temporal changes of rice calendar dates in major
91 agricultural zones across China from 2003 to 2020.

92 **2 Data and Methodology**

93 **2.1 Study area**

94 We selected seven agricultural zones in China as the study area: the Northeast Plain (**NP**),
95 Huanghuaihai Plain (**HP**), Loess Plateau (**LP**), Middle and Lower Yangtze River Region (**MLY**), South
96 China Region (**SC**), Yunnan-Guizhou Plateau (**YGP**), and Sichuan Basin and Surrounding Region
97 (**SCS**) (Fig. 1). Due to limited hydrothermal resources, the NP and HP zones mainly cultivate
98 single-season rice. Early, middle, and late rice exist in different cropping systems in the MLY zone.
99 The SC zone has a higher cropping frequency than other zones and usually cultivates rice twice a year.
100 Parts of Hainan Province cultivate rice three times a year. Agricultural zoning data were obtained
101 from Resources and Environment Science and Data Center
102 (<https://www.resdc.cn/data.aspx?DATAID=275>).

103 **2.2 Data**

104 **2.2.1 Satellite Imagery**

105 MODIS (Moderate Resolution Imaging Spectroradiometer) remote sensing data are widely used in
106 crop phenology detection because of their excellent performance in temporal and spatial continuity
107 (Reed et al., 1994; Zhang et al., 2003; Zhao et al., 2011; Son et al., 2013). We selected two MODIS
108 EVI products for the study area during 2003–2020: MOD13Q1 (TERRA data) and MYD13Q1 (AQUA
109 data) (<https://doi.org/10.5067/MODIS/MOD13Q1.061>, 250 m, 16-day). Because the TERRA and
110 AQUA data are based on the synthetic period of moving eight days from each other, the time series of
111 the two 16-day products of MOD13Q1 and MYD13Q1 have a temporal resolution of 8 days (Boschetti
112 et al., 2017). The red (ρ_{RED}) and near-red (ρ_{SWIR}) bands of MOD13Q1 and MYD13Q1 were used to
113 calculate the Normalized Flooding Index (NDFI) (Eq. 1). The Pixel Reliability, Usefulness Index, and
114 Blue Band Reflectance from MOD13Q1/MYD13Q1 were used to assess data quality. In addition, the 1
115 km spatial resolution and 8-day temporal resolution Land Surface Temperature (LST) product
116 MOD11A2 (<https://doi.org/10.5067/MODIS/MOD11A2.061>) was employed by resampling 250 m

117 spatial resolution consistent with EVI data.

$$118 \quad NDFI = \frac{\rho_{RED} - \rho_{SWIR}}{\rho_{RED} + \rho_{SWIR}} \quad (1)$$

119 All time series data were processed through the Google Earth Engine (GEE) platform and the Python
120 package of Geemap (Wu, 2020).

121 **2.2.2 Validation Data**

122 We obtained the statistical sown areas of rice at the province level during 2003-2020 from the Chinese
123 Agricultural Yearbooks (<https://data.cnki.net/yearBook/single?id=N2020120306>). We also collected
124 site-scale observations including rice seasons and key phenological dates (transplanting, flowering, and
125 maturity dates) between 2003 and 2013 from [338](#) Agricultural Meteorological Stations (AMSs,
126 <https://data.cma.cn/>) in China. Moreover, we compared ChinaRiceCalendar with other regional-scale
127 calendar datasets, including the RiceAtlas dataset based on the agricultural statistics (Laborte et al.,
128 2017), the ChinaCropPhen1km dataset based on the Global Land Surface Satellite (GLASS) leaf area
129 index (LAI) products (Luo et al., 2020), and [the RICA dataset based on the MOD13Q1/MYD13Q1](#)
130 [products \(Mishra et al., 2021\)](#).

131 **2.2.3 Additional Data**

132 Cropland data were obtained from the International Geosphere-Biosphere Program (IGBP)
133 classification of the MODIS land cover product (MCD12Q1) from 2003 to 2020
134 (<https://doi.org/10.5067/MODIS/MCD12Q1.006>). Digital elevation model (DEM) data used to create a
135 terrain mask were obtained from the Shuttle Radar Topography Mission (SRTM,
136 <https://srtm.csi.cgiar.org>). Both data are resampled to a spatial resolution of 250 m.

137 **2.3 Methodology**

138 The technology roadmap of this study is shown in Fig. 2.

139 **2.3.1 Data pre-processing**

140 The data pre-processing in the study falls into three steps:

141

142 1. The signal of agronomic flooding was used to help identify the rice transplanting period, but
143 non-agricultural wetlands may have similar flooding signals to paddy fields (Dong and Xiao,
144 2016; Han et al., 2022). Thus, the annual cropland extent from 2003 to 2020 was used to establish
145 a cropland mask to screen the cropland pixels of the MODIS EVI data.

146 2. Given that too high an elevation or too great a slope is unsuitable for paddy rice cultivation
147 (Gumma et al., 2011; Dong and Xiao, 2016), only the image pixels with an elevation below 2600
148 m and a slope less than 8° were selected to extract rice calendars (Han et al., 2022).

149 3. To reduce the impacts of cloud contamination, we deleted the image pixels with reflectance
150 greater than 0.2 in the blue band (Xiao et al., 2006).

151 2.3.2 Estimation of rice area and cropping calendar

152 We combined the PhenoRice algorithm (Boschetti et al., 2017) with a growing season division method
153 (Kong et al., 2022) to extract rice areas and cropping calendars in different growing seasons. Firstly,
154 we identified possible crop flowering periods based on a weighted-smoothed EVI time-series curve in
155 each image pixel. Then we input the possible flowering periods into the PhenoRice algorithm to divide
156 potential growing seasons and check if the corresponding EVI time series belongs to rice. Lastly, we
157 estimated rice planting, flowering, and maturity dates and categorized them into early-, middle-, and
158 late-season calendars according to transplanting time and growing period length.

159 ① **Divide potential growing seasons:** The PhenoRice algorithm requires a pre-specification of rice
160 flowering periods in different growing seasons to extract the corresponding VI time series. To
161 reduce the uncertainty caused by the artificial division of growing seasons, we employed the
162 *phenofit* R package developed by Kong et al. (2022) to identify possible flowering periods in each
163 image pixel. 1) The weighted Whittaker method in the *phenofit* R package was employed to
164 smooth the MODIS-EVI time series (Kong et al., 2022). The Whittaker smoothing function can
165 robustly capture seasonal signals with little noise interference, and it is widely used to identify
166 crop phenology (Atzberger and Eilers, 2011; Bush et al., 2017). The curve fitting mainly relies on
167 information from good-quality points, but also extracts the limited information available from the
168 marginal- and bad-quality points. During the rough fitting to the EVI time series, we categorized
169 the data quality of the observations according to their Quality Control (QC) information
170 (SummaryQA of MOD13A1) and assigned weights of 1.0, 0.5, and 0.2 to the good-, marginal-,
171 and bad-quality VI observations, respectively. 2) Following Kong et al. (2022), the possible
172 flowering date (peak point date) in each crop season was identified by the smoothed EVI time
173 series, based on the rules that only one peak value is inside a growing season and two trough
174 values define a growing season. 3) The possible flowering periods (peak point dates ± 16 days)
175 detected in each image pixel were input into the PhenoRice algorithm to generate the potential
176 growing seasons.

177 ② **Check if the pixel belongs to a rice-cultivated area:** Whether the pixel belongs to a rice
178 cultivated area during the selected growing season is checked using the following procedure
179 (Boschetti et al., 2017): 1) Compare the observed average, maximum, and minimum EVI values
180 with the corresponding thresholds for paddy fields (EVI_{avg_th} , EVI_{max_th} , and EVI_{min_th}) to reduce
181 misclassification problems with evergreen forests and non-vegetative areas; 2) Check for the
182 existence of a maximum inflection point on the EVI curve, which must show a consistent
183 increasing trend before the maxima and a consistent decreasing trend after the maxima. The time
184 interval between the inflection points of the minimum and maximum EVI values during the
185 season must fall within the range of rice vegetative growing periods [$v11$, $v12$]; 3) Check if the
186 meteorological conditions on the day of the minimum are favourable for rice crop establishment
187 based on a MODIS-LST value above a specified threshold (LST_{th}); 4) Detect a flood signal ($NDFI$
188 $\geq minndfi$) within a time window ($winfl$) centred on the minimum; 5) Check if there is a
189 consistent increase in EVI observed after the minimum; 6) Check if EVI decreases by more than
190 $decrth\%$ of the amplitude of the min-max range in a time window after the maxima ($windecr$).
191 Only if all the above requirements are satisfied, the selected growing season in the pixel is

192 labelled as a rice season. The PhenoRice parameters used in the study were calibrated by the
193 phenological observations from the AMSs in China (Table 1).

194 ③ **Estimate rice planting, flowering, and maturity dates:** The rice calendar dates were estimated
195 in the detected rice pixels within the rice seasons. On the EVI time-series curve, the onset date of
196 the field growth period corresponds to the date of the minimum point closest to the retained
197 maximum; the flowering date corresponds to the mid-point date of the period during which the
198 EVI smoothed signal remains above the 90th percentile of the min-max range; the maturity date
199 corresponds to the date when the EVI declined by *decrth*% of the amplitude of the min-max range.
200 Additionally, the study categorized the detected rice calendars into early, middle, and late seasons
201 based on the following rules: 1) the rice with a transplanting date of DOY30-130 and a growing
202 period of 70–100 days was defined as early-season rice; 2) the rice with a transplanting date of
203 DOY110–180 and a growing period of 100–130 days was defined as middle-season rice; 3) the
204 rice with a transplanting date of DOY150-230 and a growing period of 130-150 days was defined
205 as late-season rice.

206 2.3.3 Data validation

207 We validated the extracted rice areas during 2003-2020 against the statistics from agricultural
208 yearbooks at the province level. The Chinese Agricultural Yearbooks classify rice varieties into three
209 categories: ER (early rice), MR-SLR (middle rice and single-season late rice), and DLR (double-season
210 late rice). For the consistency of our rice area data with the statistics in variety categorization, we
211 calculated rice planting frequency at the village level and differentiated late rice into single-season late
212 rice and double-season late rice. Due to the difference in spatial resolution between ChinaRiceCalendar
213 and ChinaCropPhen1km, we selected the rice pixels of ChinaRiceCalendar within a one-kilometer
214 radius of the AMSs and the rice pixels of ChinaCropPhen1km within a four-kilometer radius of the
215 AMSs to compare the mean cropping dates in these rice pixels with the corresponding AMS data. Two
216 criteria were used to evaluate the accuracy of the estimated rice areas and cropping dates in each season,
217 namely Root Mean Squared Error (RMSE, Eq. (2)) and R² (Eq. (3)):

$$218 \quad \text{RMSE} = \sqrt{\frac{1}{N} \sum_{i=1}^N (\text{true}_i - \text{est}_i)^2} \quad (2)$$

$$219 \quad R^2 = \left(\frac{\sum_{i=1}^N (\text{est}_i - \overline{\text{est}})(\text{true}_i - \overline{\text{true}})}{\sqrt{\sum_{i=1}^N (\text{est}_i - \overline{\text{est}})^2} \sqrt{\sum_{i=1}^N (\text{true}_i - \overline{\text{true}})^2}} \right)^2 \quad (3)$$

220 where true_i is the true value in the *i*th province or AMS; est_i is the corresponding estimated value;
221 $\overline{\text{est}}$ and $\overline{\text{true}}$ denote the mean of the estimated and true values, respectively; *N* is the number of
222 provinces or AMSs.

223

224 Additionally, in order to investigate the historical shifts of rice phenological dates in China, we
225 analyzed the trends of rice planting, flowering, and maturity dates at the county level by a
226 Sen+Mann-Kendall trend analysis at a significance level of 0.05. The trend analysis method is detailed
227 in Gocic et al. (2013) .

228 **3 Result**

229 **3.1 Validation of rice areas**

230 The detected rice areas during 2003-2020 show a good agreement with statistical sown areas of rice in
231 various growing seasons (Fig. 3). The R^2 between the detected and statistical areas of ER, MR-SLR,
232 and DLR at the province level is 0.92, 0.83, and 0.85, respectively. The RMSE between the detected
233 and statistical areas of ER, MR-SLR, and DLR at the province level is 127.86, 313.06, and 197.47 kha,
234 respectively. The R^2 between the detected and statistical rice areas in different agricultural regions is
235 shown in Table 2. Early rice is mainly distributed in the MLY, SC, SCS, and YGP regions in China and
236 all four regions show high accuracy ($R^2 \in [0.89, 0.97]$) in the detected area of early rice. The NP, HP,
237 and LP regions show higher accuracy ($R^2 \in [0.93, 0.95]$) than the SCS, MLY, SC, and YGP regions (R^2
238 $\in [0.73, 0.82]$) in the detected area of middle rice and single-season late rice. Moreover, the MLY and
239 YGP regions have more reliable data ($R^2 \in [0.85, 0.89]$) on the area of double-season late rice than the
240 SC and SCS regions ($R^2 \in [0.78, 0.79]$).

241 **3.2 Validation of rice calendars**

242 Overall, the key phenological dates estimated in the study show high consistency with the data from
243 AMSs (Fig. 4). The R^2 between data from ChinaRiceCalendar and AMSs for transplanting, flowering,
244 and maturity dates in China is 0.95, 0.95, and 0.96, respectively. The RMSE between data from
245 ChinaRiceCalendar and AMSs for transplanting, flowering, and maturity dates in China is 8.34, 7.84,
246 and 7.77 days, respectively. Moreover, the error in detected middle-rice calendars is lower than that in
247 early-rice and late-rice calendars (Fig. 4). The RMSE of the estimated transplanting, flowering, and
248 maturity dates for early rice is 8.82, 8.27, and 10.77 days, respectively. The RMSE of the estimated
249 transplanting, flowering, and maturity dates for middle rice is 7.44, 6.53, and 5.14 days, respectively.
250 The RMSE of the estimated transplanting, flowering, and maturity dates for late rice is 8.28, 9.07, and
251 10.06 days, respectively.

252
253 Also, we calculated the RMSE of the estimated rice cropping dates in the seven agricultural regions in
254 China (Fig. 5). Except in the SC region, the RMSE averages of the estimated phenological dates are
255 around one week at the regional scale. For early-season rice, the RMSE average of the estimated
256 cropping dates is 6.76, 13.54, and 7.30 days in the MLY, SC, and YGP, respectively. For
257 middle-season rice, the range of the RMSEs in the seven agricultural regions is from 5.46 days in the
258 NP to 7.81 days in the SC. For late-season rice, the RMSE average of the estimated cropping dates is
259 8.60, 10.08, and 8.29 days in the MLY, SC, and YGP, respectively.

260 **3.3 Comparison with other calendar datasets**

261 The rice phenological dates obtained from the RiceAtlas (Laborte et al., 2017), ChinaCropPhen1km
262 (Luo et al., 2020), and RICA (Mishra et al., 2021) datasets were also validated against the spatially
263 corresponding AMS data. In China, the rice phenological dates estimated in ChinaRiceCalendar show
264 higher accuracy by growing season than those obtained from RiceAtlas and RICA. Furthermore,
265 compared to the ChinaCropPhen1km dataset, the ChinaRiceCalendar dataset have similar accuracy in
266 rice phenological dates but higher accuracy in rice areas in different growing seasons.

267

268 The RMSE between RiceAtlas' and AMSs' phenological dates for early, middle, and late rice in China
269 is 18.27, 21.03, and 13.81 days, respectively. The R² between RiceAtlas' and AMSs' phenological
270 dates for early, middle, and late rice in China is 0.65, 0.43, and 0.75, respectively.

271

272 The RMSE between ChinaCropPhen1km's and AMSs' phenological dates is 9.35 days for early and
273 middle rice, and 7.24 days for late rice in China. The R² between ChinaCropPhen1km's and AMSs'
274 phenological dates is 0.81 for early and middle rice, and 0.85 for late rice in China.

275

276 The RMSE between RICA's and AMSs' phenological dates for early, middle, and late rice in China is
277 22.80, 14.07, and 13.61 days, respectively. The R² between RICA's and AMSs' phenological dates for
278 early, middle, and late rice in China is 0.47, 0.69, and 0.73, respectively.

279

280 **3.4 Spatial distribution of rice areas and phenological dates**

281 According to the spatial distribution of the detected rice areas during 2003-2020, early and late rice
282 were mainly grown in the southern part of China, while middle rice was widely planted in China from
283 south to north (Fig. 6). Based on the mean values between 2003 and 2020, the detected planting area of
284 early rice in China was 4732 kha, and approximately 69% of the early-rice area was concentrated in the
285 MLY region; the detected planting area of middle rice in China was 13953 kha, and approximately
286 85% of the middle-rice area was distributed in the MLY, NP, and SCS regions; the detected planting
287 area of single-season late rice in China was 4361 kha, and approximately 70% of the single-season late
288 rice area was distributed in the MLY region; the detected planting area of double-season late rice in
289 China was 6423 kha, and approximately 64% of the double-season late rice area was distributed in the
290 MLY region.

291

292 The spatial variations of rice phenology are significant in early, middle, and late seasons (Fig. 7 and 8).
293 In the NP, HP, and LP, middle rice was transplanted at DOY130±21, flowered at DOY200±14, and
294 matured at DOY260±14. In the YGP, the mean transplanting date was approximately DOY60 for early
295 rice, DOY125 for middle rice, and DOY150 for late rice; the mean flowering date for early, middle,
296 and late rice was DOY180±30; the mean maturity date was approximately DOY180 for early rice,
297 DOY250 for middle rice, and DOY290 for late rice. In the MLY, the mean transplanting date was
298 approximately DOY110 for early rice, DOY160 for middle rice, and DOY170 for late rice; the mean
299 flowering date was approximately DOY160 for early rice, DOY220 for middle rice, and DOY250 for
300 late rice; the mean maturity date was DOY280±21 for the three seasons. In the SC, the mean
301 transplanting date was approximately DOY90 for early rice and DOY180 for late rice; the mean
302 flowering date was approximately DOY180 for early rice and DOY240 for late rice; the mean maturity
303 date was approximately DOY210 for early rice and DOY300 for late rice.

304 **3.5 Temporal changes in rice phenological dates**

305 Based on the trend analysis of rice phenological dates from 2003 to 2020 (Fig. 9), the transplanting
306 dates for early, middle, and late rice shifted by +5.4, +2.6, and -5.7 DOY/decade, respectively; the
307 flowering date for early, middle, and late rice shifted by +5.5, -2.8, and -2.7 DOY/decade, respectively;

308 the maturity date for early, middle, and late rice shifted by +3.2, -3.6, and -5.1 DOY/decade,
309 respectively. According to the trend analysis result in each rice-producing county in China between
310 2003 and 2020 (Fig. 10), 27%, 12%, and 3% of the counties showed a significant delay in transplanting
311 dates for early, middle, and late rice, respectively; meanwhile, 5%, 6%, and 25% of the counties
312 showed a significant advancement in transplanting dates for early, middle, and late rice, respectively.
313 Moreover, 27%, 9%, and 1% of the counties in China showed a significant delay in flowering dates for
314 early, middle, and late rice, respectively; meanwhile, 1%, 7%, and 22% of the counties showed a
315 significant advancement in flowering dates for early, middle, and late rice, respectively. Also, 24%, 6%,
316 and 2% of the counties in China showed a significant delay in maturity dates for early, middle, and late
317 rice, respectively; meanwhile, 2%, 14%, and 19% of the counties showed a significant advancement in
318 flowering dates for early, middle, and late rice, respectively. Overall, the growing season of early rice
319 tended to be delayed, while the growing season of late rice tended to advance between 2003 and 2020
320 in China. Additionally, the shifts in the phenological dates of middle rice during 2003-2020 depended
321 on the agricultural region (Fig. 10).

322 **4 Uncertainties in ChinaRiceCalendar**

323 Although the generated dataset ChinaRiceCalendar shows an advantage in rice season identification,
324 there is still uncertainty in the data source and phenology detection methods.

325
326 This study used MODIS remote sensing data to extract rice phenological dates in various growing
327 seasons in China. The MODIS remote sensing products have an appropriate temporal resolution, long
328 time series, and good time consistency for analyzing changes in rice calendars at the regional scale.
329 Moreover, the MODIS data are easy to obtain and process on the GEE platform, allowing for
330 automated and timely updating of the calendar dataset. However, the pixel-based detection of rice areas
331 may be interfered with by the contamination of clouds, aerosols, and water vapor, especially during the
332 monsoon season when rice is by far the dominant crop (Xiao et al., 2014; Mishra et al., 2021). Because
333 synthetic aperture radar (SAR) can penetrate through clouds, subsequent studies could combine optical
334 and SAR images to avoid the impacts of clouds (Shen et al., 2023). Also, most paddies in southern
335 China are smaller than the spatial resolution of MODIS data, which may result in a rough estimation of
336 rice areas. Generating more satellite remote sensing products with higher spatial resolution and
337 integrating multiple data sources from satellite-airborne-ground observations will facilitate real-time
338 monitoring of rice cropping areas at the regional scale (Zheng et al., 2022; Sun et al., 2023).
339 Additionally, precisely corresponding the image pixels from the MODIS dataset to the Agricultural
340 Meteorological Stations remains a challenge during data validation. In the future, it would be beneficial
341 to conduct a quantitative assessment to determine the representativeness of the MODIS pixels
342 surrounding the AMS site.

343
344 In this study, we improved the method of growing season division in the PhenoRice algorithm. We also
345 attempted to remove non-paddy pixels and reduce the impacts of low-quality data on the reconstruction
346 of EVI time-series curves. Nevertheless, since the PhenoRice algorithm detects rice pixels by
347 agronomic flooding signals, rainfed or upland rice systems will be much harder to detect. In China, rice
348 is mainly planted in flooded paddy fields (Luo et al., 2022), which mitigates the problems of detecting
349 rainfed or upland rice. Moreover, the VI-curve smoothing methods perform differently in different

350 regions (Luo et al., 2020). To enhance the identification of rice growing seasons in multi-cropping
351 areas, we suggested identifying the optimal smoothing method for MODIS-EVI time series in various
352 rice-based cropping systems. Although the local tuning of the PhenoRice algorithm parameters could
353 further improve the results, we employed a single configuration of temporal windows and threshold
354 values across China because automated methods that perform robustly are essential for developing
355 timely information about crop calendars over large extents (Mishra et al., 2021).

356
357 The uncertainty in crop area estimation is more significant for late rice than for early and middle rice,
358 resulting in lower accuracy of the detected rice area in southern China (MLY, SC, SCS, YGP) than in
359 northern China (NP, HP, LP). For example, there is an underestimation of the double-season late rice
360 area in Hainan Province and an overestimation of the single-season late rice area in Hubei Province.
361 Because the transplanting dates (DOY150-210) of late rice coincide with the rainy season in the main
362 rice-producing areas, there is a higher risk of misidentifying agronomic flooding signals during
363 transplanting for late rice than for early and middle rice. Furthermore, low data quality induced by
364 cloud contamination during the transplanting period contributes to the difficulties in extracting the late
365 rice area (Xiao et al., 2005; Clauss et al., 2016). Also, the diverse multi-cropping systems and the
366 complex growing environments (e.g., topography and landscape) make the area detection for late rice
367 more challenging (Dong and Xiao, 2016). The following study could consider utilizing geostationary
368 satellite observations to increase the temporal frequency of remote sensing data during the
369 transplantation period of late rice in China (Shen et al., 2023). Subsequently, we will try to automate
370 the generation of ChinaRiceCalendar based on the ‘rgee’ package (Aybar et al., 2023) and update the
371 database once a year.

372 **5 Data Availability**

373 ChinaRiceCalendar is a raster dataset with 250m, 1km, and 10km spatial resolution. The spatial
374 reference system of the dataset is Asia_North_Albers_Equal_Area_Conic. The dataset currently covers
375 the following periods: 2003-2010, 2011-2015, and 2016-2020. ChinaRiceCalendar is available at
376 <https://doi.org/10.7910/DVN/EUP8EY> (Hui Li, 2023).

377 **6 Conclusions**

378 In the study, we improved the procedure of growing season division in the PhenoRice algorithm, and
379 detected rice areas and rice phenology in early, middle, and late seasons across China from 2003 to
380 2020. Then, we established a multi-season rice calendar dataset named ChinaRiceCalendar. Firstly, the
381 detected rice areas in ChinaRiceCalendar show a good agreement with statistical sown areas of rice in
382 various growing seasons. The R^2 between the detected and statistical areas of ER, MR-SLR, and DLR
383 at the province level is 0.92, 0.83, and 0.85, respectively. Secondly, the key phenological dates in
384 ChinaRiceCalendar have high consistency with the field observations from 338 Agricultural
385 Meteorological Stations in China. The RMSE between data from ChinaRiceCalendar and AMSs for
386 rice transplanting, flowering, and maturity dates in China is 8.34, 7.84, and 7.77 days, respectively.
387 Thirdly, ChinaRiceCalendar shows higher accuracy in the detected rice area or key phenological dates
388 by growing season than RiceAtlas, ChinaCropPhen1km, and RICA in China. According to the calendar

Table.1 PhenoRice parameters used in the study

Parameters	Value	Description
EVI _{avg_th}	0.40	threshold for the average EVI within the study period ($< \text{EVI}_{\text{avg_th}}$)
EVI _{max_th}	0.50	threshold for the maximum EVI within the study period ($> \text{EVI}_{\text{max_th}}$)
EVI _{min_th}	0.25	threshold for the minimum EVI within the study period ($< \text{EVI}_{\text{min_th}}$)
<u>v11 (days)</u>	<u>40</u>	<u>shortest vegetative growth length</u>
<u>v12 (days)</u>	<u>112</u>	<u>longest vegetative growth length</u>
<u>t11 (days)</u>	<u>96</u>	<u>shortest total growth length</u>
<u>t12 (days)</u>	<u>184</u>	<u>longest total growth length</u>
LST _{th} (°C)	15	minimum land surface temperature for rice planting
Winfl (days)	24	time window for capturing flooding signals
minndfi	0	threshold for NDFI
Win _{decr} (days)	72	threshold for a decline window after EVI maximum
dec _{th}	0.50	percent decrease of EVI after EVI maximum
