**Abstract.** Plant phenology refers to the cyclic plant growth events, and is one of the most important indicators of climate change. Integration of plant phenology information is of great significance for understanding the response of ecosystems to global change and simulating the material and energy balance of terrestrial ecosystems. Based on 24552 in-situ phenology observation records of 24 typical woody plants from the Chinese Phenology Observation Network (CPON), we map the species phenology (SP) and ground phenology (GP) of forests over China from 1951-2020, with a spatial resolution of 0.1° and a temporal resolution of 1 day. A model-based upscaling method was used to generate SP maps from in-situ [SPphenology](#) observations, and then weighted average and quantile methods were used to generate GP maps from SP maps. The validation shows that the SP maps of 24 woody plants are largely consistent with the in-situ observations, with an average error of 6.9 days in spring and 10.8 days in autumn. The GP maps of forests have good agreement with the existing Land Surface Phenology (LSP) products derived by remote sensing data, particularly in deciduous forests, with an average difference of 8.8 days in spring and 15.1 days in autumn. The dataset provides an independent and reliable phenology data source on a long-time scale of 70 years in China, and contributes to more comprehensive research on plant phenology and climate change at regional and national scales. The dataset can be accessed at <https://doi.org/10.57760/sciencedb.07995> (Zhu et al., 2023).

## 1 Introduction

Plant phenology refers to plant cyclic growth and development events, which are formed by adaptation to seasonal changes in climate and environmental conditions (Lieth, 1974; Schwartz, 2003). These phenological events include critical stages such as budburst, leaf unfolding, flowering, leaf coloring, and defoliation. As a highly sensitive biological indicator of climate change (Fu et al., 2015; Richardson et al., 2013), plant phenology is not only important for comprehending ecosystem responses to global change (Inouye, 2022; Menzel et al., 2020), but also a significant factor in simulating material and energy balance of terrestrial ecosystems (Keenan et al., 2014; Wang et al., 2020b). To be helpful for biological

32 monitoring and predictions, long-term, dependable plant phenology data on a global scale are greatly desired by related  
33 scientific research personnel. Presently, such data can be procured from diverse sources (Piao et al., 2019; Tang et al., 2016),  
34 including manual in-situ observations (~~Schwartz et al., 2012~~; Templ et al., 2018), satellite remote sensing (Bolton et al.,  
35 2020; Dixon et al., 2021), and tower-based digital cameras (~~Nasahara and Nagai, 2015~~; Richardson et al., 2018), etc.  
36 Nevertheless, integrating large-scale and long-term plant phenology information continues to pose a formidable challenge,  
37 owing to the substantial gaps in spatial and temporal scales between different data sources (Fisher et al., 2006; Park et al.,  
38 2021).

39 The practice of conducting manual, in-situ observations for species phenology (SP) boasts a rich history spanning  
40 several centuries (Aono and Kazui, 2008), yielding precise phenological information for the individual plant species (Polgar  
41 and Primack, 2011). In 1963, the Chinese Academy of Sciences inaugurated the Chinese Phenology Observation Network  
42 (CPON), a standardized, nationwide network employing a multitude of professional observers and incorporating extensive  
43 ground-based observations. To date, CPON has amassed over 1.2 million ~~SPphenology~~ records pertaining to more than 900  
44 plant species across over 150 sites throughout China (Fig. 1), cementing its dominant status as a data center for phenological  
45 research in China. These ~~phenologySP~~ records have been contributed to examining the spatiotemporal patterns of plant  
46 phenological shifts (Dai et al., 2014; Ge et al., 2015), the environmental determinants influencing plant phenology (Dai et  
47 al., 2013; Wang et al., 2020a), as well as the development of phenology models in China (Tao et al., 2018; ~~Wang et al.,~~  
48 ~~2015~~). Nonetheless, the spatial coverage of in-situ ~~phenologySP~~ data remains sporadic and restricted on regional and global  
49 scales (Donnelly et al., 2022), with noticeable gaps appearing in longer time scales. The progression of species-level  
50 phenology modeling presents an opportunity to address these limitations (Fu et al., 2020; Hufkens et al., 2018). In the  
51 absence of actual observed ~~phenologySP~~ data, phenology models can be employed to generate large-scale predictions,  
52 thereby interpolating the missing ~~SP~~-data in both space and time (Cleland et al., 2007; ~~Schwartz et al., 2013~~; Wang et al.,  
53 2012). For instance, the Extended Spring Indices (SI-x) model has been successfully applied to create gridded maps  
54 illustrating the first leaf and first bloom events for three woody plants at a resolution ranging from 1° to 1 km across the  
55 contiguous United States (Ault et al., 2015; Izquierdo-Verdiguier et al., 2018). Similarly, this model-based approach can be  
56 adapted to model and map the SP data throughout China. This would enable the integration and synthesis of CPON's long-  
57 term phenology observations at regional and national scales within the country.

58 In contrast to manual in-situ observations, satellite remote sensing facilitates the monitoring and mapping of land  
59 surface phenology (LSP) on a more expansive scale. It provides more comprehensive LSP information at the landscape level  
60 (Studer et al., 2007). Over the past four decades, remote sensing technology has witnessed considerable advancements,  
61 significantly improving the spatial and temporal resolution (Misra et al., 2020; Dronova and Taddeo, 2022). At present, a  
62 multitude of LSP products derived from vegetation indices (e.g., NDVI and EVI) procured from multi-source remote sensing  
63 data are accessible, offering regional and global LSP data with varying spatial resolutions ranging from 10 km to 30 m (e.g.,  
64 ~~Ganguly et al., 2010~~; Li et al., 2019; Wu et al., 2021; ~~Zhang et al., 2020~~). The credibility of these LSP data remains largely  
65 contingent upon ground phenology (GP) validation based on in-situ observed SP data (Tian et al., 2021; Zhang et al., 2017),

66 particularly the coordination and aggregation from individual-level phenology (i.e., SP) to landscape-level phenology (i.e.,  
67 GP). Weighted average and quantile methods have been proven effective for aggregating phenology from individual to  
68 community or landscape levels (Donnelly et al., 2022; Fitchett et al., 2015). Prior research has validated weighted average  
69 method on a site scale through field investigations and remote sensing monitoring, to aggregate GP at the community or  
70 landscape levels from in-situ SP data weighted by species abundance (Liang et al., 2011). Some recent studies have  
71 suggested that the quantile method (e.g., 30th percentile) holds greater promise than the commonly used average method on  
72 a larger scale, as evidenced in Europe and the USA (Ye et al., 2022). However, there is no previous study endeavored to  
73 employ these methods for aggregating large-scale GP from SP data in China, which may constrain the availability of ground  
74 validation evidence for LSP products and hinder comprehensive understanding of the spatio-temporal characteristics of  
75 phenological changes over the country.

76 In this study, we aimed to develop long-term SP and GP maps of China with a 0.1° resolution spanning 1951-2020,  
77 supplying spatially continuous grided phenology products currently absent in the country and crucial for a wider array of  
78 applications. We utilized 24,552 in-situ phenology observations of 24 representative woody plants from 122 sites over the  
79 past six decades from CPON. Three phenophases, namely the first leaf date (FLD), first flower date (FFD), and 100% leaf  
80 coloring date (LCD), were included for each species. We employed five species-level phenology models and grided  
81 meteorological data to simulate and produce SP maps, and utilized species distribution maps as masks of SP maps for each  
82 corresponding plant species. We applied weighted average and quantile methods on SP maps to aggregate and produce GP  
83 maps, which used the distribution probabilities of each species as weights. The accuracy of SP maps was assessed through  
84 cross-validation, while the reliability of GP maps was evaluated by comparing them with existing LSP products. This study  
85 introduces a novel grid phenology dataset for China, which supplements China's existing phenology data sources and  
86 provides an independent phenology data source for LSP product verification. The dataset will facilitate more comprehensive  
87 research on plant phenology and global change by better characterizing the spatiotemporal patterns of plant phenology.

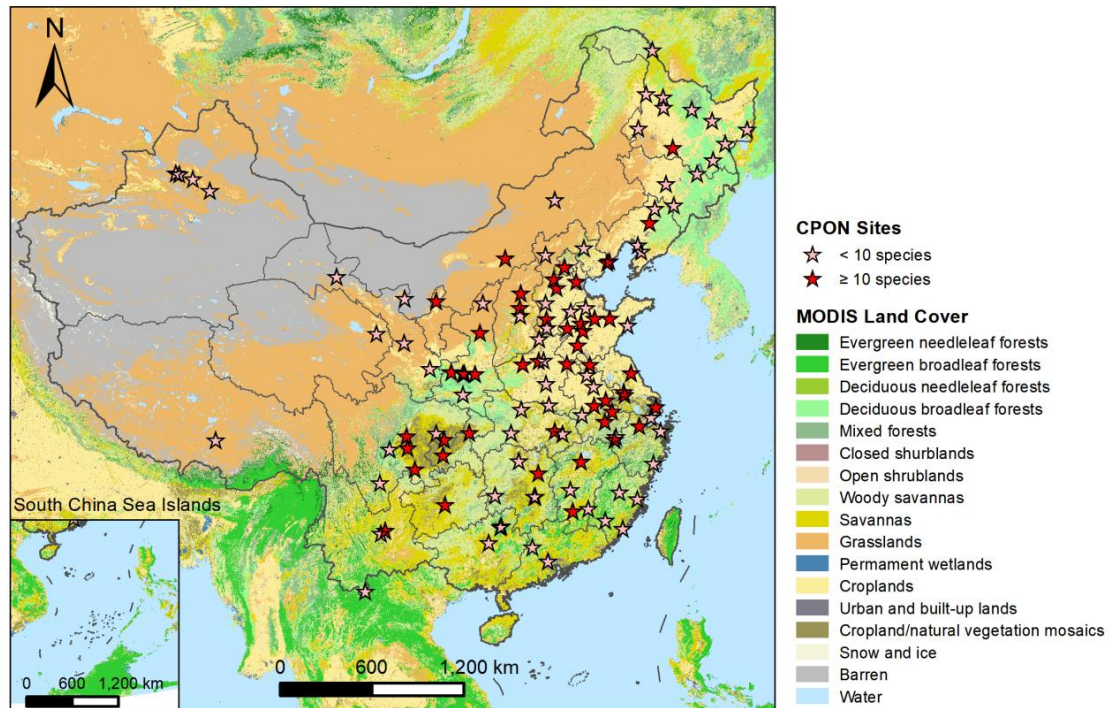

## 88 **2 Methods**

### 89 **2.1 Data acquisition and processing**

#### 90 **2.1.1 Phenology observations**

91 The in-situ phenology observations from 1963 to 2018 were obtained from the CPON. We selected 24 species of woody  
92 plants from 17 families in China (Table 1) that are common and widespread in forest ecosystems in China (Fang et al., 2011)  
93 and well-documented in CPON. These species have been observed over 55 years in 122 sites, with a total of 24,552 records,  
94 covering a range of land cover, ecological, and climatic conditions across China (Fig. 1). Each species had at least 40 years  
95 and 13 sites of phenology data. We ~~extracted~~<sup>studied</sup> three phenophases for each species: spring FLD, spring FFD, and  
96 autumn LCD. Three-sigma limits, which refers to data within three standard deviations from a mean, was used to set the

97 upper and lower limits of phenology data for each species (Pukelsheim, 1994). We identified and removed outliers beyond  
 98 the three-sigma lines, because they represented less than 1% of all data points on a standard normal distribution  
 99 curve. Outliers were eliminated for each species sites based on the principle of three sigma limits.

100

101 **Figure 1:** Geographic distribution of CPON sites (n = 122) included in the phenology dataset across China. Sites with less  
 102 than 10 recorded species are marked with pink asterisks, while sites with more than 10 recorded species are marked with red  
 103 asterisks. Note that the markings on the map of several adjacent sites may overlap each other. The background map shows  
 104 the IGBP land cover type from the MODIS Land Cover product (Friedl and Sulla-Menashe, 2022).

105

106 **Table 1:** List of 24 species of woody plants from 17 families in China. Number of records represents the total number of  
 107 three phenophases (FLD, FFD and LCD) of all sites and all years for each species.

No.	Species	Family	Life form	Number of sites	Number of years	Number of records
1	<i>Ginkgo biloba</i>	Ginkgoaceae	Tree	45	49	1110
2	<i>Metasequoia glyptostroboides</i>	Cupressaceae	Tree	37	47	860
3	<i>Magnolia denudata</i>	Magnoliaceae	Tree	42	47	980

4	<i>Salix babylonica</i>	Salicaceae	Tree	65	42	1526

108

## 109 2.1.2 Climate data

110 The daily mean temperature (T) from 1950-2020 were obtained from two sources: (1) Site T was extracted from climate  
111 observations in the China Meteorological Data Service Center (CMDSC, <https://data.cma.cn/>) and used to parameterize the  
112 phenology models. (2) Grid T was extracted from ERA5-Land climate reanalysis data (Muñoz Sabater, 2019; Muñoz-  
113 Sabater et al., 2021) from the Copernicus Climate Change Service (C3S, <https://cds.climate.copernicus.eu/>) and used for

114 phenology simulation and upscaling at a spatial resolution of 0.1° (about 10 km). Hourly grid T was averaged across four  
115 phases (4:00, 10:00, 16:00, 22:00) to derive the daily grid T.

116 The current bioclimatic (BIOCLIM+) variables were obtained from Climatologies at High Resolution for the Earth  
117 Land Surface Areas (CHELSA, <https://chelsa-climate.org/>) to determine the species distribution (Brun et al., 2022a, b). The  
118 BIOCLIM+ variables indicate the average ecological and climatic conditions during 1981-2010, with a high resolution of  
119 0.0083°. We extracted the traditional 19 bioclimatic layers (Bio1-Bio19) and the complementary 50 bioclimatic layers in  
120 China. We calculated the correlation between every two layers to reduce the impact of autocorrelation among these  
121 bioclimatic layers, and then excluded the layers with a correlation coefficient greater than 0.8 with the previous layers. As a  
122 result, 12 bioclimatic layers were retained as the environmental data inputs for the species distribution models (Table S1).  
123 These layers were resampled to 0.1° to match the resolution of the grid T data.

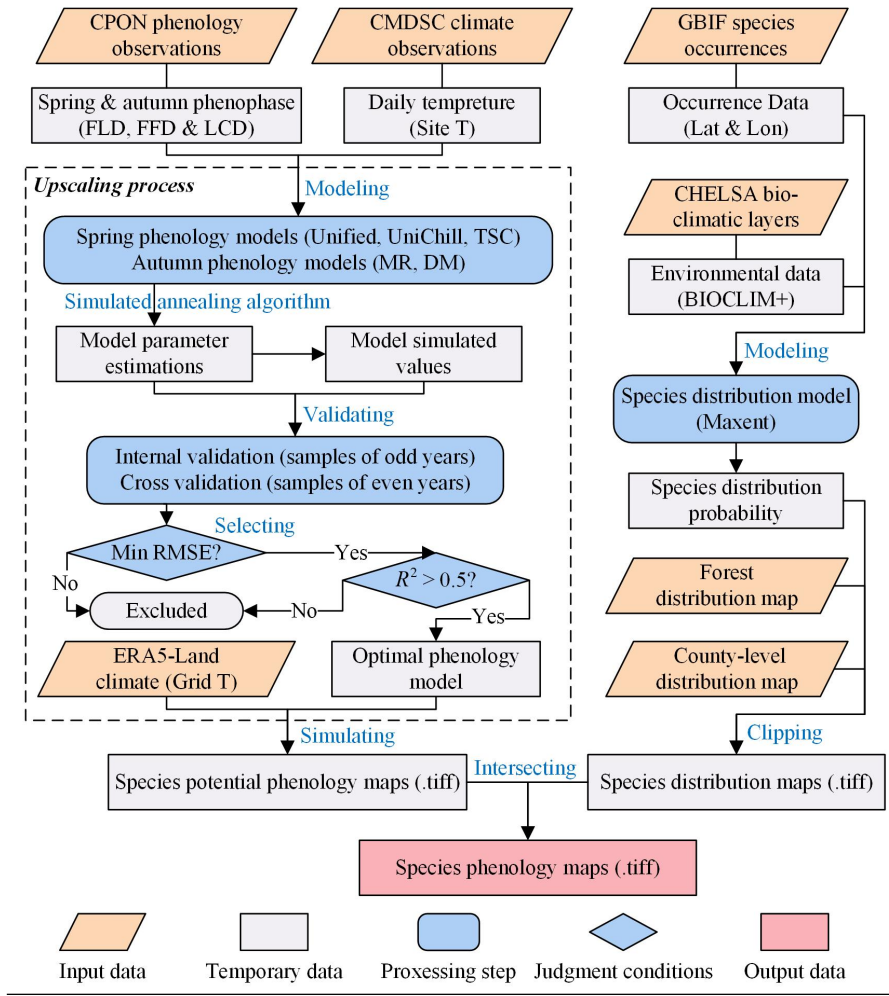

### 124 2.1.3 Forest and species distribution data

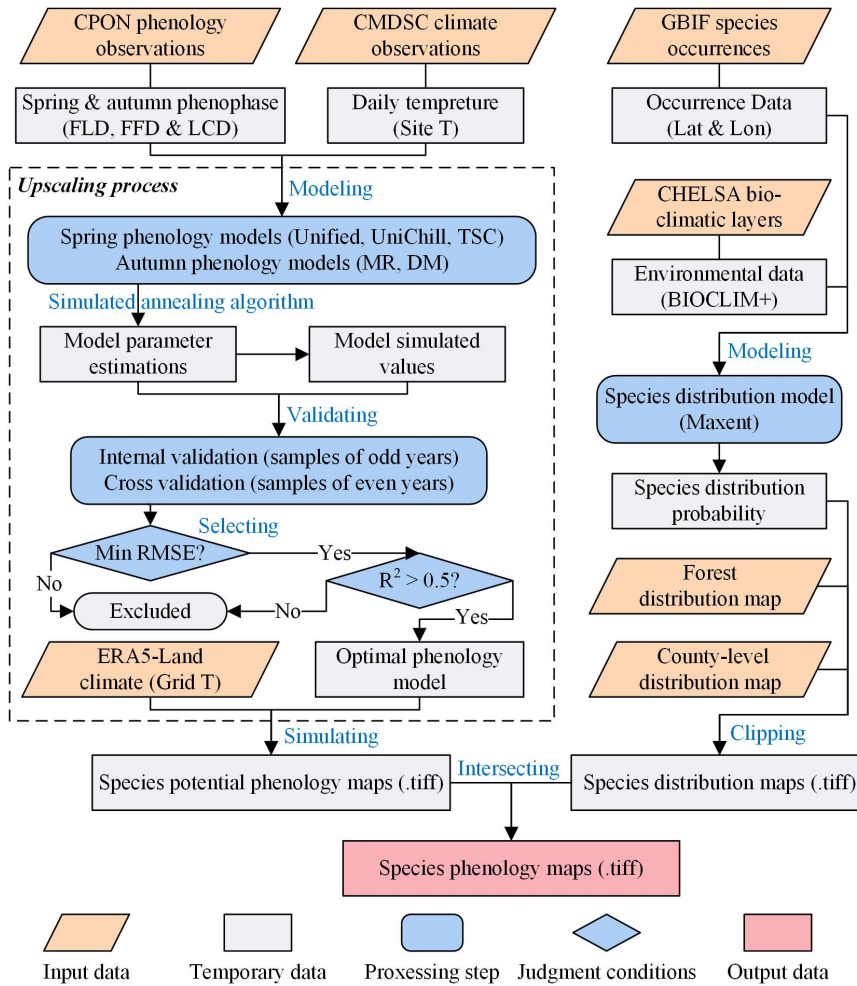

125 The forest distribution map of China was derived from the dataset of “Annual Dynamics of Global Land Cover and its  
126 Long-term Changes from 1982 to 2015” (Liu et al., 2020). Each year’s land cover (LC) layers were reclassified as forest and  
127 non-forest, and then the number of years of forest cover was obtained by adding all layers. Pixels with at least one year of  
128 forest cover were identified as forest distribution areas. The forest types were identified from the most commonly used  
129 International Geosphere-Biosphere Program (IGBP) classification from MODIS Land Cover Type (MCD12C1) Version 6.1  
130 data product (Friedl and Sulla-Menashe, 2022). We merged evergreen needleleaf forest (class 1) and evergreen broadleaf  
131 forest (class 2) into evergreen forest, and deciduous needleleaf forest (class 3) and deciduous broadleaf forest (class 4) into  
132 deciduous forest. Mixed forest (class 5) was also included in the forest type. The forest distribution map and forest type map  
133 were resampled from 0.05° to 0.1° by the majority method to match the resolution of the grid T data.

134 The county-level species distribution maps were obtained from the updated Database of China's Woody Plants (Fang et  
135 al., 2011). The distribution maps in this database were compiled from all national, provincial, and regional floras and  
136 inventory reports in China published before 2009, which are considered authoritative (Cai et al., 2021). We then obtained a  
137 total of 4371 occurrence records for 24 woody plant species~~the species occurrence records~~ from the Global Biodiversity  
138 Information Facility (GBIF, 2022; <https://www.gbif.org/>)~~(GBIF; https://www.gbif.org/)~~, and used them as the occurrence  
139 data inputs for the species distribution models ~~(GBIF, 2022)~~. The occurrence records were filtered by including the  
140 coordinate locations with uncertainty less than 2000 meters, and cleaned by removing duplicate records (Table S2).

### 141 2.2 Generating species phenology maps using a model-based upscaling method

142 The generation of species phenology maps involves two major processes: (1) Generating species potential phenology  
143 maps, and (2) Generating species distribution maps. The final SP maps were obtained by spatially intersecting these two  
144 maps. The workflow for the processes is shown in Fig. 2.

146

147 **Figure 2:** The workflow of generating SP maps using a model-based upscaling method, which involves two major  
 148 processes: (1) Generating species potential phenology maps, and (2) Generating species distribution maps. The words in blue  
 149 color represent the key processes of data generation. “.tiff” indicates the GeoTIFF format of the grid phenology or  
 150 distribution maps.

### 151 2.2.1 Species potential phenology maps

152 In the first process, we used a model-based upscaling method to convert in-situ phenology observations into grid  
 153 phenology maps. Phenology models were built using the phenophases (i.e., FLD, FFD, LCD) from CPON phenology  
 154 observations and the corresponding site T from CMDSC climate observations. For each species, we built three spring  
 155 phenology models: the Unichill, Unified (Chuine, 2000) and temporal-spatial coupling (TSC) models (Ge et al., 2014), and  
 156 two autumn phenology models: the multiple regression (MR) (Estrella and Menzel, 2006) and temperature-photoperiod (TP)

157 models (Delpierre et al., 2009). The details of the model formulae are described in Appendix S1. For each model, samples  
158 from odd years were used for phenology modeling, and samples from even years were reserved for cross validation on the  
159 model. All model parameters were estimated using the simulated annealing algorithm (Chuine et al., 1998).

160 For model validation, the models' root mean square error (RMSE) and goodness of fit ( $R^2$ ) were calculated between the  
161 model simulated values and original values. Internal validation was conducted on samples from odd years to evaluate the  
162 fitting effect of the model, and cross validation was conducted on samples from even years to evaluate the simulation and  
163 extrapolation effect of the model. The optimal phenology model for each species was selected based on the smallest RMSE  
164 in cross validation and  $R^2$  greater than 0.5 (0.3 for LCD) in both validations. If no model met these conditions, the species  
165 was excluded when generating SP maps or GP maps.

166 For simulating SP maps, daily grid T data from ERA5-Land climate reanalysis were input into the optimal phenology  
167 model and simulated pixel by pixel. This way, the phenology observations from individual sites were interpolated and  
168 upscaled into a grid phenology map based on the phenology models (Chuine et al., 2000). However, as long as there was  
169 grid T data, simulated species phenology could be obtained, even if there was no species distribution. Therefore, we named it  
170 as species potential phenology map to avoid taking simulated values as true values in areas without species distribution.

### 171 **2.1.2 Species distribution maps**

172 In the second process, we simulated the species distribution maps using both species distribution models and county-  
173 level species distribution data. Species distribution models were built for each species using Maximum Entropy Species  
174 Distribution Modelling (Maxent; Phillips et al., 2006) version.3.4.4. Maxent estimates the range of a species by finding the  
175 species distribution of maximum entropy (i.e., closest to the uniform), which is widely adopted in species distribution  
176 modeling (Phillips et al., 2006). It expresses a probability distribution where each grid cell has a predicted probability of  
177 presence for the species. To build the Maxent model, species location records from the GBIF database were used as  
178 occurrence data input, and the 12 bioclimatic layers from BIOCLIM+ were used as the environmental data input. In the  
179 model parameter settings, linear and quadratic feature types were used and 5-fold cross validation was used as the replicated  
180 run type.

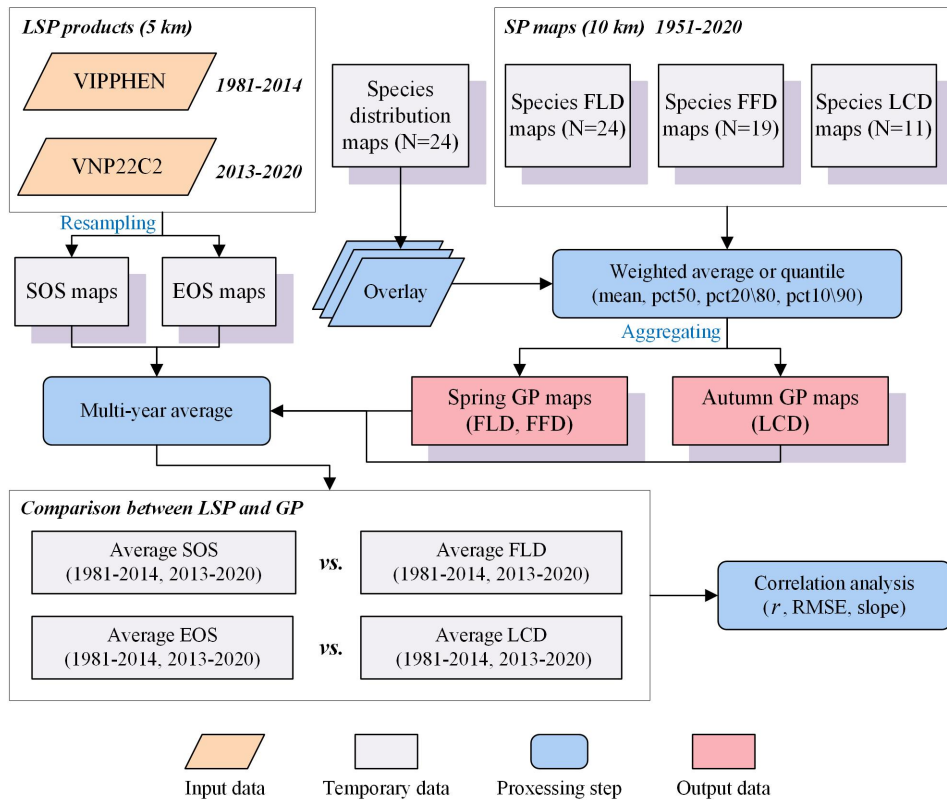

181 For model validation, the receiver operating characteristic (ROC) curve analysis method was used to test the accuracy  
182 of the Maxent prediction model. The area under the ROC curve, known as the AUC value, is usually used as an indicator of  
183 the prediction accuracy of the model (Fielding and Bell, 1997). The closer the AUC value is to 1.0, the more accurate the  
184 prediction result of the model is. The average test AUC for different species was 0.845, with a standard deviation of 0.043  
185 ([Table S2](#)).

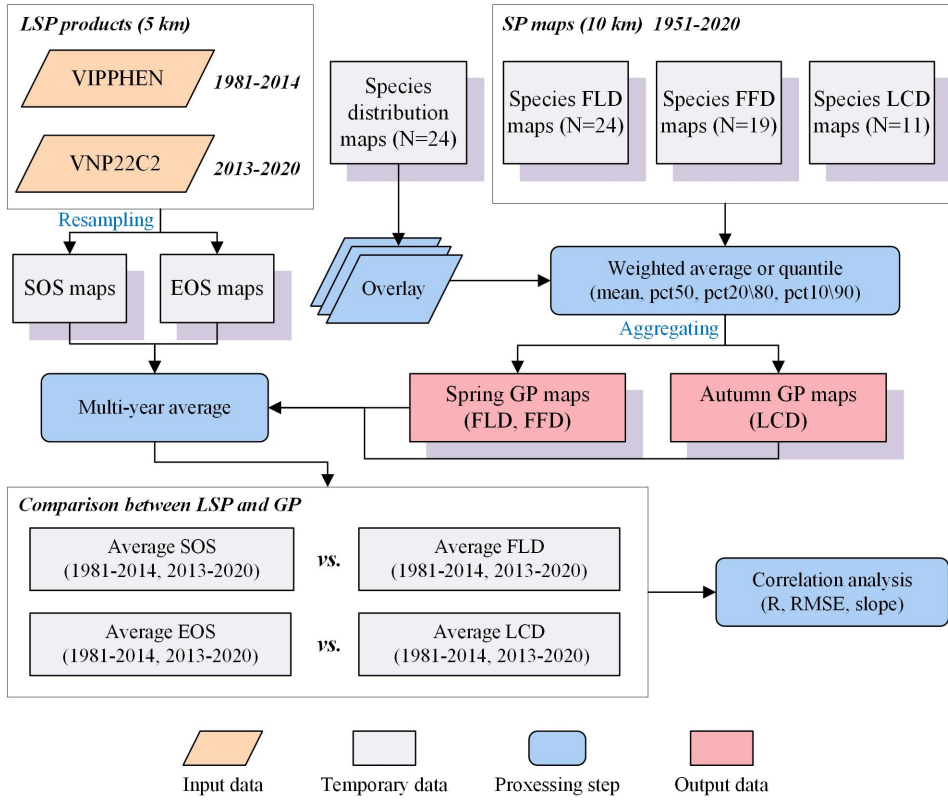

### 186 **2.3 Generating ground phenology maps using weighted average and weighted quantile methods**

187 We used four methods to aggregate from individual-level SP maps to landscape-level GP maps: (1) weighted average  
188 (mean); (2) weighted median (pct50); (3) weighted 20th percentile (pct20) for spring phenology or weighted 80th percentile

189 (pct80) for autumn phenology; (4) weighted 10th percentile (pct10) for spring phenology or weighted 90th percentile (pct90)  
190 for autumn phenology. ~~Previous studies typically used species abundance as aggregation weights at the local scale, but it is~~  
191 ~~difficult to obtain such data at the regional scale. Therefore, we used species distribution probability instead of species~~  
192 ~~abundance as aggregation weight for each species. This assumption is based on a positive correlation between species~~  
193 ~~distribution and abundance (Brown, 1984), demonstrating that species tend to be most abundant at the center of their~~  
194 ~~geographic range (Sagarin and Gaines, 2002).The weight of each species was determined by the species distribution~~  
195 ~~probability, as it is assumed that the species abundance is positively related to the species distribution probability.~~ The  
196 aggregation methods of GP in this study (e.g., pct50, pct20\80 and pct10\90) are comparable and similar to the extraction  
197 methods of LSP from remote sensing data (e.g., midpoint, dynamic threshold and maximum curvature). The workflow is  
198 shown in Fig. 3.

199

201

202

**Figure 3:** The workflow of generating GP maps from SP maps, and comparing GP maps with two LSP products. The words in blue color represent the key processes of data generation.

203

204

205

For  $n$  species, the phenophases ( $Y$ ) were first sorted from small to large. The SP of each species is  $y_i$  ( $i = 1, 2, \dots, n$ ), and the distribution probability of each species is  $p_i$  ( $i = 1, 2, \dots, n$ ). Then, the aggregated GP ( $Y_{mean}$  and  $Y_{pct}(x\%)$ ) was calculated according to the following formulas:

206

207

208

$$\omega_i = \frac{p_i}{\sum_{i=1}^n p_i} \quad (1)$$

209

$$W_j = \sum_{i=1}^j \omega_i, j = 1, 2, \dots, n \quad (2)$$

210

$$Y_{mean} = \sum_{i=1}^n \omega_i \times y_i \quad (3)$$

211

$$Y_{pct} = \begin{cases} y_1, & \text{if } W_1 > x \\ (y_j - y_{j-1}) \times \frac{x - W_{j-1}}{\omega_j}, & \text{if } W_j > x, W_{j-1} < x \\ y_n, & \text{if } W_{n-1} < x \end{cases} \quad (4)$$

212 Where  $\omega_i$  is the weight of each species,  $W_j$  is the cumulative weight from the first to the  $j$  species,  $x\%$  is the percentile tag  
213 which takes values from 10%, 20%, 50%, 80% and 90%. These formulas were used to calculate the aggregated GP maps by  
214 combining the species phenology maps with the species distribution maps and weighting them by the species distribution  
215 probability.

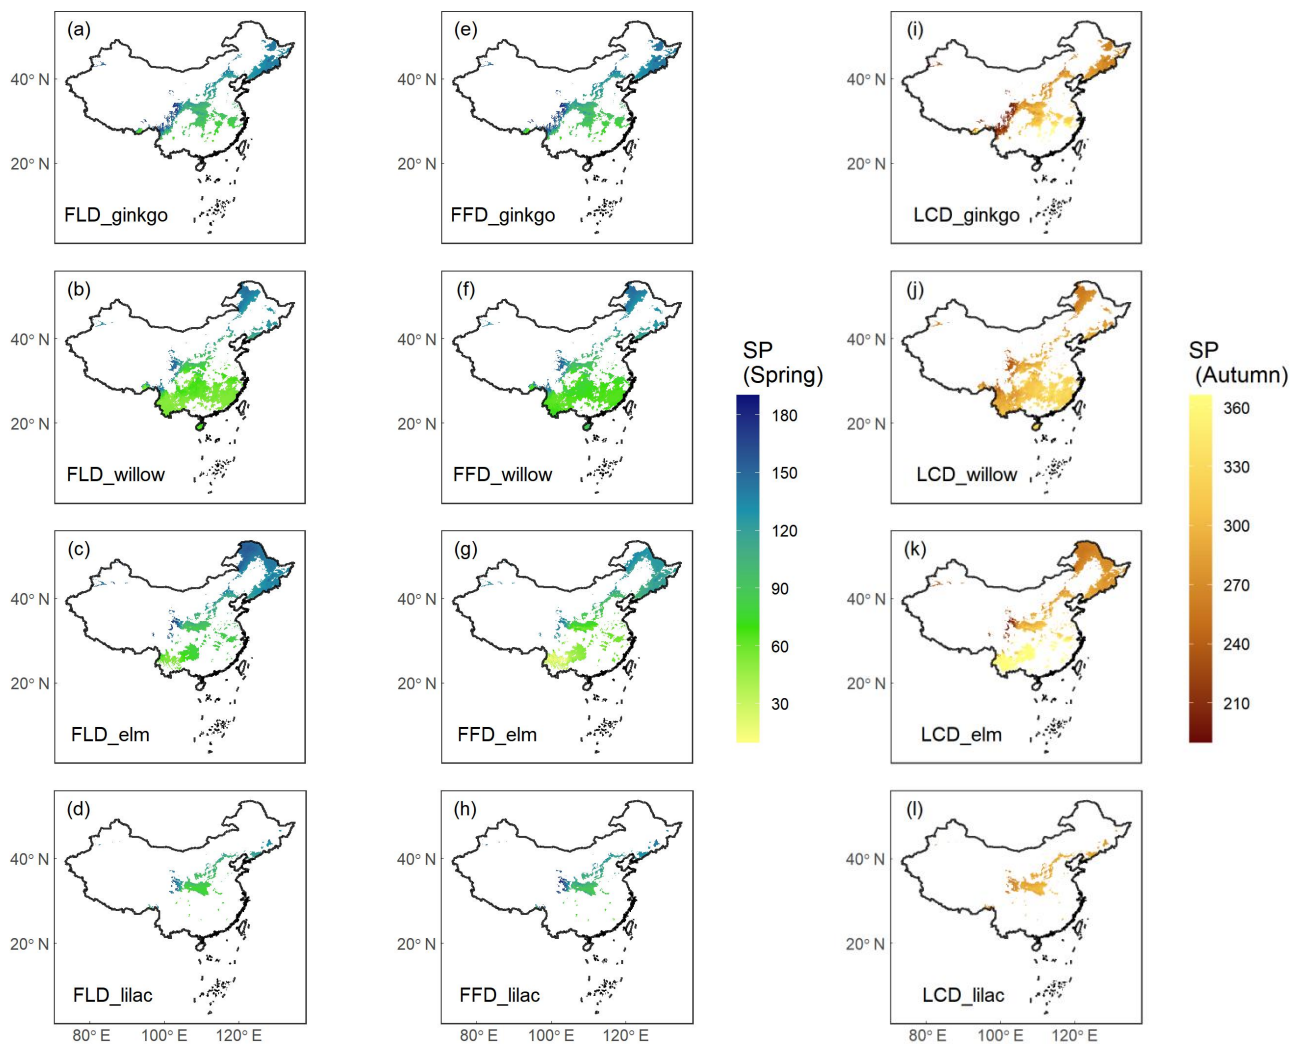

216 Finally, to assess data quality, the aggregated GP maps in this study were compared with two LSP products extracted  
217 from remote sensing in previous studies ~~to assess data quality~~: (1) VIPPHEN\_NDVI product (1981-2014), which used  
218 midpoint method to extract the start of season (SOS) and the end of season (EOS) from the AVHRR data (Didan and  
219 Barreto, 2016); (2) VNP22C2 product (2013-2020), which used maximum curvature method to extract SOS and EOS from  
220 the MODIS data (Zhang et al., 2020b). Both LSP products were resampled from 5 km to 0.1° by the average method to  
221 match the spatial resolution of GP maps. The LSP and GP maps were averaged in two segments (1981-2014 and 2013-  
222 2020), and the correlation analysis was conducted between FLD and SOS in spring and between LCD and EOS in autumn.  
223 Pearson correlation coefficient ( $R_r$ ), RMSE, and linear regression slope were used to evaluate the consistency between GP  
224 and LSP.

## 225 3 Results and discussion

226 The dataset includes two types of phenology maps over China: (1) Yearly SP maps generated by the model-based  
227 upscaling method for 24 woody plants; (2) Yearly GP maps generated by four aggregation methods, along with the  
228 corresponding quality assurance (QA) maps. The phenology maps provide spring FLD, FFD, and autumn LCD of woody  
229 plants and forests over China from 1951 to 2020, with a spatial resolution of 0.1° and a temporal resolution of 1 day. Each  
230 map is stored in a 16-bit signed integer file in GeoTIFF format, which contains a two-dimension raster (641 row  $\times$  361  
231 column). The unit of phenology data is the Julian Day of year (DOY), which represents the actual number of days from  
232 January 1st to the date of phenology occurrence. The valid values range from DOY 1 to 366, and the null values equal to -1.

### 233 3.1 Simulation and validation of species phenology maps

234 The SP maps of FLD (24 species), FFD (19 species), and LCD (12 species) were simulated using the optimal  
235 phenology models, and then masked by the species distribution maps. Here, we present the results of simulated SP maps of  
236 four typical woody species (Fig. 4), including ginkgo (*Ginkgo biloba*), willow (*Salix babylonica*), elm (*Ulmus pumila*), and  
237 lilac (*Syringa oblata*). These maps showed that the phenophases of different species have a consistent spatial pattern of  
238 variation along latitude. Specifically, spring FLD and FFD of these species were significantly later with increasing latitude,  
239 while autumn LCD was significantly earlier with increasing latitude. Despite similar spatial patterns, the phenophases of  
240 different species show distinct temporal differences at the same latitude; for example, at lower latitudes, elm has  
241 significantly earlier spring FFD and later autumn LCD than other species. Phenophases of some species were not simulated  
242 because the  $R^2$  of their optimal models was too small, e.g.,  $R^2 < 0.5$  for spring FFD, and  $R^2 < 0.3$  for autumn LCD.

244

245 **Figure 4:** Species phenology (SP) maps of four typical woody species averaged from 1951 to 2020. Columns 1-2 show the  
 246 spring phenophases (FLD and FFD), and Column 3 shows the autumn phenophase (LCD). Each row represents a species  
 247 from ginkgo (*Ginkgo biloba*), willow (*Salix babylonica*), elm (*Ulmus pumila*), and lilac (*Syringa oblata*). The unit of  
 248 **SPphenology data** is the Julian Day of year (DOY) from January 1st.

249

250 **Table 2:** The optimal phenology models and cross-validation results of 24 species. RMSE represents the root mean square  
 251 error between the model simulated values and original values.  $R^2$  represents goodness of fit of the optimal phenology model.

No.	Species	FLD	FFD	LCD

252

253

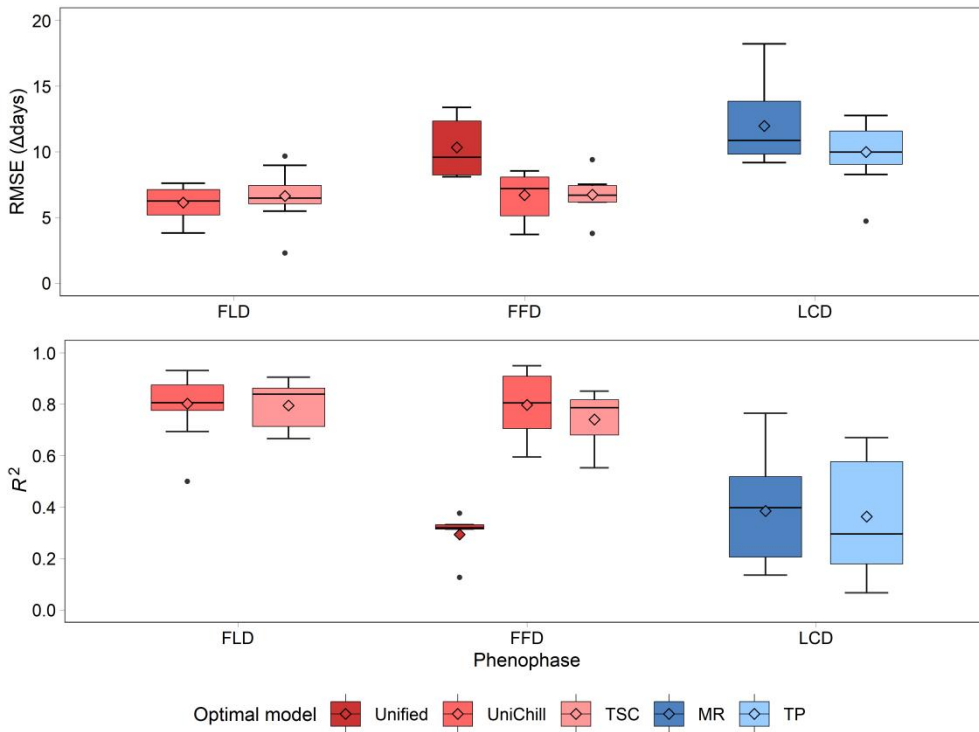

254

The simulation effects of species phenology maps were evaluated by cross-validation on the optimal phenology models (Table 2). The results showed that the simulation effects of spring phenology were significantly better than that of autumn

255 phenology (Fig. 5). Specifically, the RMSE of the optimal model of FLD (6.38 days) and FFD (7.46 days) in spring were  
256 significantly smaller than that of LCD (10.80 days) in autumn. And the  $R^2$  of the optimal model of FLD (0.799) and FFD  
257 (0.676) in spring were significantly greater than that of LCD (0.372) in autumn. However, there was no significant  
258 difference between spring FLD and FFD simulation effects ~~in spring~~. Among the optimal spring phenology models, the FFD  
259 simulation effects of UniChill and TSC models were significantly better than Unified model.~~UniChill and TSC models, as~~  
260 ~~the optimal model, had significantly better FFD simulation effects than Unified models for the different phenology models in~~  
261 ~~spring. But in autumn, the LCD simulations effects are similar for MR and TP models.~~~~MR and TP models had similar LCD~~  
262 ~~simulation effects for the different phenology models in autumn.~~

263

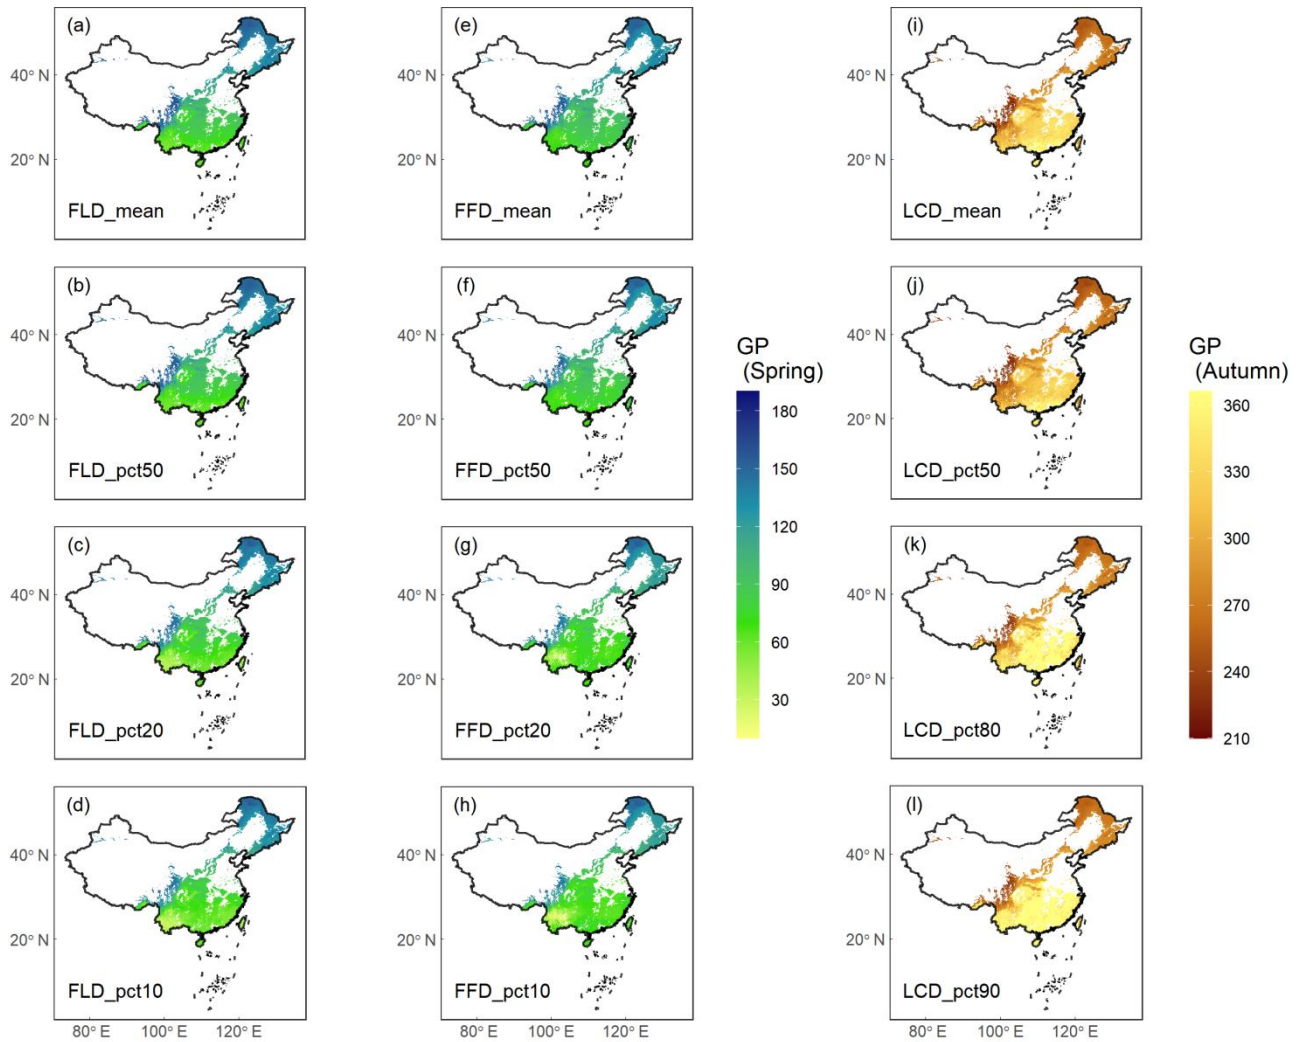

264

265

266 **Figure 5:** The RMSE (a) and  $R^2$  (b) of cross-validation on the optimal phenology models for 24 woody species. Each model  
267 is represented by a different color, with warm colors for three spring phenology models (Unified, UniChill, TSC), and cool  
268 colors for two autumn phenology models (MR, TP). The model with the smallest RMSE was selected as the optimal model  
269 for each species. The horizontal line represents the median value, the diamond mark represents the mean value, and the dot  
270 mark represents the outlier in the boxplot.

### 271 3.2 Aggregation of ground phenology maps

272 The results of GP maps generated by four different aggregation methods (mean, pct50, pct20\80, pct10\90) showed  
273 similar spatial patterns (Fig. 6), i.e., the consistent variation along latitude or altitude. With the increase of latitude or  
274 altitude, the spring GP (FLD and FFD) became later, and the autumn GP (LCD) became earlier. For different aggregation  
275 methods, the GP maps aggregated from the mean and pct50 methods were highly consistent, with  $R_r$  being 0.992; while the  
276 GP maps aggregated from the pct20\80 and pct10\90 methods were slightly different from the former two, with  $R_r$  being  
277 0.968 and 0.949, and showed larger spatial variation than the former two. The high consistency between the mean and pct50  
278 maps indicated that both the weighted mean method and weighted quantile method were robust for the aggregation of GP.  
279

280

281 **Figure 6:** Ground phenology (GP) maps of four aggregation methods averaged from 1951 to 2020. Columns 1-2 show the  
 282 spring phenophases (FLD and FFD), and Column 3 shows the autumn phenophase (LCD). Each row represents an  
 283 aggregation method from weighted average (mean), weighted median (pct50), weighted 20% or 80% percentile (pct20\80),  
 284 and weighted 10% or 90% percentile (pct10\90). The unit of GP is the Julian Day of year (DOY) from January 1st.

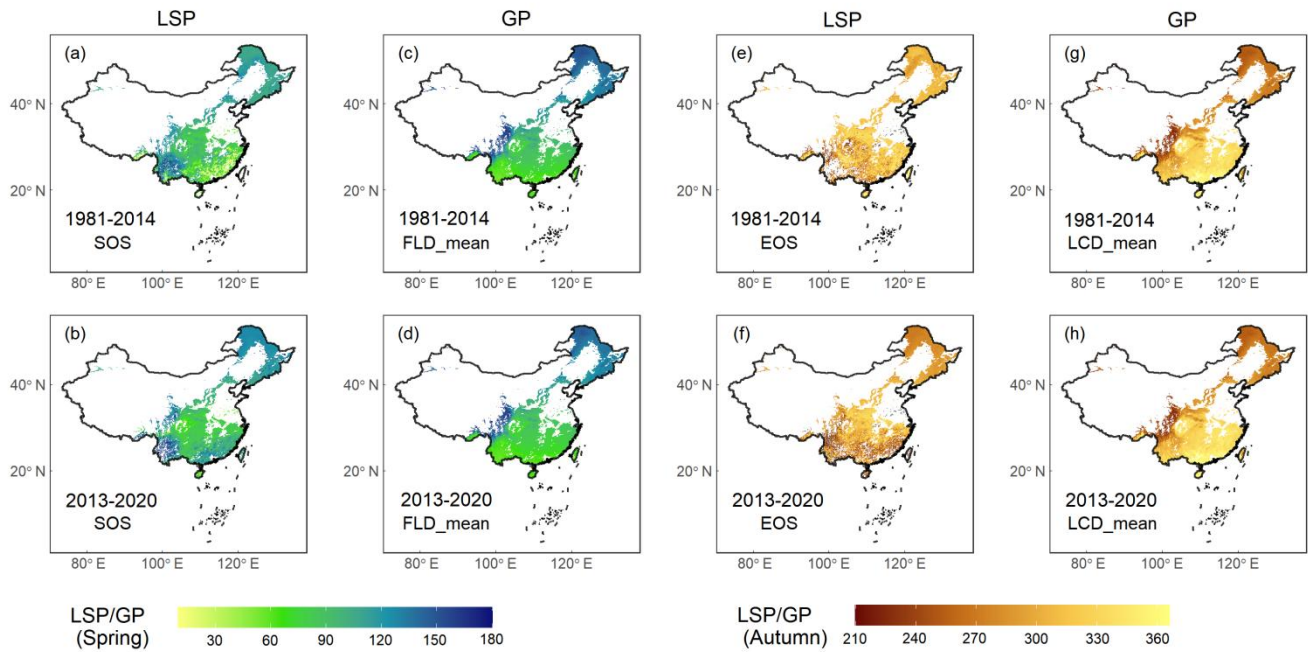

285

286 We also provided two QA maps to evaluate the reliability of the aggregation results of GP maps (Fig. S1). The first is  
 287 the total distribution probability of all species, and the second is the total number of species with distribution probabilities  
 288 greater than 0.1. In the QA maps, higher values mean larger total number or probability of species for the aggregation,  
 289 indicating that GP maps have higher reliability in these areas. The regions with the most reliable GP aggregation results were  
 290 distributed around 30° N in China. The total number of species is about 15 for FLD and FFD, and is about 6 for LCD in

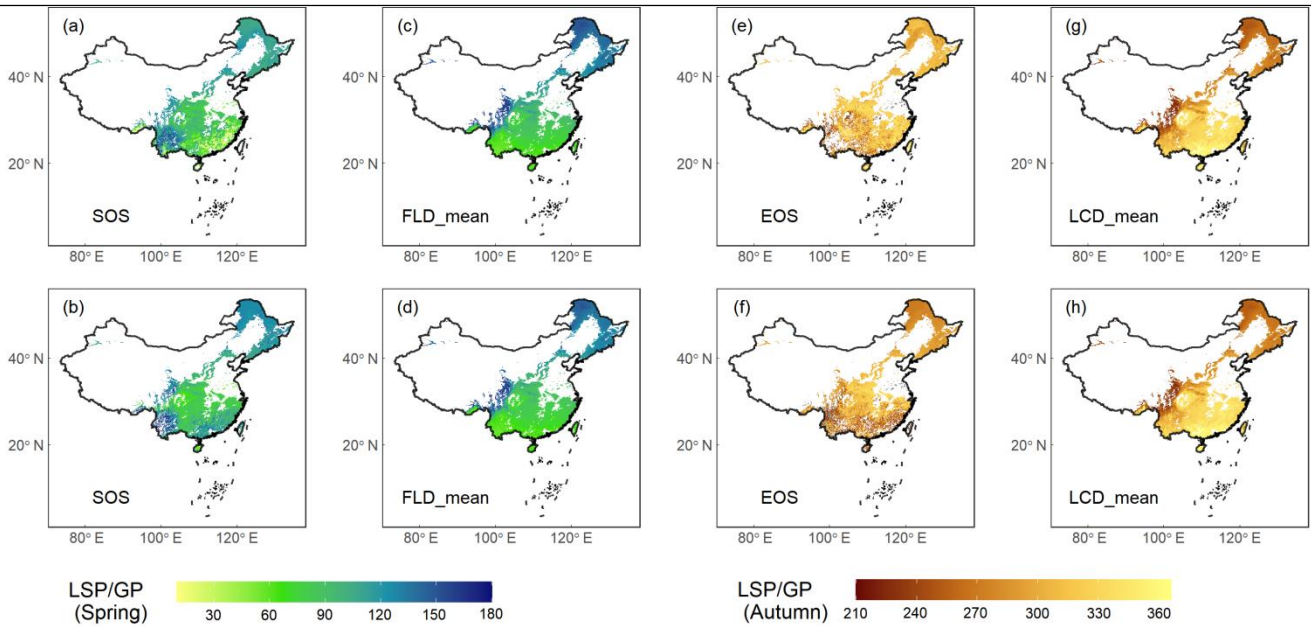

291 these regions. It should be noted that in the QA map, in areas where the total number of species is less than 5 or the total  
292 probability of species is less than 1, the aggregation results of GP may not be reliable.

### 293 3.3 Data quality and usability

294 GP and LSP were compared between FLD and SOS in spring and between LCD and EOS in autumn during two  
295 segments (1981-2014 and 2013-2020). The results showed that GP and two LSP products had similar spatial patterns in  
296 central and northern China but relatively different patterns in southern China (Fig. 7), particularly for LCD and EOS in  
297 autumn (Fig. 7e-h). This is likely due to the prevalence of deciduous forests (~~DF~~) in central and northern China (Fig. 1). In  
298 contrast, evergreen ~~forests~~ (~~EF~~) and mixed forests (~~MF~~) are found in southern China. GP in this study was generated by  
299 aggregating the SPphenology of 24 deciduous woody plants, which made up a large proportion of ~~DF~~ deciduous forests but  
300 a small proportion of evergreen or mixed forests ~~EF or MF~~. Additionally, LSP extracted from remote sensing data tends to  
301 have a larger error in evergreen and mixed forests ~~EF and MF~~ due to the lack of obvious seasonal change and frequent cloud  
302 cover in these regions (Liu et al., 2016b). As a result, the consistency between GP and LSP was relatively poor in evergreen  
303 or mixed forests ~~EF and MF areas~~ (Fig. S2), with the maximum  $R_r$  being 0.44 in spring and 0.54 in autumn, and the  
304 minimum RMSE being 28.5 days in spring and 38.5 days in autumn (Table S2). In contrast, the consistency between GP and  
305 LSP was much better in ~~DF~~ deciduous forests ~~area~~, with the maximum  $R_r$  being 0.95 in spring and 0.88 in autumn, and the  
306 minimum RMSE being 8.8 days in spring and 15.1 days in autumn, respectively.

307

308

309

310

311

312

**Figure 7:** Comparison of GP maps in this study and two LSP products (VIPPHEN and VNP22C2) extracted from remote sensing in previous studies, which was made between FLD and SOS in spring and LCD and EOS in autumn. Row 1 shows the comparison between VIPPHEN product and GP map averaged in 1981-2014, and Row 2 shows the comparison between VNP22C2 product and GP map averaged in 2013-2020. (a-b) SOS from two LSP products; (c-d) FLD aggregated by mean

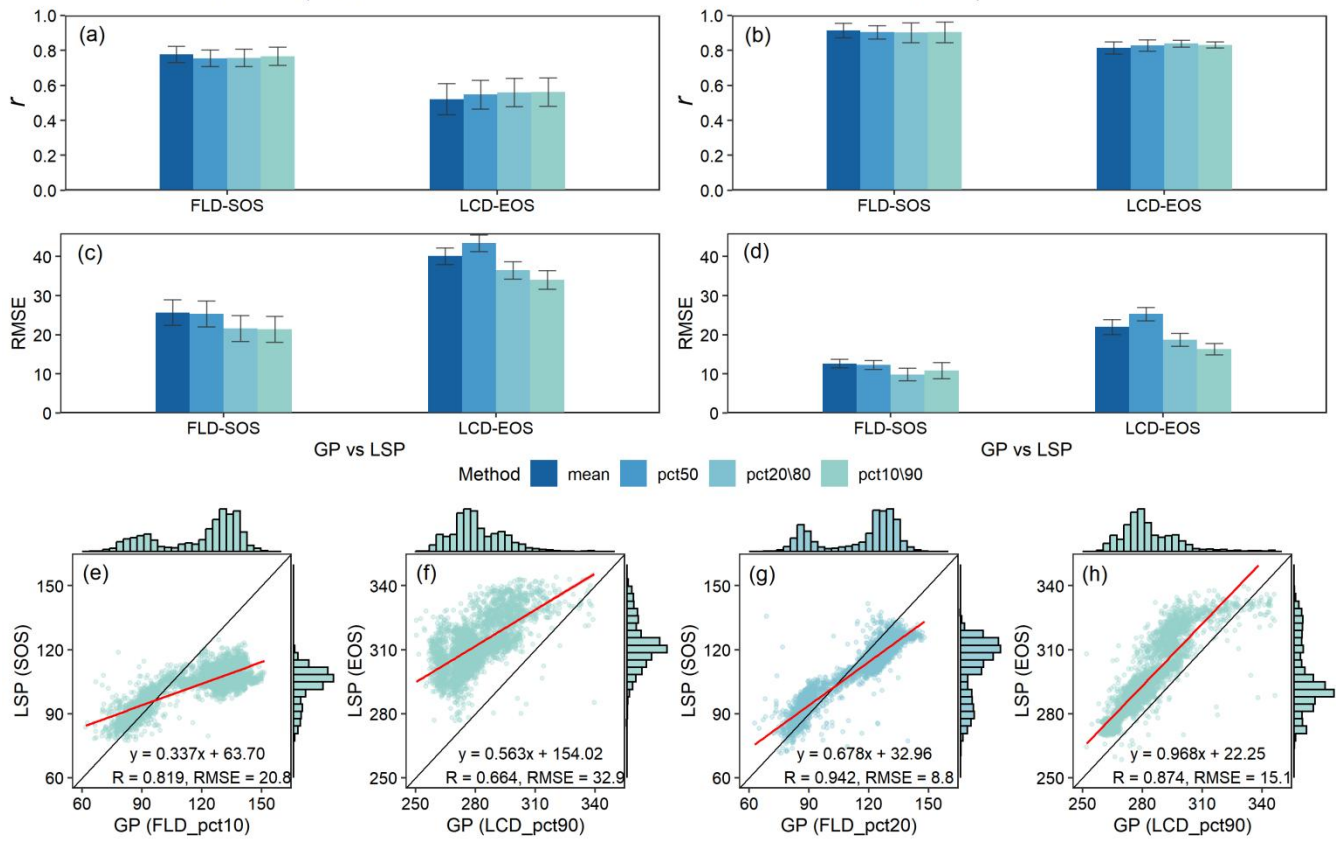

313 method; (e-f) EOS from two LSP products; (g-h) LCD aggregated by mean method. The unit of GP or LSP is the Julian Day  
314 of year (DOY) from January 1st.

315

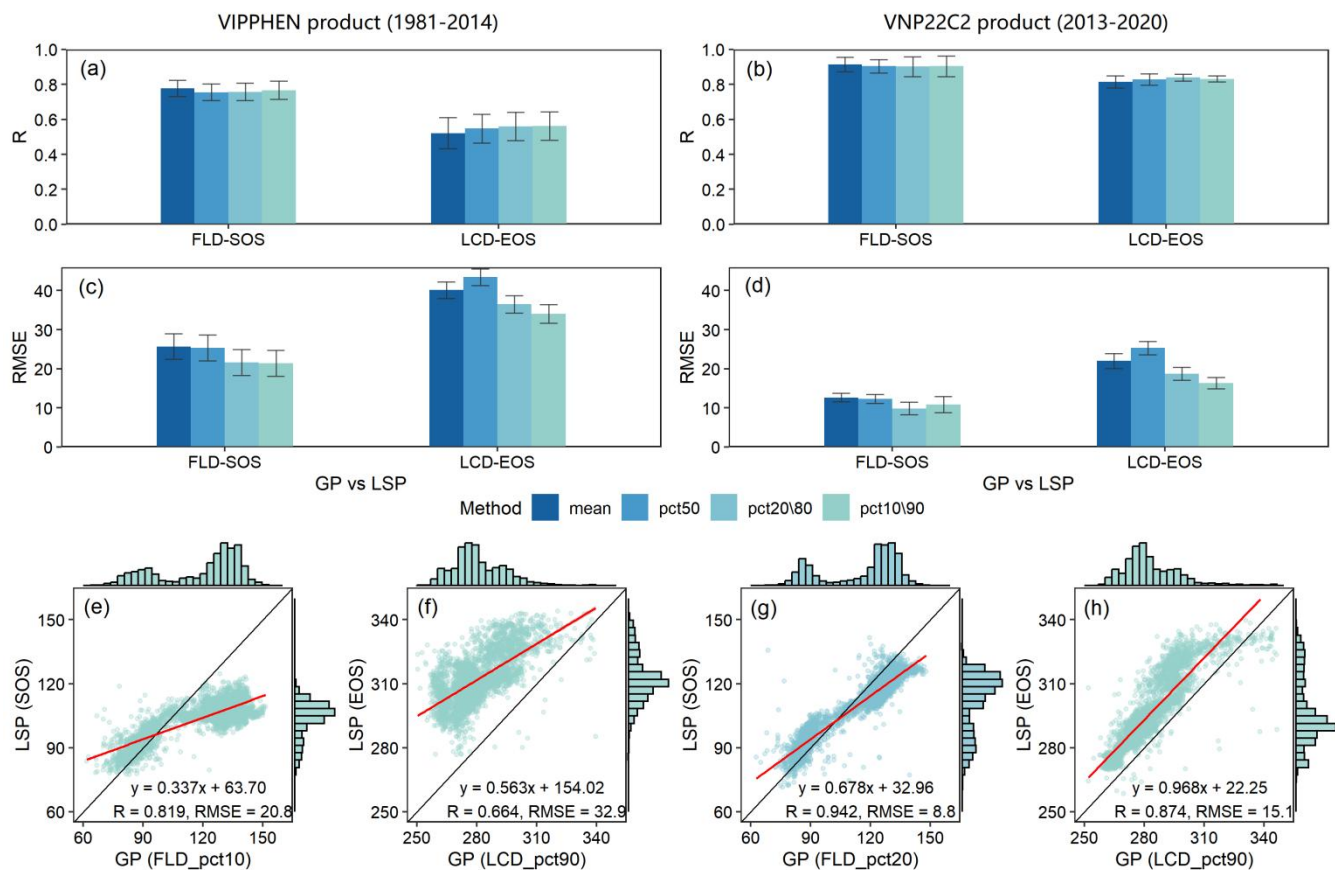

316 To further assess the quality of the data, we examined the consistency between GP and LSP specifically in ~~DF~~-areas  
317 deciduous forests. The results showed that GP and LSP had good consistency ~~in DF areas~~ for both VIPPHEN and VNP22C2  
318 products, i.e., high correlation ~~( $R$ )~~, small difference ~~(RMSE)~~, and good linear relationship (Fig. 8). Compared with the LSP  
319 of VIPPHEN product, the LSP of VNP22C2 product has better consistency with the GP of this study. In addition, for both  
320 products, the consistency between GP and LSP in spring (Fig. 8e, g) was significantly better than that in autumn (Fig. 8f, h).  
321 When comparing different aggregation methods (mean, pct50, pct20/80, pct10/90), there was no significant difference in  ~~$R$~~   
322 between GP and LSP (Fig. 8a, b). All methods produced similar  ~~$R$~~  values, ranging from 0.76-0.78 in spring and 0.49-0.53 in  
323 autumn for the VIPPHEN product, and from 0.90-0.91 in spring and 0.79-0.84 in autumn for the VNP22C2 product.  
324 However, different methods produced significantly different RMSE values between GP and LSP (Fig. 8c, d), largely due to  
325 the differences in the average values of GP under different methods. The best aggregation methods, with the minimum  
326 RMSE, were pct10 (20.8 days) in spring and pct90 (32.9 days) in autumn for the VIPPHEN product, and pct20 (8.8 days) in  
327 spring and pct90 (15.1 days) in autumn for the VNP22C2 product.

VIPPHEN product (1981-2014)

VNP22C2 product (2013-2020)

328

**Figure 8:** Comparison results of GP maps and two LSP products (VIPPHEN and VNP22C2) in DF-areas deciduous forests, which was made between FLD and SOS in spring and LCD and EOS in autumn within the time range 1981-2014 and 2013-2020. (a-b)  $R_r$  between LSP and GP under four aggregating methods; (c-d) RMSE between LSP and GP under four aggregating methods; (e-h) Linear relationship between between LSP and GP under the best aggregating method. Each aggregating method is represented by a different color. The best aggregating method was determined by minimizing the RMSE between GP and LSP in-DF-areas. The error bar in the bar plot represents the multi-year standard deviation. The red line in the scatter plot represents the linear regression line between GP and LSP, and all regression results were extremely significant ( $p < 0.001$ ).

It is worth noting that the aggregation method with the smallest difference between GP and LSP in this study was the 10th or 20th percentile in spring and the 90th percentile in autumn. It means that the spring green-up event detected by remote sensing is more consistent with the FLD of earlier-developing plant species (the first 10%-20%) on the ground, while the autumn dormancy event from remote sensing is more consistent with the LCD of later-senescent plant species (the last

343 10%) on the ground. These results reveal a potential connection between GPs and LSPs despite their different physical  
344 implications in diagnosing phenology.

345 In general, this dataset provides high reliability ~~SP and GP~~ species and ground phenology simulations of forests over  
346 China for the past 70 years. It is an independent phenology data source generated by the modeling and aggregation based on  
347 ground observations. There are several considerations in data application:

348 (1) For SP maps, the accuracy of data was determined by RMSE and  $R^2$  of cross-validation on the optimal phenology  
349 model for each species (Table 2). Additionally, the reliability of SP phenology data in space was affected by the number of  
350 sites available for modeling on each species (Table 1). For instance, the accuracy of *Betula platyphylla*'s FLD was very high  
351 overall (RMSE = 3.80 and  $R^2 = 0.915$ ), but the local accuracy might be relatively poor in areas with sparse sites due to very  
352 few sites of *Betula platyphylla* in space ( $n = 13$ ). In this study, the SP maps of 24 species in China were found to be largely  
353 consistent with the in-situ observations, with an average error of 6.4, 7.5 and 10.8 days for FLD, FFD and LCD,  
354 respectively. These errors were the same or smaller than those of phenology modelling in previous studies. For example, the  
355 simulation error of spring FLD and FFD was 7-9 days in central Europe (Basler, 2016) and was 12.3-12.7 days in the United  
356 States (Izquierdo-Verdiguier et al., 2018), while the simulation error of autumn LCD was 10.3-13.0 days in France  
357 (Delpierre et al., 2009) and 5.9-22.8 days in the United States (Jeong and Medvigy, 2014). Therefore, compared with other  
358 studies on the regional scale, the SP maps of China in this study were found to have relatively high accuracy.

359 (2) For GP maps, the reliability of data can be determined by QA maps which provide the total number or probability of  
360 species. Additionally, the reliability can also be evaluated by comparing GP data with other LSP products, with high  
361 consistency indicating good reliability. Since GP data actually provide phenology estimates of the deciduous DF components  
362 in the forests, it has better reliability in the ~~DF areas~~ deciduous forests but less reliability in evergreen or mixed forests ~~EF or~~  
363 MF areas. In this study, GP maps of forests in China were found to have good consistency with the existing LSP products,  
364 particularly in ~~DF area~~ deciduous forestss, where the correlation coefficients of FLD and LCD were 0.91 and 0.84,  
365 respectively. The differences between GP and LSP in FLD and LCD were also found to be relatively small in ~~DF area~~  
366 deciduous forests, being 8.8 days and 15.1 days, respectively. Previous studies have shown poor consistency between single  
367 species and LSP, with correlation coefficients ranging from 0.50 to 0.51 in the United States (Peng et al., 2017) and  
368 Germany (Kowalski et al., 2020), and differences ranging from 12 to 14.5 days in the United States (Peng et al., 2017) and  
369 Canada (Delbart et al., 2015). In contrast, research comparing average or quantile values of multiple species has shown  
370 better results similar to this study. For example, the correlation coefficients between the average (or weighted average) GP  
371 and LSP were found to be 0.61 to 0.71 in Europe (Rodriguez-Galiano et al., 2015; Tian et al., 2021). The correlation  
372 coefficients between the 30th percentile GP and LSP were found to be 0.54 to 0.57 in China (Wu et al., 2016). The  
373 differences between the GP and LSP in previous studies were 10.3-12.4 days in China (Wu et al., 2016), 13.9 days in  
374 Europe, and 12.3 days in the United States (Ye et al., 2022), which was larger than the results of FLD but smaller than that  
375 of LCD in this study. Although the landscape-level GP data aggregated from species-level SP phenology data in this study

376 showed good reliability, limitations in available species and different aggregation methods suggest that future comparisons  
377 between GP and LSP in other regions still need to be improved.

378 (3) For phenology maps in different seasons, the reliability of phenology data in spring was found to be significantly  
379 higher than that in autumn. The underlying reason is that the mechanism of autumn phenology is more complex compared to  
380 that of spring phenology (Menzel, 2002). Moreover, the driving mechanisms for influencing factors of the autumn phenology  
381 are complex not yet fully understood, which poses an additional challenge (Gill et al., 2015; Wu et al., 2018). For example,  
382 temperature has large effects on the autumn phenology than the spring phenology (Fu et al., 2018). In addition to  
383 temperature, other environmental factors such as precipitation (An et al., 2020), photoperiod (Lang et al., 2019), solar  
384 radiation (Wu et al., 2021b), spring phenology (Liu et al., 2016a), and growing-season productivity (Zani et al., 2020) may  
385 also drive autumn phenology. Thus, modeling autumn phenology is more challenging compared to spring phenology  
386 (Melaas et al., 2016), resulting in poorer model performance and inferior data quality of SP or GP maps in autumn.

#### 387 **4 Data availability**

388 The annual SP and GP maps over China can be accessed at <https://doi.org/10.57760/sciencedb.07995> (Zhu et al., 2023).  
389 This dataset is licensed under a CC-BY 4.0 license. The spatial reference system of the dataset is EPSG:4326(WGS84).

#### 390 **5 Conclusions**

391 In this study, mainly based on CPON historical phenology observations, we developed a new long-term gridded  
392 phenology dataset: SP maps of 24 woody plants and GP maps of forests over China from 1951–2020, with a spatial  
393 resolution of 0.1° and a temporal resolution of 1 day. For the generation of SP maps, we adopted a model-based upscaling  
394 method to realize the scale expansion of SPphenology date from in-situ to regional scales in China. For the generation of GP  
395 maps, we adopted weighted average and weighted quantile methods to realize the aggregation from species to community or  
396 landscape levels in China. Dataset quality assessment shows that the average error of SP maps is 6.9 days in spring and 10.8  
397 days in autumn, and the minimum difference between GP maps and existing LSP products is 8.8 days in spring and 15.1  
398 days in autumn. Compared to the previous studies (Basler, 2016; Delpierre et al., 2009; Izquierdo-Verdiguier et al., 2018;  
399 Jeong and Medvigy, 2014; Tian et al., 2021; Wu et al., 2016; Ye et al., 2022), the SP maps in this study have the same or  
400 smaller simulation error, and the GP maps in this study have good agreement with other LSP products, so the data has high  
401 accuracy and reliability. This dataset is the first phenology map of China. It can be used to investigate the spatial pattern of  
402 plant phenology more clearly along the geographic gradient (e.g., longitude, latitude, and altitude), and to reveal the  
403 temporal trends (e.g., interannual, decadal, and secular) of plant phenology across China. The dataset can also provide  
404 important data support for global change impact assessment, terrestrial ecosystem simulation, and natural resource  
405 management.

406 **Author contribution**

407 QG and JD designed the study and planned the modeling. HW developed the model code. WL and YH performed the  
408 simulations. MZ processed the modeling data, performed the computations and drafted the manuscript. JD and JA critically  
409 revised the manuscript. All authors discussed and contributed to the modeling and manuscript.

410 **Competing interests**

411 The authors declare that they have no conflict of interest.

412 **Acknowledgements**

413 This study was jointly supported by National Key Research and Development Program of China (2018YFA0606102),  
414 National Natural Science Foundation of China (42271062), and Strategic Priority Research Program (A) of Chinese  
415 Academy of Sciences (XDA19020303; XDA26010202). Phenology data was provided by CPON. Temperature data was  
416 provided by Copernicus Climate Change Service (C3S).
