**Abstract.** Saharan dust outbreaks have profound effects on ecosystems, climate, human health and the cryosphere in Europe. However, the spatial deposition pattern of Saharan dust is poorly known due to a sparse network of ground measurements. Following the extreme dust deposition event of February 2021 across Europe, a citizen science campaign was launched to sample dust on snow over the Pyrenees and the European Alps. This somewhat improvised campaign triggered wide interest since 152 samples were collected in the snow in the Pyrenees, the French Alps and the Swiss Alps in less than four weeks. An analysis of the samples showed a large variability in the dust properties and amount. We found a decrease in the deposited mass and particle sizes with distance from the source along the transport path. This spatial trend was also evident in the elemental composition of the dust as the iron mass fraction decreased from 11% in the Pyrenees to 2% in the Swiss Alps. At the local

scale, we found a higher dust mass on south facing slopes, in agreement with estimates from high-resolution remote sensing data. This unique dataset, which resulted from the collaboration of several research laboratories and citizens, is provided as an open dataset to benefit a large community and enable further scientific investigations.

## 1 Introduction

Aeolian dust from the Sahara has a wide range of impacts on the Earth and society. For instance, airborne Saharan dust particles affect the Earth's radiative budget, cloud formation, solar energy production, and air traffic (Rieger et al., 2017; Varga, 2020; Ginoux, 2017; Nickovic et al., 2021) and could also impact human health (Tobías and Stafoggia, 2020). Once deposited, Saharan dust particles also provide nutrients to marine, aquatic and terrestrial ecosystems (Okin et al., 2004; Yu et al., 2015). Mountain regions are especially affected by the deposition of Saharan dust through several physical processes. Dust deposited on snow and ice modifies microbial abundance and diversity (Greilinger and Kasper-Giebl, 2021). Dust is also responsible for a darkening of snow- and ice-covered surfaces, which enhances the melting rates, leading to earlier meltwater runoff and the exposition of bare soil to the atmosphere (e.g. Skiles et al., 2018; He and He, 2022; Réveillet et al., 2022). Despite the episodic nature of dust outbreaks, a single event can have a major impact on snow cover duration. For instance, the dust deposition event that occurred in March 2018 over Eastern Europe led to a shortening of the snow cover duration by 12 to 30 days (Dumont et al., 2020). Such an effect strongly depends on the deposited dust mass and the dust optical properties (Réveillet et al., 2022).

While dust characteristics are well monitored at a few specific sites, little is known about the spatial variability of dust deposition, especially in complex mountain terrains where measurements are scarce (Baladima et al., 2022; Pey et al., 2020). The physico-chemical and optical properties of the dust particles are generally considered spatially homogeneous (Mărmureanu et al., 2019; Di Biagio et al., 2019). The mass of dust used in impact studies often originates from atmospheric models and is subject to significant uncertainties (Skiles and Painter, 2019). Indeed, dust deposition fluxes can differ by several orders of magnitude between models (Tuzet et al., 2019; Baladima et al., 2022). Finally, methods to estimate dust content on snow cover from satellite imagery are based on strong assumptions regarding the optical properties of dust particles, which are rarely supported by field data (Dumont et al., 2020) and are known to vary widely with the dust source region (Caponi et al., 2017; Skiles et al., 2018; He and He, 2022; Di Biagio et al., 2019).

In February 2021 (4 to 8 February and 18 to 25 February), two major Saharan dust outbreaks affected a large stretch of western Europe, turning the sky and the snow cover orange (Francis et al., 2022). Both events were associated with atmospheric rivers (Francis et al., 2022). The mass of dust deposited at the surface and the aerosol optical depth exceeded two standard deviations from the mean observed between 1980 and 2020 (Varga, 2020; Francis et al., 2022). The first event (4-8 February) was especially strong in terms of dust deposition in southern Europe and was widely reported in the media (see video supplement). The second event (18-25 February) transported dust as far as Scandinavia. Because these events occurred in winter, they represented a unique opportunity to study this phenomenon beyond conventional measurement networks. Indeed, the snow cover retained most of the dust particles and thus contained valuable information on the mass and type of the deposited dust even weeks after deposition (Tuzet et al., 2019). All this prompted us to organise a citizen science campaign to collect dust samples

across the European Alps and the Pyrenees. The campaign was launched the day after the publication of the first photographs of orange snow in social media and lasted four weeks. The samples were analysed to determine the mass, size distribution, chemical composition and optical properties of the dust. This study presents the citizen science campaign and the results of the  
45 sample analysis.

## 2 Data and Methods

### 2.1 Citizen campaign

We initiated a citizen science campaign to collect samples of the "orange snow" on 6 February 2021, i.e., a day after the widespread deposition of orange dust on snow in the Pyrenees and the Alps. The sampling protocol was designed to be as  
50 simple as possible (Fig. 1). We asked participants to collect a snow sample of  $10 \times 10 \text{ cm}^2$  area (or any known area) up to the depth of the entire dust layer and to report the location of the sampling site. We recommended to take a photograph of the sampling site with a smartphone to obtain the coordinates of the sampling site. The call was first posted on social media (Twitter, YouTube, Facebook) and quickly relayed by traditional media, mostly local newspapers, TV and radio. Some people brought the samples directly to us in Toulouse or Grenoble; otherwise, we went to collect them. In any case, the snow was  
55 melted before reaching the laboratory.

### 2.2 Meteorological conditions

To characterise the meteorological conditions during the 4-8 February 2021 deposition event, we used simulations from the atmospheric transport model MOCAGE (Josse et al., 2004) and SAFRAN meteorological reanalysis (Vernay et al., 2022). Deposition and meteorological conditions were analysed at three sites: Pic du Midi ( $42.84^\circ\text{N}$ ,  $-0.44^\circ\text{E}$ ) in the Pyrenees, Queyras  
60 ( $44.74^\circ\text{N}$ ,  $6.82^\circ\text{E}$ ) in the southern Alps and Chartreuse ( $45.29^\circ\text{N}$ ,  $6.77^\circ\text{E}$ ) in the northern Alps. The dust load values were obtained using hourly dust deposition from MOCAGE. Dry and wet depositions were redistributed according to precipitation from the SAFRAN reanalysis. We further evaluated the accuracy of the total dust mass deposition from MOCAGE by comparison with the average of the three closest samples for each site (see Sect. 2.3).

### 2.3 Dust mass and size distribution

65 First, the samples were homogenised, and 5 mL of each sample was kept for size distribution analysis. The rest of the sample was then filtered, dried, and weighed to provide the dust concentration. The analytical uncertainty of the measured dust mass is within 5 %.

Dust size distributions were measured with a Coulter counter following Delmonte et al. (2004). This instrument counts and measures the size of insoluble particles above  $0.6 \mu\text{m}$ . However, the size distributions measured with the Coulter counter are  
70 hampered by poor counting statistics above a certain size (example shown in Fig. 2). We thus separated the distribution in a lower part, usually well measured (typically better than 10% uncertainty), and the tail of the distribution, which is highly

- 1) Prélevez l'intégralité de la couche de neige orange
- 2) Prendre une photo avec un smartphone (géolocalisé)
- 3) Stockez chez vous (pas besoin de garder au frais)
- 4) Notez le diamètre de votre récipient de prélèvement

**Figure 1.** Original sampling protocol posted on Twitter (in French). Translation in English: 1) Sample the whole layer of orange snow 2) Take a picture with a smartphone (geolocated) 3) Store the sample at home (no need to keep it cool) 4) Write down the diameter of the container

uncertain, although it may represent a significant fraction of the total mass (Fig. 2). For each sample, we performed three measurements with the Coulter counter. The cut diameter between both parts of the distribution was estimated as the lowest diameter where none of the three individual measurements detected any particle.

## 75 2.4 Elemental composition

Before the analysis of the elemental composition, a picture of the dried filters was taken using a Universal Serial Bus (USB) microscope for a visual inspection of the filters and the detection of potential contamination with anthropogenic fibres such as microplastic fibres from the clothes of the person in charge of the sampling. The elemental composition of the filters was determined using an X-ray fluorescence (XRF) analyser (ThermoFisher Scientific™ Niton™ XL3t). The direct analysis of  
80 the filters, with relatively thin dust layers, required the development of a specific calibration procedure. Standard reference

**Figure 2.** Volume size distributions measured by the Coulter counter for a sample. Panel (A): differential distribution. Panel (B): cumulative distribution. The shaded area shows the poorly constrained part of the distribution, yet it may represent a significant part of the total volume. The three lines correspond to three measurements for this sample.

materials, including loess soil RTH 912 and Saharan dust samples, were analysed both after the deposition of a thin layer on a filter and using the standard cup of the XRF analyser. Using these paired measurements, a calibration function was developed by regression for every element between the instrumental calibration for powdered rock measurements in the cup against the measurements of thin layers in filters. Satisfactory results were obtained for Al, Ca, K, Ti, Fe, P, Mn, Si, Rb, As, Pb, V, Cu and Sr. The calibration function is provided along with the dataset. However, most of the concentrations were below the quantification limits for Rb, As, Pb, V, and Cu. In addition, we also calculated the Si/Al and Fe/Ca ratios and the mass fraction of Fe since these values were used in previous studies to determine the source region of the dust (Caponi et al., 2017).

## 2.5 Optical properties

For the analysis of optical properties, two specific samples were taken to ensure that a sufficient dust mass was available. We took two additional samples at a similar elevation of 2100 m near Pic du Midi de Bigorre in the Pyrenees and Col du Lautaret in the Alps.

The experimental setup used is extensively described by Hubert et al. (2017), and only a summary of the method is provided hereafter. A few tens of milligrams of dust were introduced into a vessel glass in which continuous mechanical agitation was maintained using a magnetic stirrer. By means of a continuous flow ( $\approx 2 \text{ L min}^{-1}$ ) of pure nitrogen, particles were carried through the multipass cell of a Fourier transform infrared spectrometer (ThermoFisher Scientific™ iS50) to record the extinction spectra in the spectral range of  $650\text{--}4000 \text{ cm}^{-1}$  with a resolution of  $1 \text{ cm}^{-1}$ . To measure the size distribution of the particles over a larger range than that measured using the Coulter analyser, the flow was split into two parts at the exit of the infrared cell: one part was directed to a scanning mobility particle sizer (TSI™ 3936L75), which measures the particle number

concentration as a function of the electric mobility diameter from 14.6 to 661 nm (64 bins/decade), and the second part was  
100 directed to an aerodynamic particle sizer (TSI™ 3321), which measures the particle number concentration as a function of the  
aerodynamic diameter from 0.542 to 20  $\mu\text{m}$  (32 bins/decade). The size distributions of the two samples of interest are reported  
in Fig. S5, assuming that the electric mobility diameter is equal to the geometric diameter ( $d_g$ ) and converting the aerodynamic  
diameter ( $d_a$ ) measured by the aerodynamic particle sizer into  $d_g$  using Eq. 1 (DeCarlo et al., 2004):

$$d_g = d_a \sqrt{\frac{\chi \rho_0}{\rho_p}} \quad (1)$$

105 where  $d_g$  and  $d_a$  are the geometric and aerodynamic diameters, respectively,  $\chi$  is the dynamic shape factor (we assume  $\chi \approx 1$ ),  
 $\rho_0$  is the standard density of water ( $1 \text{ g cm}^{-3}$ ) and the mean density of Saharan particles,  $\rho_p = 2.7 \text{ g cm}^{-3}$  (Schladitz et al.,  
2009). Then, each experimental size distribution was adjusted by a unimodal log-normal distribution whose number concentra-  
tion, mean diameter and geometric standard deviation are  $N = 8800 \text{ cm}^{-3}$ ,  $\bar{d}_g = 0.37 \mu\text{m}$  and  $\sigma_g = 1.71$  for the Lautaret sample  
and  $N = 3680 \text{ cm}^{-3}$ ,  $\bar{d}_g = 0.42 \mu\text{m}$  and  $\sigma_g = 1.77$  for the Pic du Midi sample. These parameters are associated with the particle  
110 size distributions of dust travelling in the cell and not those of the bulk sample for which the coarse particles (typically  $> 3 \mu\text{m}$ ,  
see section 2.3) are not resuspended in our experiment or are quickly deposited following sedimentation.

After purging the whole setup with pure nitrogen, the extinction spectrum in the infrared domain,  $\Gamma_{\text{sample}} = -\log \frac{I(\tilde{\nu})}{I_0(\tilde{\nu})}$  was  
recorded, where  $I(\tilde{\nu})$  and  $I_0(\tilde{\nu})$  are the signals recorded with and without particles, respectively.

The mass extinction efficiency (MEE, in  $\text{m}^2 \text{ g}^{-1}$ ) at a given wavenumber,  $\tilde{\nu}$ , is defined as the ratio of the particles' light  
115 extinction coefficient ( $b_{\text{ext}}$  in  $\text{m}^{-1}$ ) and the mass concentration,  $c$  in  $\text{g m}^{-3}$ , of the particles:

$$MEE(\tilde{\nu}) = \frac{b_{\text{ext}}(\tilde{\nu})}{c} \quad (2)$$

where  $b_{\text{ext}}$  was calculated as the ratio of the measured extinction spectrum  $\Gamma_{\text{sample}}$  and the optical path length (10 m in this  
study).

## 2.6 Radionuclide analyses

120 Some of the filters were analysed using ultralow background Germanium HyperPure gamma spectrometry detectors installed  
in the underground facilities at University Paris-Saclay (Gif-sur-Yvette) and Modane (Underground Lab of Modane, France).  
To obtain sufficient counting statistics, filters were analysed for ca.  $2 \times 10^5$  s, approximately two days. The results obtained on  
the most heavily loaded filter (ALP-34-FE; 0.3 g of dust) and those obtained on a filter prepared with a similar quantity (0.3 g)  
of IAEA-444 soil-certified material were compared. All results were expressed in  $\text{Bq kg}^{-1}$  with activities decay-corrected to  
125 the sampling date. In addition to artificial  $^{137}\text{Cs}$  (detected at 662 keV), natural fallout radionuclide activities (i.e.,  $^7\text{Be}$  at 477  
keV and  $^{210}\text{Pb}$  at 46 keV) were also quantified.  $^{210}\text{Pb}_{\text{xs}}$  activities (representing the atmospheric fraction of  $^{210}\text{Pb}$  alone) were  
calculated by subtracting the supported activity (determined using two  $^{226}\text{Ra}$  daughters,  $^{214}\text{Pb}$  (average count number at 295.2  
and 351.9 keV) and  $^{214}\text{Bi}$  (609.3 keV)) from the total  $^{210}\text{Pb}$  activity.

To obtain larger quantities of radionuclide fallout, we performed two specific samplings in regions with significant deposition  
130 levels in spring 2021 (i.e., in addition to the samples from the citizen science campaign). Initially, we sampled dust layers at  
the surface of snow cover randomly, but this yielded too little material ( $< 1$  g per 20 L of snow). Therefore, we specifically  
collected dust that accumulated in the hollows that formed at the surface of snow cover by meltwater runoff. To select suitable  
sampling locations, we closely investigated the surface of snow patches and excluded areas where autochthonous sediment (i.e.,  
produced within the catchment from runoff, mass movements, etc.) was present, as this would contaminate the allochthonous  
135 dust from the Sahara. This sampling was performed during the late snowmelt period (May 22-31, 2021) from two snow patches  
(locations:  $42.903119^{\circ}\text{N}$ ,  $0.122031^{\circ}\text{E}$  and  $42.902679^{\circ}\text{N}$ ,  $0.137037^{\circ}\text{E}$ , Barèges, Pyrenees, France). Dust was collected using  
a shovel and stored in a fridge box for transportation. In the laboratory, the snow was melted in the spring sun, and clear  
water was poured off after the dust settled on the bottom of the refrigerator box. The remaining water was boiled until the dust  
was dry. We needed approximately 60 L of snow to collect 13 g of dust. This sample was prepared in a standard container for  
140 gamma spectrometry and analysed similarly for  $^{137}\text{Cs}$ ,  $^7\text{Be}$  and  $^{210}\text{Pb}$  as for the abovementioned filters. As sufficient quantity  
was available for this later sample, it was also analysed for plutonium contents and isotopic ratios ( $^{239}\text{Pu}$ ,  $^{240}\text{Pu}$ ,  $^{241}\text{Pu}$ ,  $^{242}\text{Pu}$ )  
at CEA, Arpajon, France, after radiochemical preparation and MC-ICP-MS measurements following all the methods detailed  
in Evrard et al. (2014) to gain additional insights into the potential sources of these radionuclides, given the public debate  
raised regarding the origin of  $^{137}\text{Cs}$  and potentially the other artificial radionuclides found in the dust (Berger, 2021).

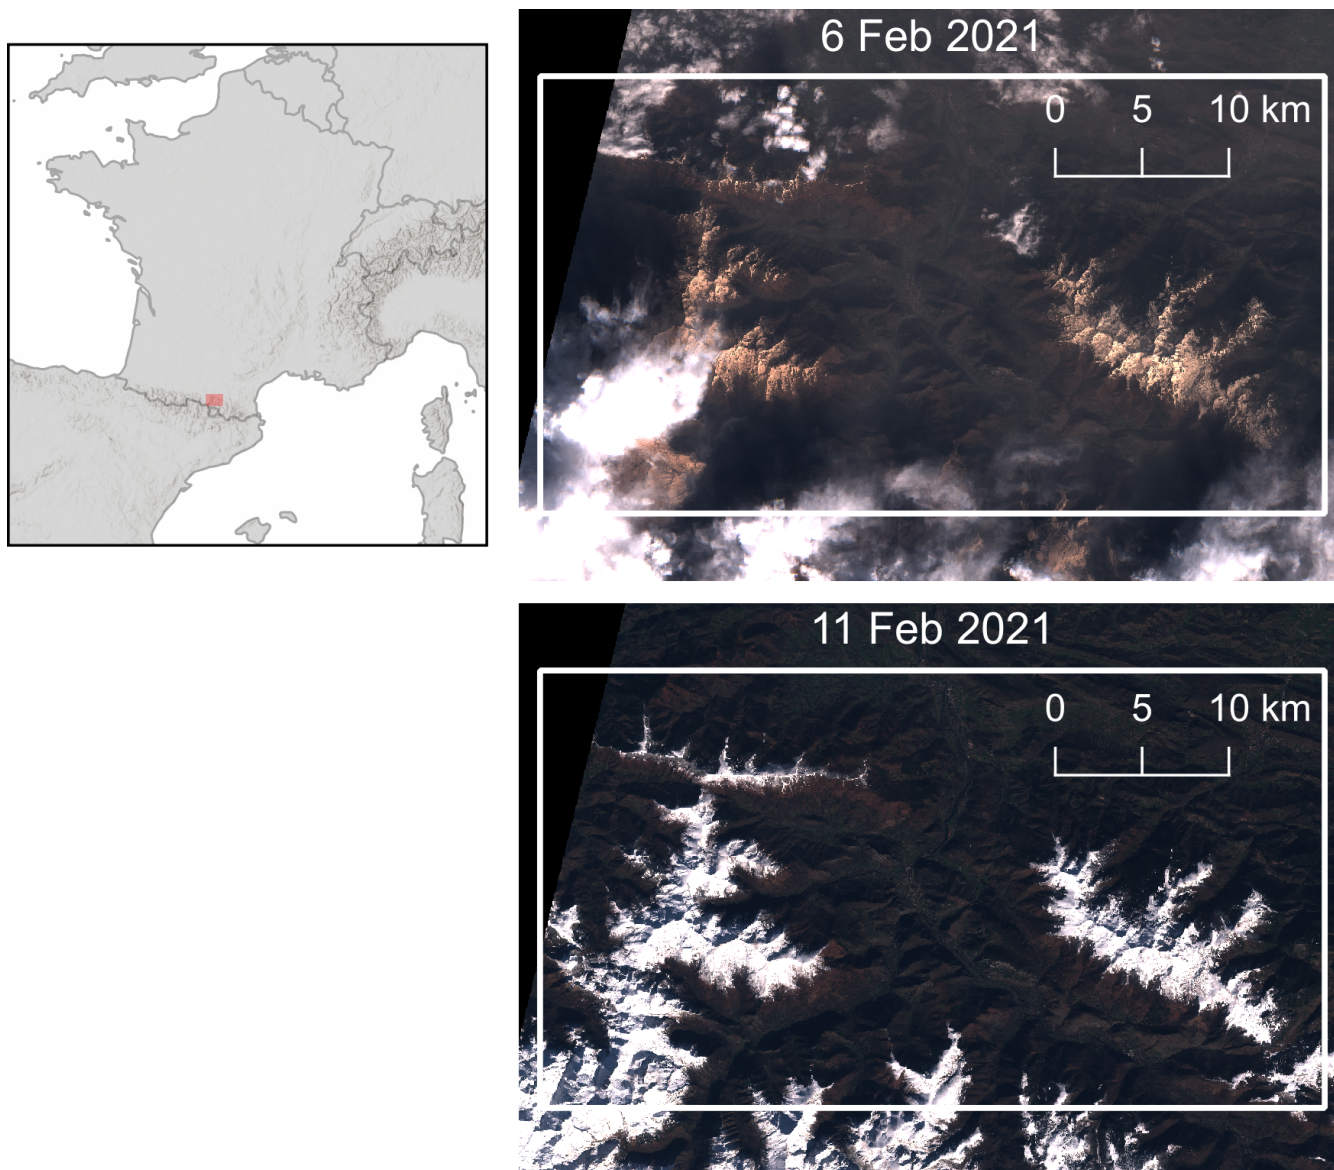

## 145 2.7 Satellite data

A multispectral image was captured by Sentinel-2B on 6 February 2021 at 10:49 UTC over the Pyrenees, i.e., the morning just  
after the dust deposition. In this image, we selected the only clear-sky area of  $1150\text{ km}^2$  spanning the snow-covered massifs  
of Tabe and Vicdessos. Then, we selected the same region in the Sentinel-2A image that was captured five days later on 11  
February 2021 (Figure 3). We chose this image because fresh snowfall occurred between the two dates. This allowed us to  
150 consider the 11 February image as a reference to remove the effect of the topography on the reflectance of the 6 February  
image (as done by Dumont et al., 2020). This "terrain normalisation" was performed using band 3 (green), and the dust content  
(dust concentration in ppm) was computed using band 8 (near infrared) following Eq. 1 in Dumont et al. (2020).

We performed this analysis with level-2A surface reflectance products processed with the MAJA atmospheric correction and  
cloud screening software (Hagolle et al., 2015, 2017). We used the snow maps derived from the same Sentinel-2 images to  
155 exclude from the analysis the pixels that were not covered by snow in both images (data available from Gascoin et al., 2019).  
These snow maps were computed at a spatial resolution of 20 m and then resampled to 10 m with the nearest neighbour method  
to match the resolution of band 3 and 8.

We studied the spatial variability of the resulting satellite-derived dust content, grouping the pixel values by topographic  
aspect classes to compare it with the spatial distribution obtained from the in situ samples.

160 The dust concentration retrievals from Sentinel-2 were computed in terms of mass fraction (mass mixing ratio, Flanner  
et al., 2021), whereas the analysis of the samples provided the total dust mass per unit area. To compare the same physical  
quantity between satellite retrievals and in situ samples, the snow density and the vertical profile of dust concentration should

**Figure 3.** True colour composites of Sentinel-2 images captured on 6 and 11 February 2021. Both images were used to estimate the dust content on 6 February 2021 (the day after the dust deposition).

be known. In the absence of field observations, the estimation of such parameters would require additional modelling work, which is outside the scope of this article. Therefore, we limited our analysis to the comparison of the spatial variability of the dust concentrations from Sentinel-2 with the dust mass from the in situ samples.

### 3 Results

#### 3.1 Citizen campaign

In total, in less than four weeks, 152 samples were collected: 84 in the French Alps, 9 in the Jura Mountains (France), 1 in the Massif Central (France), 26 in the French and Spanish Pyrenees and 32 in the Swiss Alps (Fig. 4). Among these 152 samples, 136 were taken within days after the first event in February, and 16 (2 in the French Alps and 14 in the Swiss Alps) were collected in March, thus combining the effect of two dust events. The 152 samples were collected by more than 85 individual participants. In the remainder of the text, the analysis was restricted to the 136 samples that contained only dust from the first event.

#### 3.2 Meteorological conditions

MOCAGE simulations show the hourly meteorological conditions and deposition rates during the dust outbreak that occurred between 4 and 8 February 2021 (see Fig. 5 for Pic du Midi and other sites in supplemental Figs. S1 and S2). At the three selected sites, the snow cover was first affected by dry dust deposition, influenced by southerly winds. Then, during wet deposition, the wind changed to the south-west and west with a decreasing wind speed. According to the simulations for the Pyrenees and the southern Alps, most of the deposition was dry, with 85 and 90% of the total loads at the end of the dry deposition for the Pic du Midi and the Queyras, respectively (Fig. 5, S1). In the northern Alps, the partitioning between wet and dry deposition was approximately half; for instance, 53% of the total load was due to dry deposition at the Col de Porte (Fig. S2). However, some avalanche forecasters in the Pyrenees observed that after 2-3 days of dust in suspension, dust was massively deposited as wet deposition (rain), followed by a graupel shower and then a short snowstorm the following night. Snowfall in the following days covered the dust layer in most parts of the Alps and Pyrenees. However, the dust layer remained easily identifiable in the snowpack below the clean snow layers by digging a snow pit.

#### 3.3 Dust mass and size distribution

##### 3.3.1 Dust mass

A total of 114 sample-derived masses were obtained over the Alps and the Pyrenees. The missing values (approximately 16%) were due to leaks, which made the samples unusable.

Fig. 6 displays the spatial distribution of the dust mass per unit area obtained from in situ measurements. The dust mass per unit area ranges from 0.2 to 58.6 g m<sup>-2</sup> depending on the location, highlighting strong spatial variability. The mean value is 9.4 g m<sup>-2</sup> when considering all the samples. Higher dust depositions are observed in the Pyrenees (Fig. 7A), with a mean mass per unit area of 21.2 g m<sup>-2</sup>, compared to the French Alps (7.2 g m<sup>-2</sup>) and the Swiss Alps (4.5 g m<sup>-2</sup>). This suggests a decrease in the deposited mass along the plume trajectory with distance from the source in the Sahara (Fig. 7B).

These measurements allow us to estimate that the MOCAGE simulation underestimates the deposition fluxes by a factor equal to 51.6 for the Pic du Midi site, 13.5 for the Queyras site and 36.4 for the Chartreuse site (Sect. 3.2).

**Figure 4.** Location of the sample collected during the citizen field campaign. Blue stars indicate the Chartreuse (C), Queyras (Q) and Pic du Midi (P) locations. The red triangle indicates the location of the two samples used for radionuclide analysis

**Figure 5.** (A) Temporal evolution of the hourly dry (yellow) and wet (red) dust loads during the event at Pic du Midi (2100 m a.s.l.). The total cumulative mass deposition is shown by the black line. Depositions were computed based on MOCAGE outputs and corrected according to the observations. The dry vs. wet deposition was determined based on SAFRAN precipitation data (see section 2.2). Temporal evolution of the hourly wind speed (B) and direction (C) and the hourly precipitation (D) from SAFRAN reanalysis data. The yellow (red) shaded area represents the dry (wet) deposition of the event, according to SAFRAN precipitation.

The distribution of dust mass per unit area with slope aspect indicates that a larger dust mass per unit area is generally observed for the south and south-west facing slopes in all three studied areas (Fig. 7C). This conclusion holds both when slopes are computed from a 25 m resolution digital elevation model (Fig. 7C) and from a 500 m resolution DEM (Fig. 7D). This indicates that dust deposition prevailed on slopes facing the dominant wind during the event (see video supplement, Fig. 5, S1 and S2).

The dust mass per unit area does not show a gradient with elevation (not shown). This result could be due to the sampling pattern, covering a restricted elevation range: 45% of the samples were collected between 1500 and 2000 m a.s.l. and 26% between 2000 and 2500 m a.s.l. Only three samples were collected below 1000 m a.s.l. and one above 2500 m a.s.l.

### 3.3.2 Dust size distribution

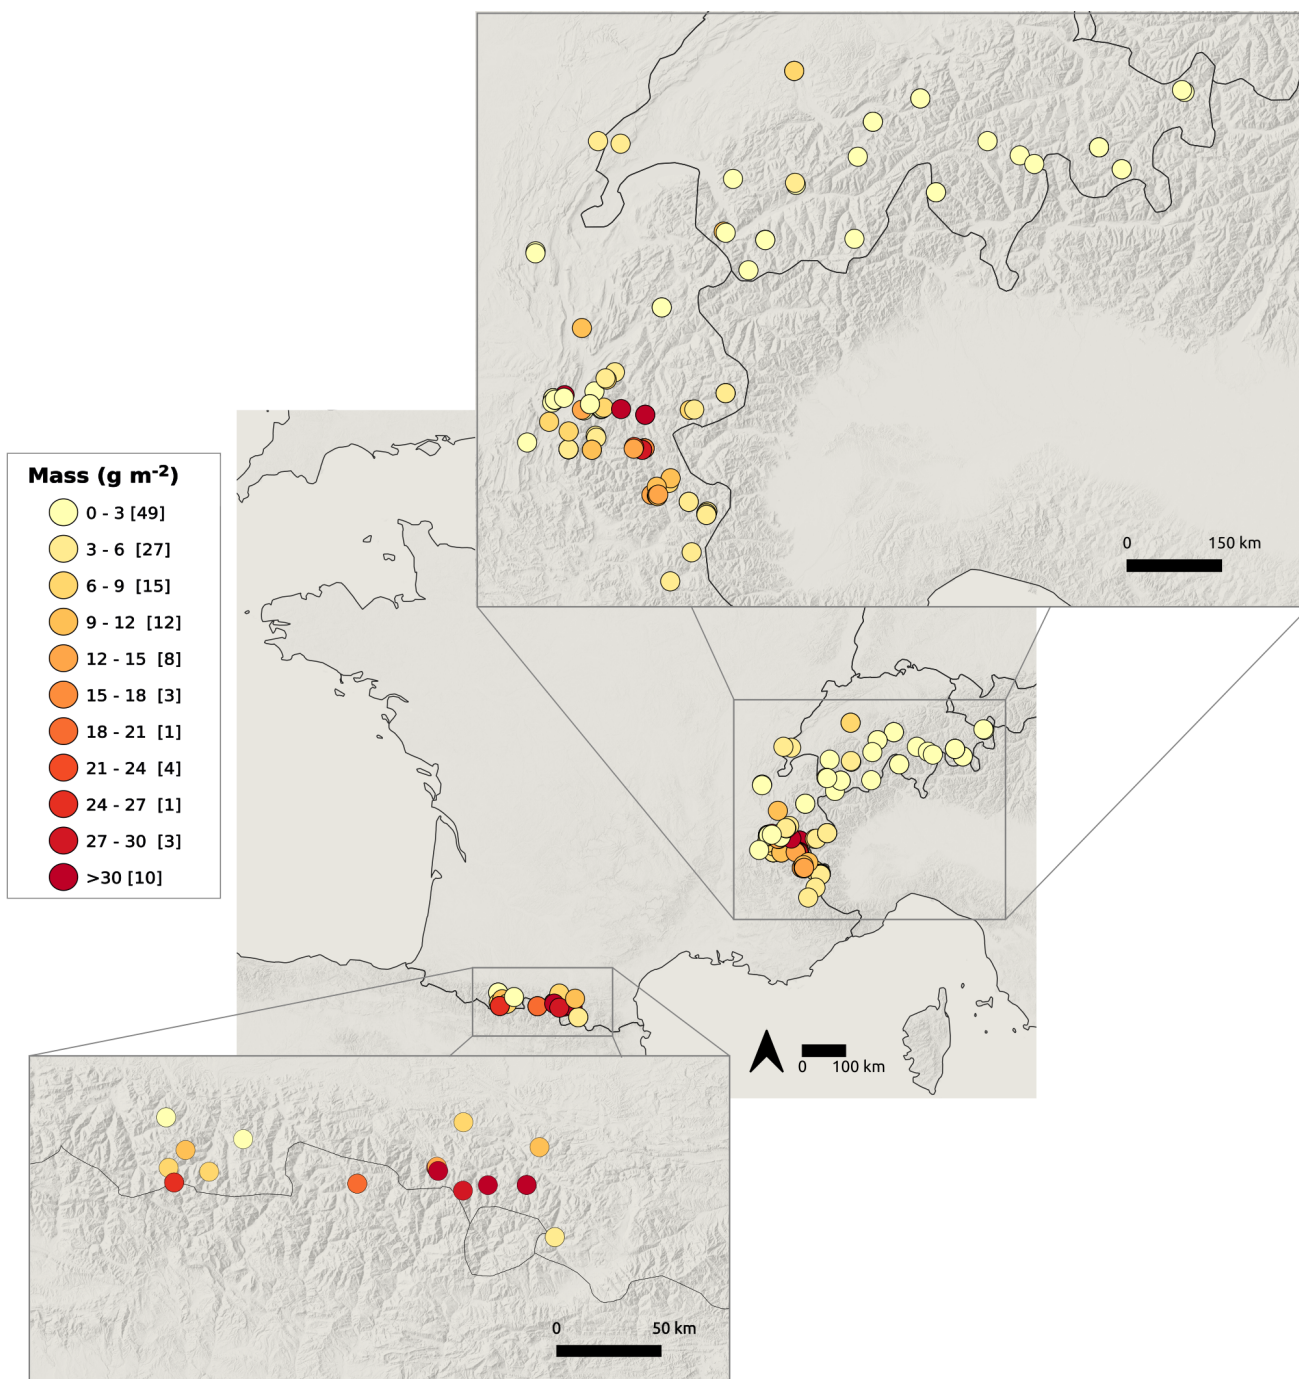

A total of 95 samples were analysed with the Coulter counter, providing 95 size distribution values over the Alps and Pyrenees (Fig. S3). The distribution tails show the occurrence of a fraction of rather large particles with diameters around 50  $\mu\text{m}$ , whereas the mean diameter of the well-measured fraction of the distribution is much lower, around 19  $\mu\text{m}$  for the volume distribution and 12  $\mu\text{m}$  for the surface distribution. This analysis shows that adding the distribution tail into calculating the average diameters influences the average volume diameter. The volume distribution can be converted into a mass estimation using a dust density of 2.5  $\text{g cm}^{-3}$ , which can be compared to the gravimetric measurement on the filters (Fig. S4).

The mean dust diameter measured with the Coulter counter spans a range of 8 to 38  $\mu\text{m}$  when considering the samples over all the massifs. The maximum size may be underestimated due to the size cut-off (see section 3.3.2). The dust size distribution depends on the location, with larger sizes generally observed closer to the source (Fig. 8B). In the Pyrenees samples, the size spans a range of 15.4-27  $\mu\text{m}$  (with a mean of 21  $\mu\text{m}$ ) and varies between 9.8 and 38  $\mu\text{m}$  (mean = 21  $\mu\text{m}$ ) and 8.2 and 19.6  $\mu\text{m}$  (mean = 15  $\mu\text{m}$ ) for the French and Swiss Alps, respectively (Fig. 8A). Contrary to the mass distribution, there is no evidence that the dust size is related to the slope aspect (Fig. 8C, D), and we did not find a trend with elevation in the dust mass distribution either.

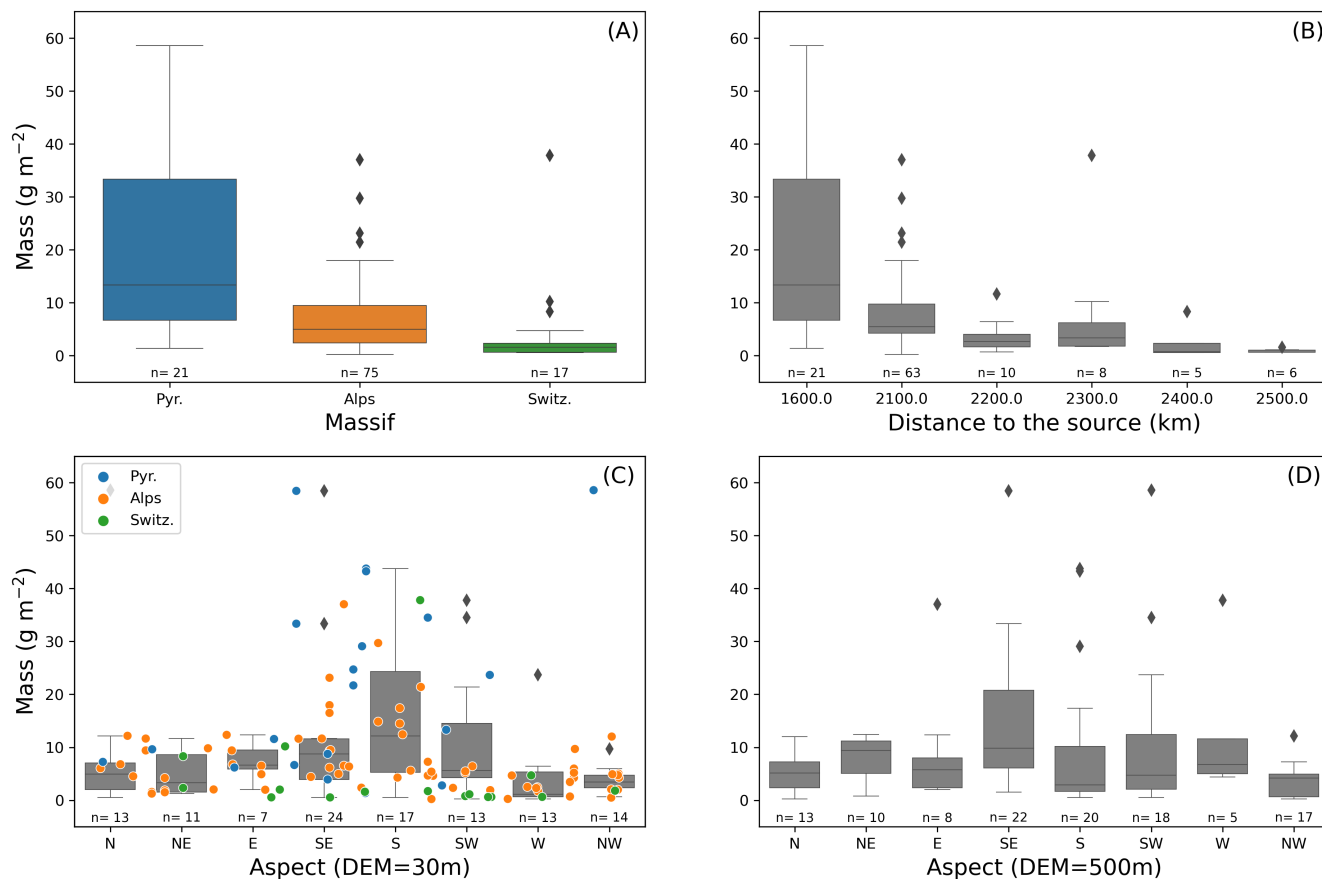

### 3.4 Elemental composition

105 samples were analyzed for the elemental composition. No major contamination with trace metals could be detected in the filters. The concentration of contaminants such as Pb remains low for most of the filters, i.e., close to the natural value for the upper continental crust (17  $\mu\text{g kg}^{-1}$ ). However, one sample (Alp-60) has a large concentration ( $>100 \mu\text{g kg}^{-1}$ ). Clear spatial trends can be identified for elemental concentrations depending on the mountain range. Concentrations of Ca, Fe, Mn and Ti decrease from the Pyrenees to the Swiss Alps, while an opposite trend is identified for Al, P and Si, and no trend is observed for K (Figs. 9 and 10), showing concentration dispersion for each mountain range and against distance to the source). Since the mass deposition is much higher in the Pyrenees (Fig. 7A), the elemental deposition density is higher for all elements in the Pyrenees (Fig. 12).

We also investigated the spatial variability of the ratio between elemental concentrations. Figure 11 shows the variability of the Si/Al and Fe/Ca ratios and that of the mass fraction of Fe. The values for Si/Al vary between 1.7 and 2.8. The ratio between

**Figure 6.** Mass of deposited dust per unit area. The number in brackets in the legend indicates the number of samples.

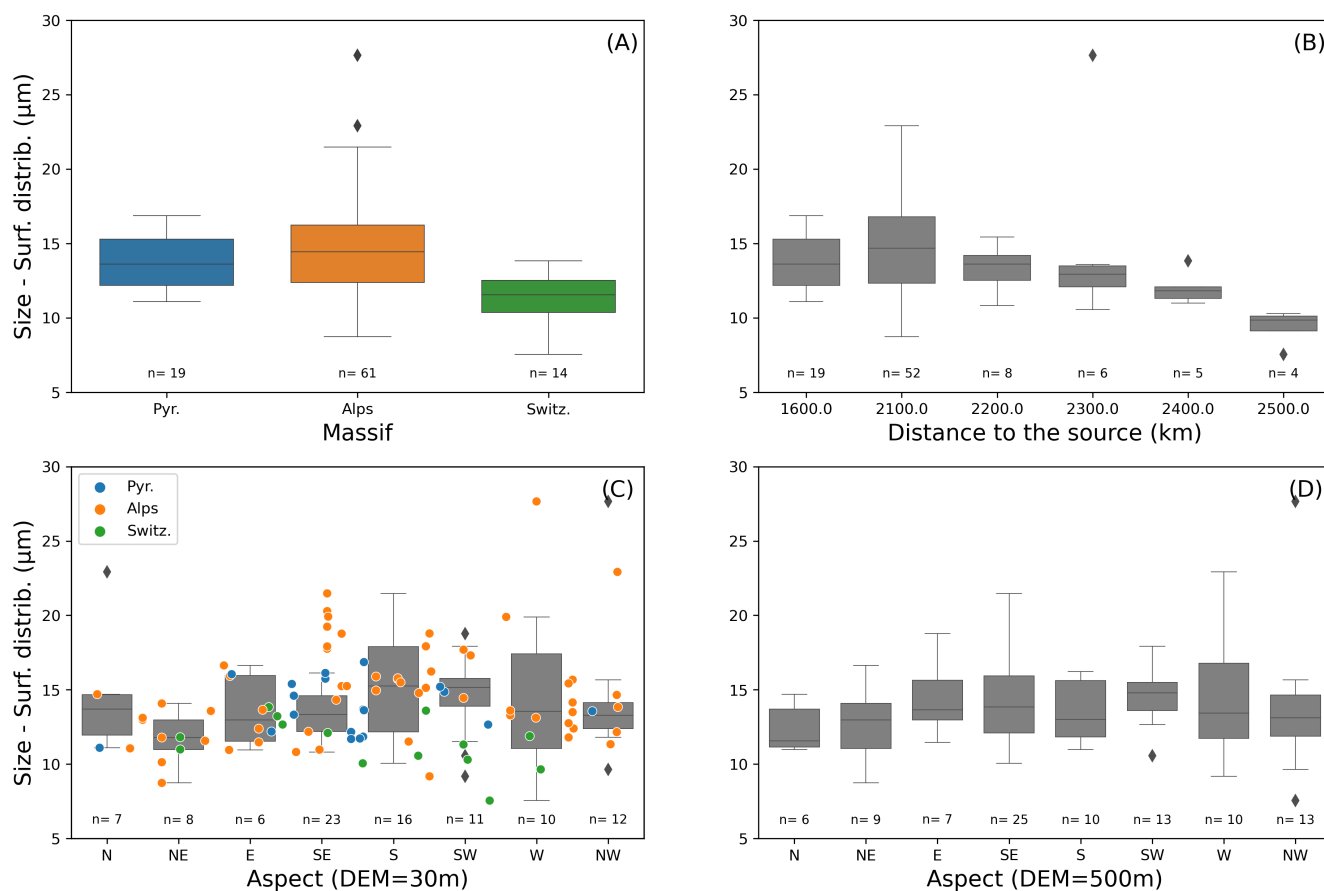

**Figure 7.** Distribution of the deposited mass dust per unit area against the massif (A), the distance to the source (B) and the aspect computed with a 25 m resolution DEM (C) and a 500 m resolution DEM (D). The boxes show the quartiles of the distribution corresponding to the spatial variability. Minimum/maximum ranges are indicated by the whiskers, and outliers are represented by the black points. The distance to source is estimated from the location 31.21N, -0.37E, estimated from MOCAGE data (video supplement).

230 Fe and Ca varies between 1 and 2. The values for the Swiss samples are likely unreliable given their very low Ca concentrations (Fig. 12). The mass fraction of Fe varies from 2% to almost 11% from the Swiss mountains to the Pyrenees.

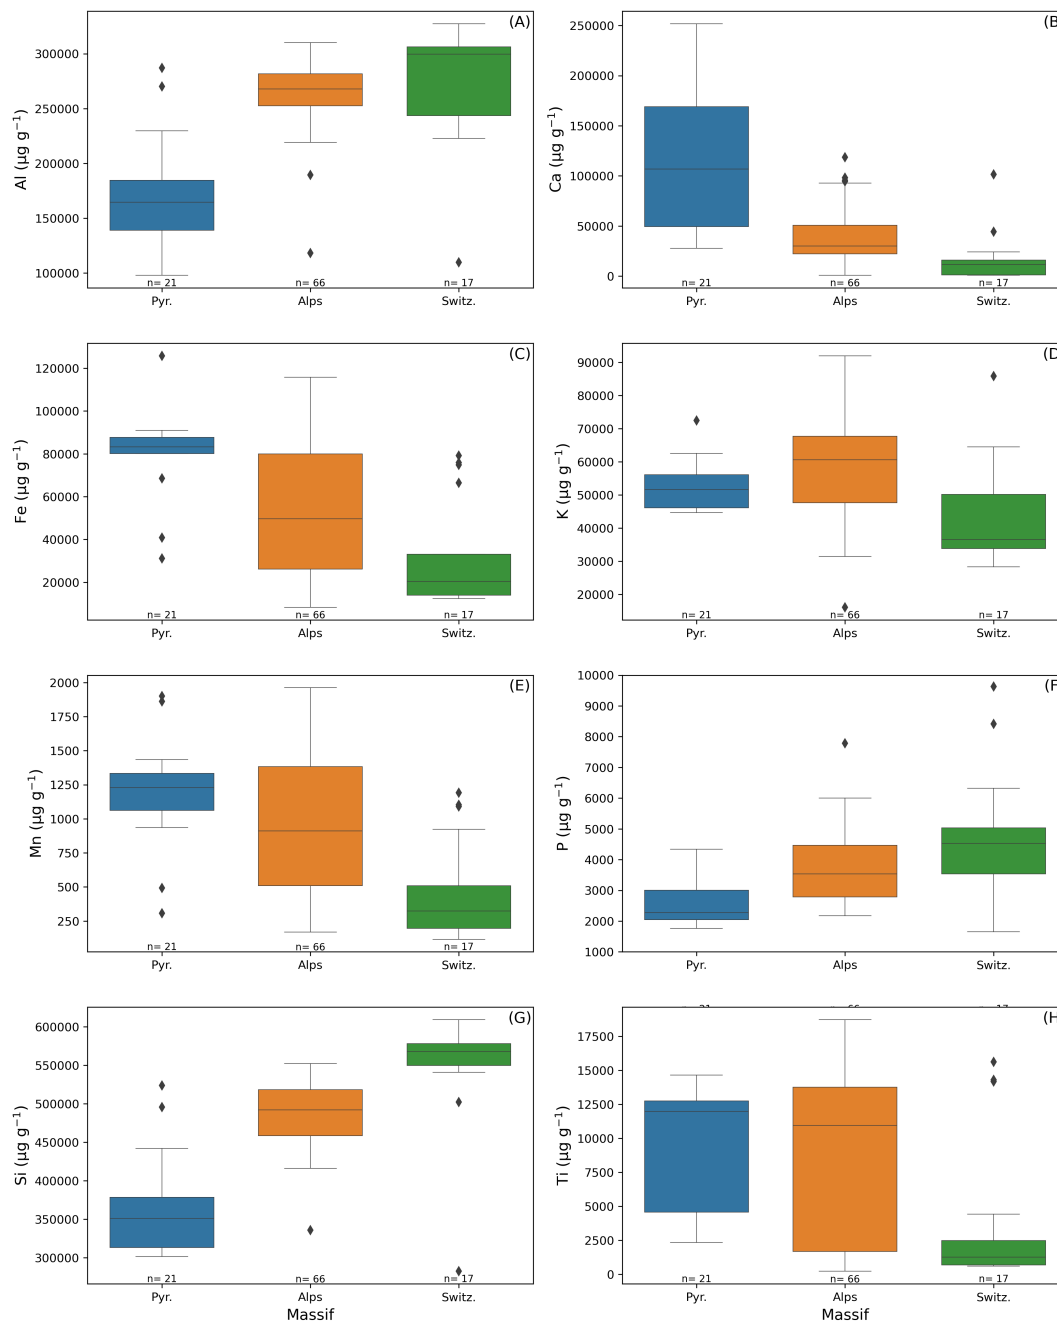

Using a digital microscope, we found plastic fibres in a few samples. This means that local contamination may affect the results of some analyses. However, it has likely not influenced the elemental concentrations of the filters.

### 3.5 Optical properties

235 The infrared normalised extinction spectra obtained for the two samples are very similar (Fig. 13). The main feature at 1035  $\text{cm}^{-1}$  can be assigned to the asymmetric stretching of the Si-O-Si bond of illite. From 1500  $\text{cm}^{-1}$ , the extinction gradually increases due to scattering with a steeper slope for the Pic du Midi sample compared to that of the Lautaret. This can be

**Figure 8.** Distribution of the size of the dust deposition against the massif (A), the distance to the source (B) and the aspect computed with a 30 m resolution DEM (C) and a 500 m resolution DEM (D). The boxes show the quartiles of the distribution corresponding to the spatial variability. The number of values used is indicated under each box. Minimum/maximum ranges are indicated by the whiskers, and outliers are represented by the black points. The size for each massif, against the aspect, is shown in Figure (C).

**Figure 9.** Distribution of elemental concentrations against the massif (A) Aluminium, (B) Calcium, (C) Iron, (D) Potassium, (E) Manganese, (F) Phosphorus, (G) Silicon and (H) Titanium. The boxes show the quartiles of the distribution corresponding to the spatial variability. The number of values used is indicated under each box. Minimum/maximum ranges are indicated by the whiskers, and outliers are represented by the black points.

explained by the higher values of  $\overline{d_g}$  and  $\sigma_g$  for the Pic du Midi sample. These spectra have been smoothed by applying the Savitzky-Golay filter to identify other bands. A zoom (650–2000  $\text{cm}^{-1}$ ) for each spectrum is shown in Figure S6 with the assignment of all the characteristic bands of illite, quartz and calcite (see also Table 1).

Using Equation 3 below, we simulate the extinction spectrum for the two samples by calculating a linear combination of the extinction spectra of the three minerals identified in Figure S6:

$$\Gamma_{sample}^{simul} = \sum_i C_i \Gamma_i \quad (3)$$

where  $\Gamma_i$  is the extinction spectrum of the mineral  $i$  and  $C_i$  are coefficients that are fitted by a least-squares fitting method minimising the differences between the calculated extinction and the experimental extinction ( $i = q, il$  and  $c$  for quartz, illite and calcite). The calculation of the extinction spectrum for each mineral was performed using Mie optical theory (Herbin et al., 2017) by introducing their complex refractive indices (CRI) recently determined by Deschutter (2022) as input data and a size distribution calculated using the fitted moments of the distribution listed in part 6.3.1. of Deschutter (2022).

The simulated spectra, as well as the differences,  $\Gamma_{sample}^{simul} - \Gamma_{sample}$  are plotted in Fig. S6 for the two samples. The simulated extinction spectra fit very well with the experimental spectra, especially in the spectral window of 750–1550  $\text{cm}^{-1}$  where the mean relative difference is less than 5%. There are no direct relationships between the coefficients listed in the legend of Fig. S6 and the concentrations of the minerals in the two natural samples, but it gives trends for the relative proportion of each mineral. Both samples likely contain a large proportion of illite compared to quartz and calcite. The Pic du Midi sample does not contain calcite because  $C_c = 0$  for this sample.

To estimate the mass extinction efficiency (MEE), the mass concentration is derived from the fitted size distribution assuming spherical particles with a mean density of  $\rho_p = 2.7 \text{ g cm}^{-3}$ . The values of the MEE are reported in Fig. S7 in the 650–4000  $\text{cm}^{-1}$  spectral range. The maximum MEE is 0.39  $\text{m}^2 \text{ g}^{-1}$  at 1035  $\text{cm}^{-1}$  and 0.25  $\text{m}^2 \text{ g}^{-1}$  at 1035  $\text{cm}^{-1}$  for the Lautaret and Pic du Midi samples, respectively.

Vibrational mode	Centre of the band $\text{cm}^{-1}$	Mineral
$\nu(\text{Si-O-Si})$ symmetric	782, 800	Quartz
$\delta(\text{CO}_3)$ out of plan	76	Calcite
$\delta(\text{Al-Al-OH})$	917	Illite
$\nu(\text{Si-O-Si})$ asymmetric	1034	Illite
$\nu(\text{Si-O-Si})$ asymmetric	1100, 1163	Quartz
$\nu(\text{CO}_3)$ asymmetric	1460	Calcite

**Table 1.** Assignment of the vibration modes ( $\nu$ : stretching mode and  $\delta$ : bending mode) with the corresponding mineral

### 3.6 Radionuclide analyses

260 The combination of both the low quantity of dust material collected on the filters (= 0.3 g) and their relatively low activity in artificial radionuclides was insufficient to quantify the content in  $^{137}\text{Cs}$  ( $< 11.9 \text{ Bq kg}^{-1}$ ) in the dust filter with the highest dust quantity (0.3 g). In a sample with a similar material quantity and prepared under the same conditions but containing higher  $^{137}\text{Cs}$  activities (IAEA-444 soil material), this  $^{137}\text{Cs}$  activity could be quantified ( $72.9 \pm 8.5 \text{ Bq kg}^{-1}$ ) in good agreement with the certified value ( $68.5 \pm 1.4 \text{ Bq kg}^{-1}$ ).

265 With a higher quantity of dust material available (i.e., 13 g), the Barèges sample showed a  $^{137}\text{Cs}$  activity of  $19.0 \pm 0.5 \text{ Bq kg}^{-1}$ . This activity is higher than that typically observed in the upper layer of soils collected ca.  $40^\circ$  north ( $5 \pm 2 \text{ Bq kg}^{-1}$ ), which is likely explained by the very small particle size of dust deposited, as clays are known to be enriched in fallout radionuclides (Evrard et al., 2020).

In addition to  $^{137}\text{Cs}$  detection, the activities in natural fallout radionuclides that were well detectable in both the ALP-34-FE  
270 filter and the much more abundant dust sample from Barèges demonstrated that both dust samples collected in 2021 were strongly tagged by short-lived radionuclides associated with rainfall ( $^7\text{Be}/^{210}\text{Pb}_{xs}$  ratios  $> 4$ ), demonstrating their very recent deposition or their recent exposure to precipitation. These ratios are consistent with those analysed in other wet rainfall samples across Europe, as reviewed by Gourdin et al. (2014), and they remained of the same order of magnitude as those ( $> 4$ ) analysed in fresh sediment collected in Central France by Le Gall et al. (2017).

275 We found that the  $^{240}\text{Pu}/^{239}\text{Pu}$  isotopic signature of the Barèges dust sample was  $0.173 \pm 0.008$ .

### 3.7 Satellite data

Figure 14 shows the large spatial variability of the satellite-derived dust content, ranging from 0 to 8000 ppm. The dust concentration obtained from the satellite is retrieved as a mass fraction (mass of dust per unit of snow mass, see Sect. 2.7) and hence is not directly comparable to the dust mass obtained from the in situ samples (in  $\text{kg m}^{-2}$ , i.e., a mass per unit area).  
280 However, we observe a similar distribution of both quantities with the terrain aspect, with increased dust amount on south facing slopes in both datasets (Fig. 7).

## 4 Discussion

The analysis of the samples reveals the strong spatial variability of the deposition rates, with higher mass found at the locations where the dust plume arrived first (Pyrenees, mean  $21.2 \text{ g m}^{-2}$ ) than at the locations where the dust was deposited the latest  
285 (Swiss mountain ranges, mean  $4.5 \text{ g m}^{-2}$ ). A similar spatial trend is found in the particle size with a decrease in mean diameter from 21 (Pyrenees) to  $15 \mu\text{m}$  (Switzerland). For the mass only, this large-scale pattern is superimposed on a more local gradient, as we find more dust mass on the south and south-east facing slopes at the massif scale. This gradient is evident from the snow samples but also from remote sensing data. This suggests that large-scale monitoring using satellite data should be possible, although further work is needed to establish a more direct comparison and therefore evaluate the uncertainty of such retrievals.

290 Because the wind was blowing from the south and south-east during the dry deposition event, the higher accumulation on south  
facing slopes is consistent with the orographic effect (Mott et al., 2018). Regarding the dust size distribution, the comparison  
between the mass measured on the filters and the mass estimated from the size distribution shows that a substantial part of the  
dust mass is likely related to large particles, with a diameter larger than  $50 \mu\text{m}$  (mass fraction likely higher than 50 %). Other  
studies have reported long-range transport of giant dust particles (with a diameter larger than  $100 \mu\text{m}$ ) (Varga et al., 2021;  
295 Adebisi et al., 2023).

The elemental composition of the samples also exhibits a large-scale gradient except for potassium. Fe/Ca and Si/Al ratios  
are similar to other values found in the literature for Saharan dust (Caponi et al., 2017), while the mass fraction of iron decreases  
from 11 % in the Pyrenees to 2 % in the Swiss mountain ranges. This wide range of values was also reported in Di Biagio et al.  
(2019). In the latter study, it is also shown that the optical properties of the dust strongly vary with the elemental iron, suggesting  
300 that the optical properties of the dust in the UV-VIS-VNIR range vary along transport within this single dust deposition event.

For the radionuclide analyses, the results obtained on the 13-g Barèges sample show that this larger sample quantity greatly  
facilitates gamma spectrometry measurements and collecting a sample quantity of at least  $\approx 10 \text{ g}$  of dust could therefore be an  
objective in the case of future occurrence of Saharan dust episodes in Europe, should other participatory dust collection cam-  
paigns be initiated. In addition to  $^{137}\text{Cs}$  detection, obtaining such a larger quantity of material would allow a better multiproxy  
305 characterisation of the dust, not only in gamma-emitting radionuclides (e.g.,  $^{137}\text{Cs}$ ,  $^7\text{Be}$  and  $^{210}\text{Pb}$ ) that can be quantified using  
physical and nondestructive measurement techniques but also in alpha-emitting radionuclides (e.g., Pu isotopes), which require  
time-consuming and destructive analyses (the typical test catch is 5 g per sample for Pu analyses).

The plutonium analyses conducted on the Barèges dust sample showed that the  $^{240}\text{Pu}/^{239}\text{Pu}$  isotopic signature of this sample  
( $0.173 \pm 0.008$ ) perfectly matches that of the global fallout in the Northern Hemisphere ( $0.176 \pm 0.007$ ) largely dominated  
310 by USA and USSR thermonuclear tests conducted in the late 1950s and the early 1960s (Kelley et al., 1999). This is also  
corroborated by the  $^{239+240}\text{Pu}/^{137}\text{Cs}$  value of 0.021 found for the Barèges sample, remaining in the global fallout range  
(0.018-0.030) (UNSCEAR, 2008). These results confirm those obtained on Saharan dust samples collected in Southern France  
in 2004 (Masson et al., 2010). Although the  $^{240}\text{Pu}/^{239}\text{Pu}$  isotopic signature of the fallout associated with the few atmospheric  
French nuclear tests conducted in the Sahara has not yet been published in public, it is unlikely that this signature perfectly  
315 coincides with that of the so-called global fallout (given that different types of bomb engines and fuels were used by the  
different countries). Accordingly, the public assertion that the  $^{137}\text{Cs}$  borne by Saharan dust originates from the French nuclear  
tests conducted in the Sahara between 1960 and 1966 is likely wrong (Berger, 2021). It is more likely to correspond to  $^{137}\text{Cs}$   
released by the much more numerous and powerful tests conducted by the USA and the USSR in the Northern Hemisphere  
between 1954 and 1963 (French tests corresponded to 0.017% of the total power generated by the worldwide tests during this  
320 period according to data from UNSCEAR (2008)). Nevertheless, more work is needed to define the Pu isotopic signature of the  
French test fallout in the Sahara. Furthermore, more dust samples collected at different locations should be analysed to confirm  
the current results.

Saharan dust plays an important role in the biogeochemical cycles of nutrient-poor environments such as some oceanic  
areas, tropical forests and high-altitude oligotrophic lakes. A Saharan deposition event could supply an important proportion of

325 the minerals, especially phosphorus inputs in high-altitude areas (Okin et al., 2004). Gross et al. (2015) examined phosphorus  
concentrations for five dust events over Cape Verde. P concentrations were highly variable, ranging from 1500  $\mu\text{g g}^{-1}$  to 5500  
 $\mu\text{g g}^{-1}$ . Our dataset shows that for a single event, the concentration range increased with distance from the source: while P  
concentrations were homogeneous in the Pyrenees ( $959\pm 215 \mu\text{g g}^{-1}$ ), a larger dispersion was observed in the Swiss Alps  
( $1738\pm 637 \mu\text{g g}^{-1}$ ). Dam et al. (2021) showed that P speciation evolves while crossing the Atlantic Ocean. The larger the  
330 distance from the source along the transport path, the more Fe/Al-P and less Ca-P minerals are present in the dust in relation  
to particle sorting and weathering. The homogeneous sampling of a single event that we performed in the current research  
showed similar behaviour, with a relative enrichment in P and Al and a relative loss of Ca and Fe during transport.

## 5 Conclusions

We presented data from 136 dust samples collected in snow after a major dust event in February 2021 in south-west Europe.  
335 The samples were spatially distributed from the Pyrenees to the French and Swiss Alps, covering a wide range of topographic  
features. We obtained the samples from a citizen science campaign, which required a simple sampling protocol. We analysed  
various physicochemical properties, including deposited mass per unit area, particle size, elemental composition, radionuclide  
concentrations, and optical extinction. To our knowledge, this is the first time that such a large number of dust samples from  
a single dust event were collected and analysed with multiple analytical tools. We provide the results of these analyses along  
340 with the geographic coordinates of every sampling site.

The dataset should be useful to evaluate the skills of atmospheric transport models (e.g. Baladima et al., 2022). The measured  
properties of the dust could also be used for impact studies, such as for quantifying the impact of the dust on snow cover duration  
in Europe (e.g. Réveillet et al., 2022).

The analysis of the dataset already revealed noteworthy results:

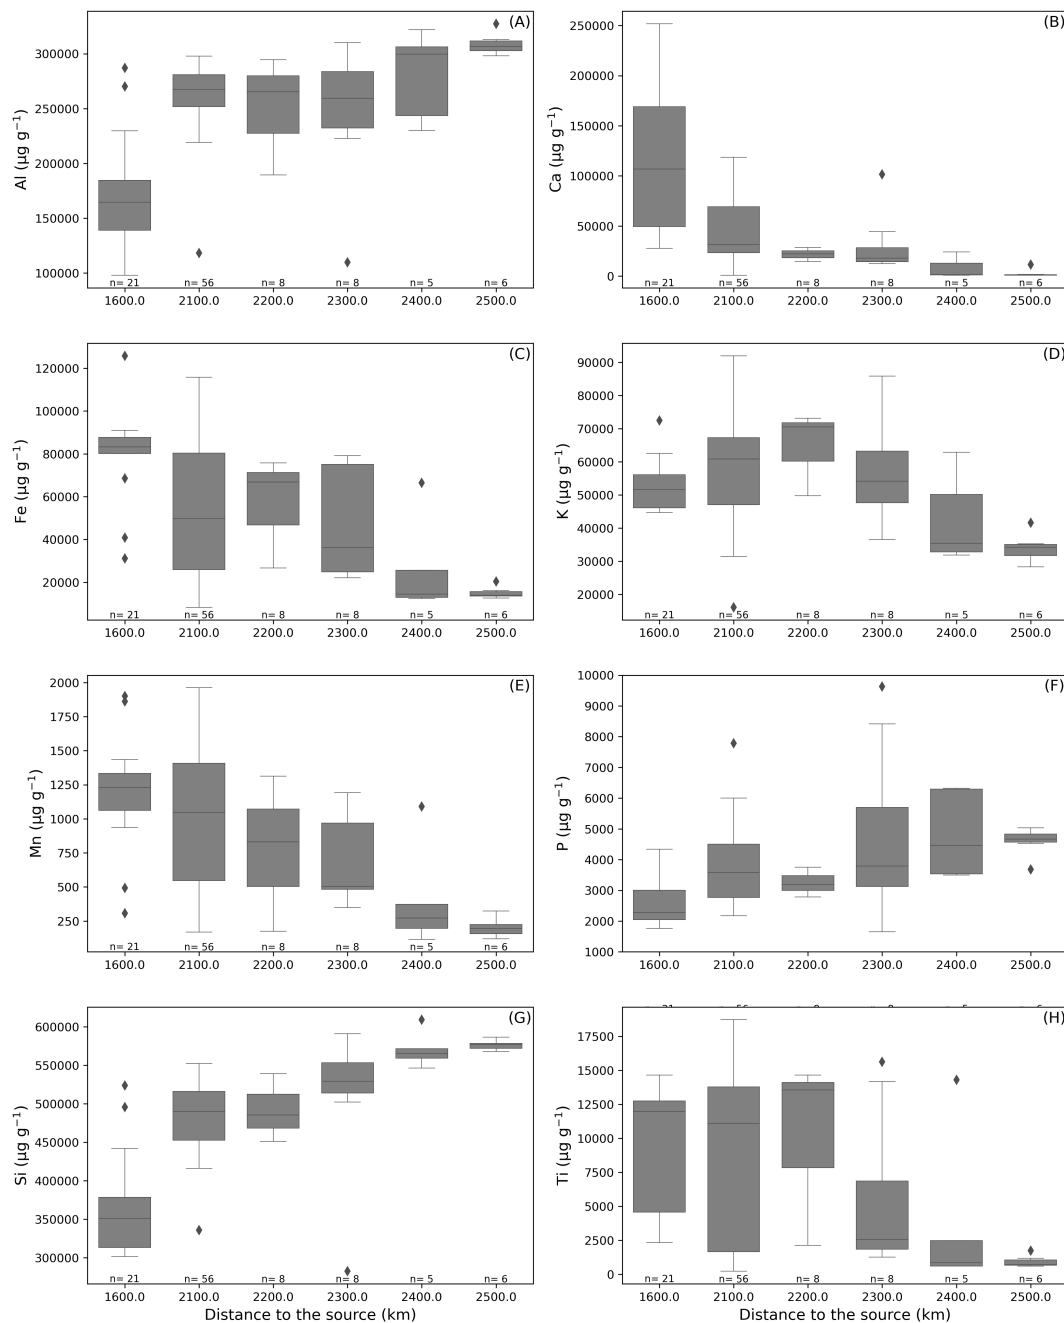

- 345 – We find a gradient in the dust mass and the dust size distribution with the distance along the dust plume. Larger masses  
and sizes are found at the locations where the dust plume arrived first (the Pyrenees in this case). This gradient is also  
found in the elemental composition. For instance, the total elemental iron mass is higher in samples from the Pyrenees  
than in those from the Swiss mountain ranges. This suggests that dust optical properties could vary along transport within  
a single event. An opposite trend is observed for P, with important implications for the biogeochemical functioning of  
350 ecosystems.
- In addition to this large-scale spatial pattern, we find a higher dust mass on the south and south-east facing slopes,  
suggesting preferential dust deposition on windward slopes.
- A plutonium analyses show that the isotopic signature of the dust perfectly matches that of the global fallout in the  
Northern Hemisphere, contrary to what was announced by the media (i.e., origin associated with the French nuclear tests  
355 in the 1970s in the Sahara).

- Sentinel-2 multispectral remote sensing imagery is promising for characterising this spatial variability, although further work is needed to evaluate the uncertainties of this method.

It is remarkable to find consistent spatial trends, which are compatible with physical processes despite the heterogeneity of the sample sources of this campaign. Although some participants are snow measurement experts, many others were not trained to collect environmental samples and data. Tools and containers to collect the samples were not standardised. The sampling method was as simple as possible to avoid discouraging nonexpert people. Therefore, we could obtain sufficient samples to compensate for errors and inaccuracies during the data collection process. However, the sampling protocol of future campaigns should be improved for optical property measurements and radionuclide analyses since more dust mass is needed for such measurements than what could be sampled.

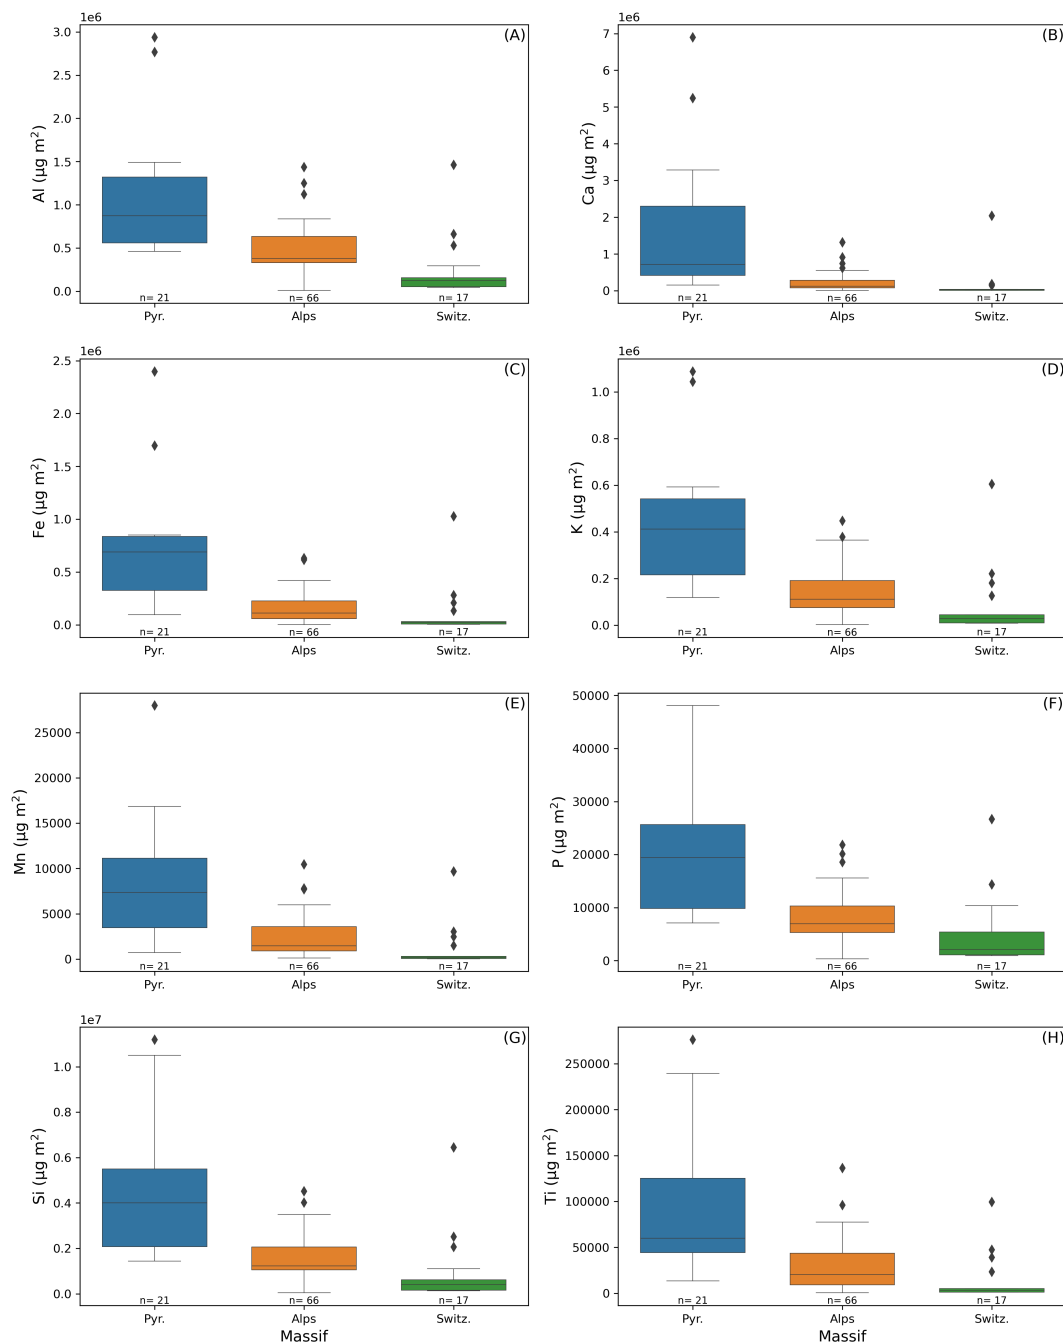

The above results show that involving citizens in the data collection process can lead to scientific advances beyond the current knowledge. This campaign was also a unique opportunity to generate informal exchanges between scientists and citizens. From our perspective as scientists, it was particularly stimulating to meet people curious about our work and supporting our research. We will continue to use this dataset to try to answer some of the key questions that we were asked by the participants. In particular, we aim to better characterise the impact of dust deposition on (i) snowmelt runoff, hydrological resources and ski resort management (Dumont et al., 2020; Réveillet et al., 2022), (ii) glacier mass balance, (iii) avalanche hazard (Dick et al., 2022) (iv) and ecosystem productivity.
