8  **Abstract**

9  Earth system models (ESMs) are progressively advancing towards the kilometer scale (k-scale).

10  However, the surface parameters for Land Surface Models (LSMs) within ESMs running at the k-

11  scale are typically derived from coarse resolution and outdated datasets. This study aims to develop

12  a new set of global land surface parameters with a resolution of 1 km for multiple years from 2001

13  to 2020, utilizing the latest and most accurate available datasets. Specifically, the datasets consist

14  of parameters related to land use and land cover, vegetation, soil, and topography. To demonstrate

15  the capability of these new parameters, we conducted 1 km resolution simulations using the E3SM

16  Land Model version 2 (ELM2) over the contiguous United States. Our results demonstrate that

17  land surface parameters contribute to significant spatial heterogeneity in ELM2 simulations of soil

18  moisture, latent heat, emitted longwave radiation, and absorbed shortwave radiation. On average,

19  about 31% to 54% of spatial information is lost by upscaling the 1 km ELM2 simulations to a 12

20  km resolution. Using eXplainable Machine Learning (XML) methods, the influential factors

21  driving the spatial variability and spatial information loss of ELM2 simulations were identified,

22  highlighting the substantial impact of the spatial variability and information loss of various land

23  surface parameters, as well as the mean climate conditions. The new land surface parameters are

24  tailored to meet the emerging needs of k-scale LSMs and ESMs modeling with significant

25  implications for advancing our understanding of water, carbon, and energy cycles under global

26  change.   The   1   km   land   surface   parameters   are   publicly   available   at

27  https://doi.org/10.25584/PNNLDH/1986308 (Li et al., 2023).

Open Access Earth System Science Data Discussions

28  **1. Introduction**

29  Aided by advancements in computing power, it has become increasingly feasible to run land

30  surface models (LSMs) and Earth system models (ESMs) at the kilometer scale (k-scale) to

31  improve our understanding of Earth system processes. The emergence of k-scale modeling has the

32  potential to improve the accuracy of climate simulations significantly and allow for explicit

33  modeling of physical processes that were previously poorly represented in climate models (Nat.

34  Clim. Chang. 2022), such as modeling of mesoscale convective systems in the atmosphere (Slingo

35  et al., 2022) and mesoscale eddies in ocean (Hewitt et al., 2022). Simultaneously, land modeling

36  has also witnessed a surge of interest in hyper-resolution modeling, initially proposed by Wood et

37  al. (2011), which aims to model land surface processes at a horizontal resolution of 1 km globally

38  and 100 m or finer for continental or regional domains. The motivation behind hyper-resolution

39  modeling is to address the requirements of operational forecasting like extreme events, and to

40  enhance our understanding of hydrological and biogeochemical cycling, and land–atmosphere

41  interactions. High-resolution LSMs have been increasingly applied in various fields, as

42  demonstrated by recent examples, such as 30-meter soil moisture simulations over the contiguous

43  United States (CONUS) (Vergopolan et al., 2020, 2021, 2022), 500-meter hyper-resolution

44  modeling of surface and root zone soil moisture over Oklahoma (Rouf et al., 2021), 1-km

45  simulations over Southwestern US (Singh et al., 2015), 3-km simulations over eastern Tibetan

46  Plateau to understand hydrological changes over mountainous regions (Yuan et al., 2018; Ji and

47  Yuan, 2018), 6-km simulations over China to reduce simulations errors of hydrological variables

48  (Ji et al., 2023). High-resolution modeling can better capture the land surface heterogeneity and

49  could improve simulations of terrestrial water, energy, and biogeochemical cycles, as well as land

50  and atmosphere coupling (Giorgi and Avissar, 1997; Chaney et al., 2018; Zhou et al., 2019; Liu et

51    al., 2017; Bou-Zeid et al., 2020; Chen et al., 2020; Nitta et al., 2020; Vrese et al., 2016). Singh et

52    al. (2015) demonstrated that increasingly capturing topography and soil texture heterogeneity at

53    finer resolutions (e.g., 1 km) improves land surface modeling of water and energy variables. Li et

54    al. (2022) have shown that the spatial heterogeneities of land surface parameters (including land

55    use and land cover (LULC) and topography) are essential for modeling the spatial variability of

56    land surface energy and water partitioning. Hao et al. (2022) found that 1 km simulations with sub-

57    grid topographic configurations can better capture the topographic effects on surface fluxes.

58

59    The parameters for LSMs within ESMs being run at the k-scale are typically derived from coarse

60    resolution datasets or outdated datasets. Consequently, k-scale modeling may not accurately

61    represent fine-scale land surface heterogeneity unless high-resolution land surface parameters at

62    the kilometer or finer scales are utilized. Publicly available land surface parameters are primarily

63    provided at coarse resolutions and based on outdated datasets. For example, the Community Land

64    Model version 5 (CLM5; Lawrence et al., 2019) typically relies on land surface parameters with

65    spatial resolutions ranging from 1km to 0.5º based on source datasets that were processed more

66    than 10 years ago (see Table 1 for details). Although LULC-related parameters are available at a

67    relatively high resolution of 0.05º, they are temporally static and were derived from a combination

68    of data from different years spanning 1993 to 2012 (Table 1). Leaf area index (LAI) was derived

69    from the now outdated products of Moderate Resolution Imaging Spectroradiometer (MODIS)

70    collection 4 (Myneni et al., 2002). The canopy height for tree Plant Functional Types (PFTs) is

71    based on forest canopy height data derived from the Geoscience Laser Altimeter System (GLAS)

72    aboard ICESat, collected in 2005 (Simard et al., 2011). Canopy height for short vegetation is

73    represented by PFT-specific values that remain invariant in space (Bonan et al., 2002). Soil sand

Data
Discussions

74    and clay content were obtained from the International Geosphere-Biosphere Programme (IGBP)

75    soil dataset (Global Soil Data Task 2000) consisting of 4931 soil mapping units (IGBP, 2000).

76    These CLM5 land surface parameters have been widely utilized in the LSMs and ESMs

77    community, despite being developed over a decade ago. Subsequently, Ke et al. (2012; hereafter

78    referred to as K2012) developed an updated set of LULC and vegetation-related land surface

79    parameters for CLM4 at a resolution of 0.05º. These parameters were developed based on MODIS

80    collection 5 products or datasets derived from MODIS collection 5 products, including PFTs and

81    non-vegetation land cover, LAI, and Stem Area Index (SAI). K2012 has also been widely used by

82    LSMs, including CLM (e.g., Leng et al., 2013; Singh et al., 2015; Ke et al., 2013; Xia et al., 2017)

83    and the Energy Exascale Earth System Model (E3SM) Land Model (ELM) (e.g., Caldwell et al.,

84    2019; Leung et al., 2020; Li et al., 2022). However, the CLM5 and K2012 datasets, with their

85    relatively coarse resolution and reliance on outdated data from over a decade ago, may not fully

86    meet the requirements for k-scale modeling. Additionally, these datasets include LULC, LAI, and

87    SAI that are year invariant. Consequently, they are inappropriate for studies involving LULC

88    changes, such as urbanization. In addition, some recently developed land surface processes and

89    their associated parameters are not included in previous datasets. For instance, Hao et al. (2021)

90    introduced a sub-grid topographic parameterization of solar radiation with five associated

91    topographic factors in ELM, which have been found to significantly affect the surface energy

92    budget.

93

94    High-resolution and up-to-date datasets at kilometer or finer resolutions are now widely available

95    and can be utilized to derive more accurate land surface parameters for k-scale LSM simulations.

96    For example, the MODIS Land Cover Type Collection 6 (MCD12Q1 C6) data product provides

97    global land cover types yearly from 2001 to the present (Friedl et al., 2019; Sulla-Menashe et al.,

98    2019) at 500-meter resolution. Compared to the MODIS Collection 4 (used in CLM5 land surface

99    parameters) and Collection 5 products (used in K2012 land surface parameters), the C6 data

100   represents a significant advancement in algorithm improvements and the quality of land cover

101   information. Despite the availability of high-resolution MODIS LAI products, such as the 500 m

102   MCD15A2H (Myneni et al., 2021), they suffer from noise and gaps with spatially and temporally

103   inconsistent values due to clouds, seasonal snow cover, instrument issues, and uncertainties in

104   retrieval algorithms (Yuan et al., 2011). To address these limitations, Yuan et al. (2011)

105   reprocessed MODIS LAI products and generated a more accurate and spatiotemporally continuous

106   and consistent LAI dataset that is available continuously to the present period. Additional high-

107   resolution and up-to-date datasets are available for preparing land surface parameters, such as soil

108   texture and soil organic matter at 250-meter resolution (Poggio et al., 2021) and vegetation height

109   at 10-m resolution (Lang et al., 2022).

110

111   This study aims to develop a new set of global land surface parameters with a resolution of 1 km

112   for multiple years, utilizing the latest and most accurate available datasets. These parameters will

113   be tailored to meet the needs of k-scale Earth system modeling. The newly developed land surface

114   parameters include four categories: (1) LULC-related parameters, such as the spatial distributions

115   of PFTs, lakes, wetlands, urban areas, and glaciers; (2) vegetation-related parameters, including

116   PFTs' LAI and SAI for multiple years ranging from 2001 to 2021, and the canopy top and bottom

117   height; (3) soil-related parameters, such as soil textures and soil organic matter; and (4)

118   topography-related parameters, such as slope, aspect, and sub-grid topographic factors. We

119   employed the ELM version 2 (ELM2) as a testbed to demonstrate the capability of the new high-

120    resolution parameters by conducting a 5-year 1 km resolution simulation over the CONUS. We

121    performed a spatial scaling analysis on four ELM2 simulated variables, which included soil

122    moisture, latent heat, emitted longwave radiation, and absorbed shortwave radiation, to underscore

123    the significance of high-resolution land surface parameters on ELM2 simulations. We employed

124    eXplainable Machine Learning (XML) methods to evaluate the most important factors of land

125    surface parameters and climate conditions (e.g., mean temperature and precipitation) in driving the

126    spatial variability and spatial information loss of ELM2 simulations.

127    **2. Development of 1km land surface parameters**

128    In this study, all the land surface parameters were developed globally at a resolution of

129    approximately 1 km (i.e., 1/120°, hereafter referred to as 1 km; Table 1). The LULC-related

130    parameters, soil properties, canopy height, and elevation were processed via Google Earth Engine

131    (GEE; Gorelick et al., 2017). The LAI was processed using an area-weighted average from its

132    original 450 m resolution obtained from Beijing Normal University (Yuan et al., 2011). The

133    detailed methods for deriving these parameters are described below.

Earth System
Science
Data

## 2.1 LULC-related parameters

This study utilized MODIS MCD12Q1 version 6 (Friedl et al., 2022) to derive the PFT and other non-vegetation land types at a resolution of 1 km for 2001–2020. The original MODIS land cover data was first resampled to 1 km from its original 500 m resolution using a majority resampling method in GEE. At such a high 1km resolution, we did not consider the proportion of different land cover types within each grid. Instead, we assigned 100% of a grid cell to the major land cover type. Specifically, the MCD12Q1 LC_Type 5 PFT classification layer was used to determine the distributions of the seven PFTs, as well as lake, urban, and glacier, following the method outlined in Ke et al. (2012) and summarized below:

- The seven PFTs include needleleaf evergreen trees (NET), needleleaf deciduous trees (NDT), broadleaf evergreen trees (BET), broadleaf deciduous trees (BDT), shrub (SHR), grass (GRS), and crop (CRO). These PFTs were further reclassified into 15 categories (Table S1) that are typically used in LSMs based on the rules presented in Bonan et al. (2002a) with the assistance of 1 km precipitation and surface air temperature from WorldClim V1 (Hijmans et al., 2005).

- Grass was reclassified as C3 and C4 grass using the approach presented by Still et al. (2003), with the assistance of monthly LAI (processed in section 2.2.1) and meteorological variables from WorldClim V1.

- The "non-vegetated land" was classified as barren soil class.

- The "permanent snow and ice" was assigned as the glacier land unit. Global lakes were identified based on the classification of "water bodies" over the global land, constrained using the global land mask obtained from Natural Earth (https://www.naturalearthdata.com/).

163 • The urban land unit was determined based on the MODIS "urban and built-up"

164 classification. These urban grids were further classified into three urban classes, namely,

165 tall building district (TBD), high density (HD), and medium density (MD), based on

166 Jackson et al. (2010; hereinafter referred to as J2010). J2010 generated global urban extent

167 maps for the TBD, HD, and MD classes at a spatial resolution of 1 km, based on rules of

168 building height and vegetation coverage fraction

169 (https://gdex.ucar.edu/dataset/188a_oleson/file.html). However, the J2010 dataset is

170 temporally static and cannot reflect changes in urban boundaries over time. Therefore, we

171 reclassified the yearly MODIS urban land class as TBD, HD, and MD based on the J2010

172 dataset using the nearest neighbor sampling method for each year.

173 After determining the distribution of 15 PFTs, bare soil, lake, glacier, and urban land, any

174 remaining 1 km grids were assigned as ocean (Table S1). It should be noted that the wetland land

175 unit was not explicitly classified in this study. This is because, instead of treating wetlands as an

176 individual land unit, many LSMs (e.g., ELM2 and CLM5) integrate wetland functioning processes

177 prognostically within other land units where a surface water storage component is implemented to

178 represent wetland functioning.

179

180 **2.2 Vegetation-related parameters**

181 **2.2.1 Monthly LAI and SAI**

182 The monthly LAI parameters were obtained from Beijing Normal University (BNU_LAI; Yuan et

183 al., 2011). BNU_LAI is a reprocessed version of the MODIS LAI C6 product, which has

184 undergone comprehensive quality control and use of multiple algorithms (Yuan et al., 2011). The

185 data have better performance in validation against reference LAI and are more spatiotemporally

186    continuous and consistent than the original MODIS LAI (Yuan et al., 2011). The 8-day BNU_LAI

187    product at a resolution of 15 seconds (~450 m) over 2001–2020 was downloaded from

188    http://globalchange.bnu.edu.cn/research/laiv061. Subsequently, the data were resampled to a

189    resolution of 1 km using an area-weighted average method and averaged temporally for each

190    month. The processed monthly LAI at 1 km resolution was subsequently assigned to each of the

191    15 PFTs described above at each grid. The monthly SAI was then calculated based on the

192    processed monthly LAI using the methods and PFT parameters described in Zeng et al. (2002).

193

194    **2.2.2 Vegetation canopy height**

195    The global vegetation canopy height dataset used in this study was obtained from Lang et al. (2022).

196    Lang et al. (2022) developed a probabilistic deep learning model to retrieve canopy height from

197    the Sentinel-2 images by fusing Global Ecosystem Dynamics Investigation (GEDI). This dataset

198    is the first globally consistent and wall-to-wall canopy height at a 10 m spatial resolution and

199    includes canopy height for all vegetation types. The canopy height served as the canopy top height

200    parameter. Canopy bottom height was calculated by multiplying PFT-based ratios derived from

201    the ratio of ELM's (same as CLM5) canopy top and bottom heights for different PFTs (Table S2).

202

203    **2.3 Soil-related parameters**

204    We obtained the Soilgrid v2 data with an original resolution of 250 m (Poggio et al., 2021) to

205    prepare soil properties. Soilgrid is generated using machine learning based on multiple data

206    sources of soil profiles and remote sensing data (Hengl et al., 2017). Soilgrid v2 provides percent

207    clay, percent sand, and soil organic matter for six soil layers: 0–5 cm, 5–15 cm, 15–30 cm, 30–60

208    cm, 60–100 cm, and 100–200 cm. The original SoilGrid version 2 data obtained from GEE were

209    processed at 1 km resolution with multiple layers using an area-weighted average method. To

210    facilitate the demonstration, we restructured the six soil layers vertically into ELM's ten effective

211    soil layers (0–1.8 cm, 1.8–4.5 cm, 4.5–9.1 cm, 9.1–16.6 cm, 16.6–28.9 cm, 28.9–49.3 cm, 49.3–

212    82.9 cm, 82.9–138.3 cm, 138.3–229.6 cm, and 229.6–380.2 cm) using the nearest neighboring

213    method. It should be noted that the lake module in ELM2 and CLM5 requires soil properties, but

214    the Soilgrid v2 data may not provide coverage over water surfaces. To address this, we utilized the

215    nearest neighbor sampling method to map the 1 km soil properties onto the terrestrial water surface.

216

217    **2.4 Topography-related parameters**

218    The 90 m digital elevation from MERIT Hydro (Yamazaki et al., 2019) was used to derive

219    topography-related parameters. We first acquired the 1km elevation and standard deviation of

220    elevation using GEE based on the original 90 m elevation. Further, we calculated the slope, aspect,

221    sky view factor, and terrain configuration factor from the 1km elevation using the parallel

222    computing tool developed by Dozier (2022). The sky view factor represents the proportion of

223    visible sky limited by adjacent terrain, and the terrain configuration factor describes the proportion

224    of adjacent terrain which is visible to the ground target. Finally, to drive the parameterization of

225    sub-grid topographical effects on solar radiation (Hao et al., 2022) in ELM2, we calculated the

226    $\sin(slope) \cdot \sin(aspect)$ and $\sin(slope) \cdot \cos(aspect)$ for calculating the local solar incident

227    angle, and two normalized angle-related factors, the sky view factor, and terrain configuration

228    factor by $\cos(slope)$.

229

230

Earth System
Science
Data

Open Access   Discussions

231   **3. K-scale demonstration simulation over CONUS**

232   **3.1 Experiment design**

233   To demonstrate the capability of 1 km datasets, we conducted ELM2 simulations over CONUS at

234   the resolution of 1 km, using the newly developed 1 km land surface parameters for 2010. We used

235   atmospheric forcing from the Global Soil Wetness Project Phase 3 (GSWP3; Kim, 2017) with a

236   spatial resolution of 0.5º to drive ELM. The spatial homogeneity of atmospheric forcing within

237   0.5º grid cell guarantees that the spatial variability of ELM simulated variables (e.g., latent heat)

238   within 0.5º grid cell is solely attributable to the heterogeneity of the 1 km land surface parameters.

239   There are approximately 12 million effective grids over CONUS. We ran ELM for five years

240   (2010–2014), and the last year's simulation was used for analysis. We specifically analyzed the

241   annual mean of surface layer soil moisture (SM, $m^3/m^3$), latent heat (LH, $W/m^2$), emitted

242   longwave radiation (ELR, $W/m^2$), and absorbed shortwave radiation (ASR, $W/m^2$).

243   **3.2 Spatial scaling analysis**

244   We conducted a spatial scaling analysis following the method described in Vergopolan (2022) on

245   the 1 km ELM simulation data to better understand how k-scale spatial heterogeneity in the four

246   ELM-simulated variables (mentioned in Section 3.1) induced only by spatial heterogeneity of land

247   surface parameters changes across spatial scales. First, we performed upscaling by averaging the

248   1 km (=1/120°) land surface parameters and the four ELM-simulated variables to coarser spatial

249   scales, $\lambda_{scale}$ of 1/60°, 1/40°, 1/30°, 1/24°, 1/20°, and 1/10°, and calculated the spatial standard

250   deviation ($\sigma_{scale}$) within each 0.5° × 0.5° box at each spatial scale (Table 2). Second, we quantified

251   the changes in spatial variability at different spatial scales compared to the original 1km resolution

252   by calculating the ratio of $\sigma_{scale}$ to $\sigma_{1\,km}$. Third, we fitted a $\log\left(\frac{\sigma_{scale}}{\sigma_{1\,km}}\right) \propto \beta \times \log\left(\frac{\lambda_{scale}}{\lambda_{1\,km}}\right)$

253   relationship, where $\beta$ is an indicator to quantify data spatial variability persistence across scales

254  (Hu et al., 1997). A more negative $\beta$ indicates a larger dependency of data spatial variability on

255  spatial scales, resulting in a higher information loss, denoted as $\gamma = (1 - \sigma_{scale}/\sigma_{1\,km}) \times 100\%$.

256  Given the possibility that β may not demonstrate significant temporal variation (Mälicke et al.,

257  2020), and considering that our scaling analysis is intended for demonstration purposes, our spatial

258  scaling analysis is based on the annual mean of ELM2 simulations.

259  Table 2. Spatial resolution and pixel number at different spatial scales.

| $\lambda_{scale}$ | 1 | 2 | 3 | 4 | 5 | 6 | 12 |
|---|---|---|---|---|---|---|---|
| Spatial resolution | 1km (1/120°) | 2km (1/60°) | 3km (1/40°) | 4km (1/30°) | 5km (1/24°) | 6km (1/20°) | 12km (1/10°) |
| Pixel number within 0.5° × 0.5° box | 60 × 60 | 30 × 30 | 20 × 20 | 15 × 15 | 12 × 12 | 10 × 10 | 5 × 5 |

260

261  **3.3 Attribution analysis utilizing XML methods**

262  We conducted additional analysis to determine the primary land surface parameters that influence

263  the spatial scaling of ELM simulations. We employed XML methods, specifically the eXtreme

264  Gradient Boosting(XGBoost; Chen and Guestrin, 2016) machine learning algorithm and the game

265  theoretic approach SHapley Additive exPlanations (SHAP; Lundberg and Lee, 2017; Lundberg et

266  al., 2018, 2020). XML methods were utilized to assess the influence of land surface parameters on

267  the spatial variability and information loss of ELM2 simulations across the CONUS. Taking spatial

268  variability as an example, we first computed the standard deviation (σ) within each 0.5º x 0.5º grid

269  for both 1 km resolution land surface parameters and simulations. Then, we train a machine

270  learning model to predict the spatial variability of each simulated variable (i.e., SM, LH, ELR,

271  ASR). We used the spatial variability (i.e., σ) and mean (μ) of the land surface parameters and μ

272  of precipitation and temperature as predictor variables, and the simulated variable's σ as the target

273  variable. After training the machine learning model, we used SHAP to quantify the relative

274  importance and determine which factors were most important in driving the spatial variability of

275    the simulations. Similarly, we used this approach to identify the most critical drivers of information

276    loss.

277

278    **3. Results**

279    **3.1 Demonstration of the global 1km land surface parameters**

280    LAI generally shows high values in humid and warm regions, such as tropical rainforests,

281    southeastern US, and southern Asia, and low values over arid or cold regions, such as central

282    Australia, southwestern US, Middle East, Central Asia, and northern Canada (Figure 1a). At high

283    resolution, the LAI dataset clearly reflects the detailed heterogeneity of vegetation distributions.

284    In subregion R1 (Figure 1b), a relatively small LAI is distributed over mountain ridges and zero

285    LAI over water surfaces (e.g., lakes). In subregion R2 (Figure 1c), the LAI pattern shows a large

286    proportion of forest fragmentation caused by deforestation. In subregion R3 (Figure 1d), the LAI

287    shows the distribution of agricultural land along with the river, river mouth, and lakes under an

288    arid climate. R4 shows how urbanization affects vegetation distributions (Figure 1e).

289    Figure 2 demonstrates the distribution of plant functional types and other non-vegetation land units.

290    High-resolution LULC types over multiple years can benefit studies related to LULC changes like

291    urbanization and deforestation. Canopy height generally follows a similar spatial pattern with LAI,

292    with high values in humid and warm regions and low values over arid or cold regions (Figure 3a).

293    The percent clay shows high values over Southeast Asia, India, central Africa, and southeast South

294    America, and low content over North Europe, South Africa and Alaska (Figure 3b). The

295    topography factors follow the elevation patterns (Figures 3c and 3d), where there are large slopes

296    and standard deviation of elevation over mountainous regions, such as the Rocky Mountains in

297    North America, the Himalayas Mountains in Asia, and Andes Mountains in South America.

**3.2 Demonstration 1km simulation over CONUS**

ELM simulations at a 1 km resolution display significant spatial heterogeneity over CONUS (Figure 4). The values of SM, LH, ELR, and ASR across CONUS follow approximately normal distributions, with averages of 0.3 m³/m³, 39.0 W/m², 371.7 W/m², 156.7 W/m², respectively (as shown in the histogram plots in Figure 4). SM shows drier conditions over the West and Southwest and wetter conditions over the Midwest, Corn Belt, Mississippi River basin, and Northeast (Figure 4a). LH shows high values over the central and southeast, and lower values over the west and southwest (Figure 4b). The ELR generally shows higher values over regions with high surface temperature in the south (Figure 4c). The ASR shows higher values over the southwestern regions determined by incoming solar radiation and albedo (Figure 4d). Despite the high-resolution heterogeneity shown at 1 km resolution, we can still see the spatial patterns distinguished at coarse

319    resolution, i.e., 0.5º × 0.5º. These coarser footprints are from the GSWP3 atmospheric forcing with

320    0.5º resolution. As concluded by Li et al. (2022), atmospheric forcing is one primary heterogeneity

321    source for land surface modeling. Therefore, k-scale atmospheric forcing needs to be developed to

322    further advance k-scale offline land surface modeling.

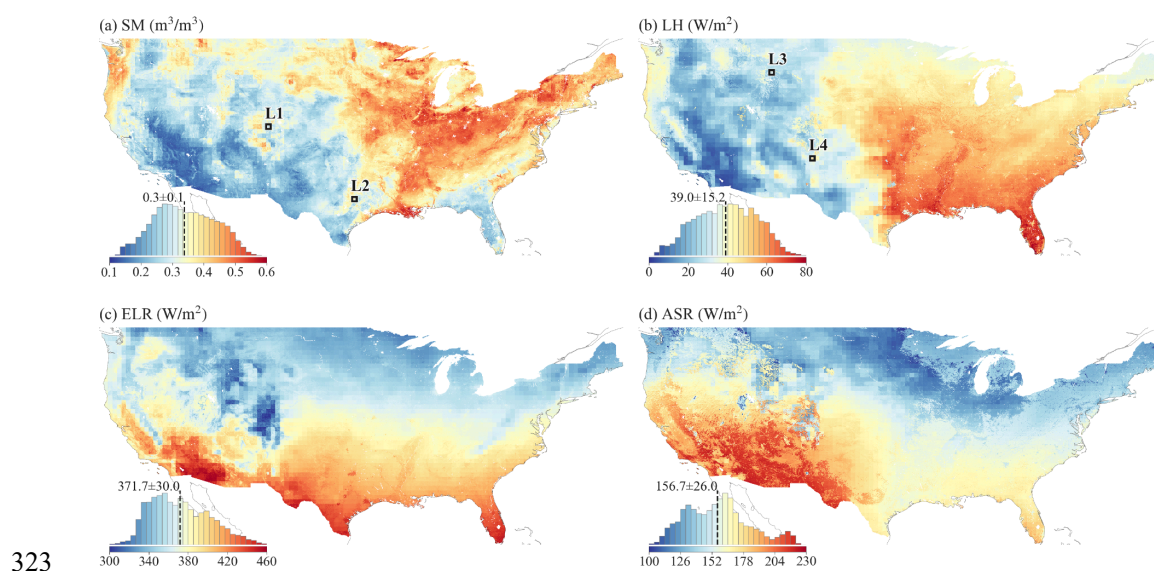

323

324    Figure 4. The annual mean of 1 km simulations of (a)SM, (b)LH, (c) ELR, and (ASR) over

325    CONUS. The 0.5° × 0.5° boxes marked as L1, L2, L3, and L4 in (a) and (b) are selected to

326    demonstrate the spatial scaling analysis. The inserted histogram plot illustrates the distribution of

327    ELM2 simulations.

328

329    **3.3 Demonstration of spatial scaling across scales**

330    We next demonstrate the relationships between spatial variabilities and spatial scales for SM and

331    LH. Four locations (in Figures 4a and 4b) are specifically chosen to showcase varying levels of

332    spatial information loss: L1 and L3 demonstrate a relatively large loss for SM and LH, respectively,

333    while L2 and L4 represent a relatively small loss for SM and LH, respectively.

334    At location L1 (Figure 5a), when the 1 km simulation is upscaled to coarser resolutions (i.e., larger

335    spatial scale ratios), the spatial variability of SM decreases, resulting in a negative slope of β. As

336    shown in Figure 6a, compared to the original 1 km resolution, the information loss γ reaches up to

337    54.9% at the 12 km spatial scale. The spatial pattern of SM is consistent with the spatial pattern of

338    percent clay (Figures 6a vs. 6b and 6c vs. 6d), indicating that soil texture contributes significantly

339    to the spatial variability of SM. However, SM has a more negative β than the percent clay (β = –

340    0.28 vs. –0.19 at L1, as shown in Figure 5a), suggesting that SM variability is amplified likely by

341    other processes that are also influenced by soil texture. In contrast to location L1, location L2

342    exhibits less negative β values for both SM and percent clay, suggesting that their spatial

343    variabilities exhibit less scale dependence (Figures 5a, 6c, and 6d). Both SM and percent clay at

344    location L2 approximately maintain their spatial patterns of high values in the west and low values

345    in the east across spatial scales (Figures 6c and 6d).

346    For LH, there is a more negative β value at location L3 than at location L4 (β = –0.27 at L3 vs. –

347    0.08 at L4, as shown in Figure 5b), which indicates a larger decrease of spatial variability across

348    spatial scales and lower variability persistence at location L3 than location L4 (Figure 7). The

349    spatial pattern of LH is consistent with the spatial pattern of LAI (Figures 7a vs. 7b and 7c vs. 7d)

350    at different spatial scales, suggesting that vegetation plays a significant role in the spatial

351    variability of LH. Similar to comparison between SM and soil texture, LH has a more negative β

352    than LAI (Figure 5b).
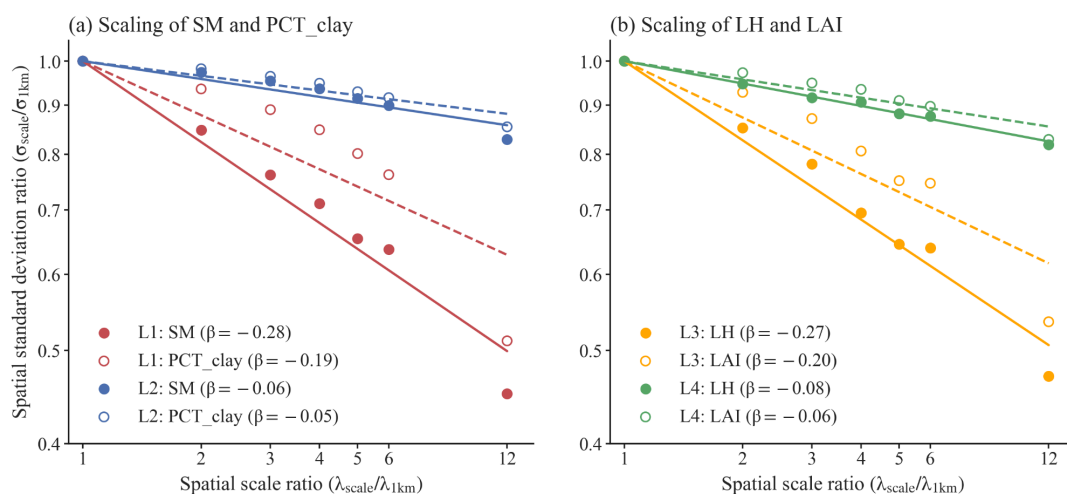

Figure 5. The scaling of spatial variabilities for (a) SM and percent clay, and (b) LH and LAI. Both the x-axis and y-axis are in logarithmic scale. The slope of the linear regression line, β, quantifies the strength of the negative relationship between spatial scale and spatial variability. A more negative β value indicates a higher spatial-scale dependency and increased information loss at coarser spatial scales. Four 0.5° × 0.5° boxes (displayed in Figure 4), namely L1 to L4, are chosen to contrast larger and smaller negative β values for SM and percent clay (L1 and L2) and for LH and LAI (L3 and L4).

367 **3.4 The spatial variability of water and energy simulations and their drivers**

368 We quantified the spatial variability simulated at 1 km resolution using σ within each 0.5º × 0.5º

369 box across CONUS. Four ML models were built to explore the spatial relationships between σ and

370 its potential drivers including σ of the land surface parameters and the temperature and

371 precipitation averaged over the grid box. Overall, the ML models performed well in predicting the

372 σ of the simulated variables, with small root mean square error (RMSE) and large $R^2$ (see Figure

373 S1). SM shows larger spatial variability in the US Southern Coastal Plain, lower Mississippi River,

374 Northeast, Southeast, and regions around the Great Lake (Figure 8a), which is roughly consistent

375 with the spatial heterogeneity of the high-resolution SM simulation in Vergopolan et al. (2022).

376 Based on the SHAP method, the spatial variability of SM across CONUS is driven by various

377 factors, mainly including the spatial variabilities of percent sand and percent clay, mean

378 precipitation, the σ and μ of soil organic matter, the σ of canopy height, and mean temperature

379 (Figure 8b). Mean precipitation and temperature reflect climate conditions (Figure S3), which are

380 related to the water supply and water demand of soil water content. The spatial heterogeneity of

381 soil properties, such as texture and organic matter content, affects soil hydraulic properties and

382 generate more spatially variable soil water content. Vegetation characteristics, such as canopy

383 height and LAI, could influence SM spatial variability through their effect on roughness length

384 and rooting depth.

385 The spatial variability of LH is large in the southeastern, central, and western mountainous regions

386 of the US (Figure 8c). Vegetation properties and climate conditions mainly drive the variability of

387 LH (Figure 8d). The μ and σ of LAI can affect transpiration and soil evaporation, while canopy

388 height can influence surface roughness length and, in turn, evapotranspiration. Mean precipitation

389    and temperature reflect the overall climate conditions related to the water and energy available for

390    latent heat.

391    ELR and ASR exhibit large spatial variability mainly over the western US, with ASR additionally

392    showing significant spatial variability across the Northern US (Figures 8e and 8g). This variability

393    is primarily driven by climate conditions such as mean precipitation and temperature, topographic

394    features such as standard deviation of elevation and slope, and vegetation properties including LAI

395    and canopy height (Figures 8f and 8h). These factors are related to the radiation input and surface

396    properties, such as albedo and roughness length, which impact the energy cycles and availability

397    of ELR and ASR.
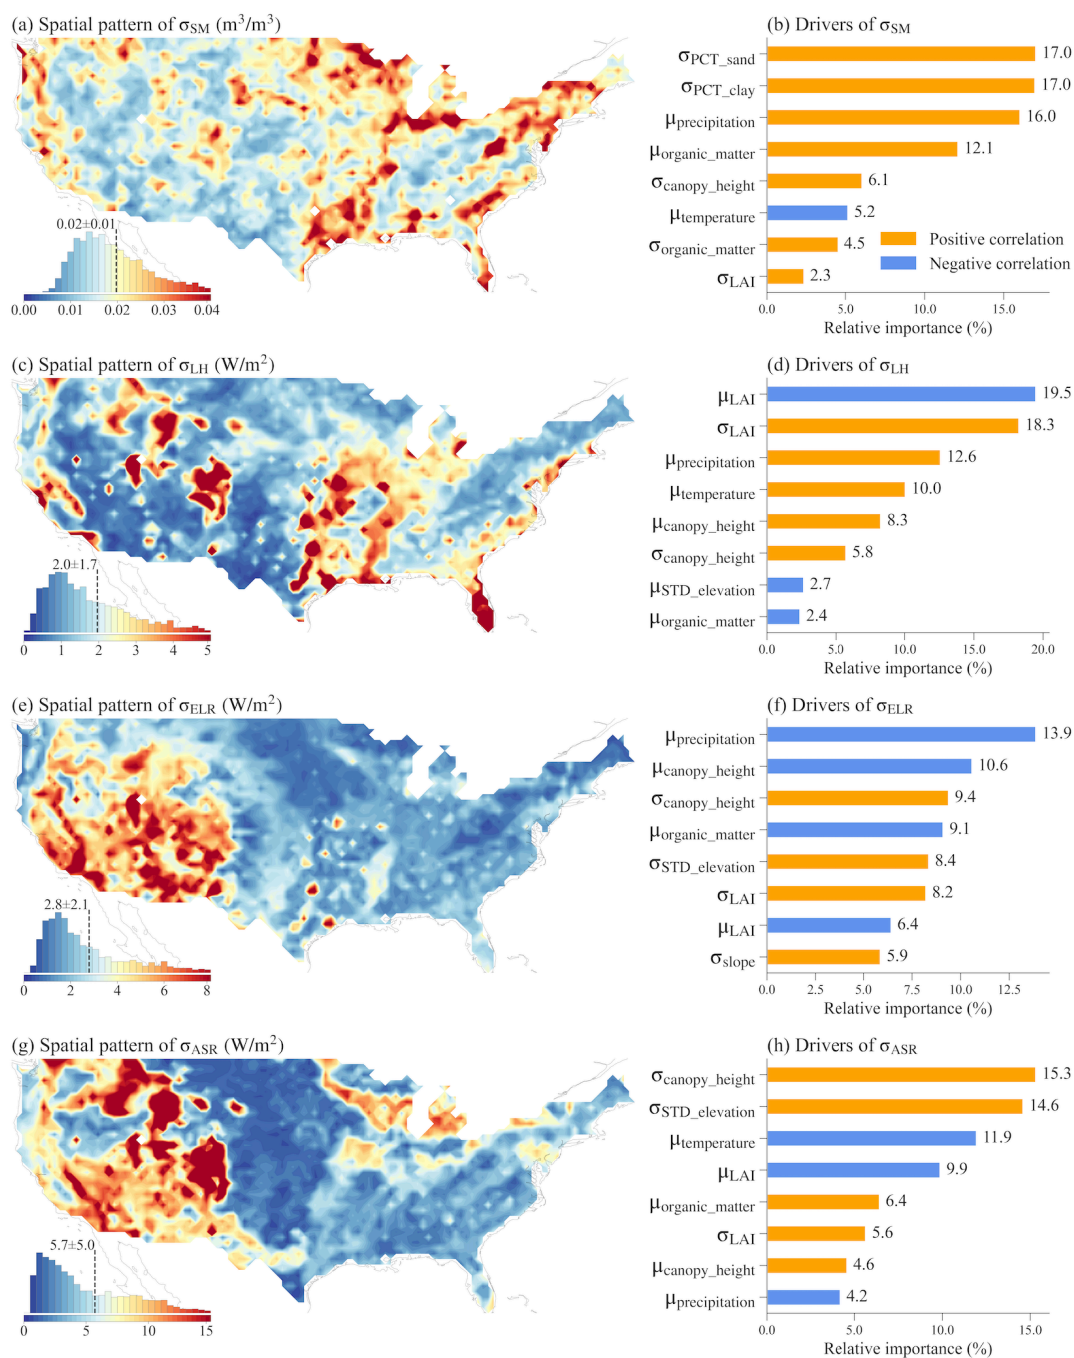

Figure 8. The spatial variability over each 0.5º × 0.5º grid cell (left plots) and the top eight most important drivers (right plots) of the spatial variability for SM, LH, ELR, and ASR. The inserted

401 histogram plot illustrates the probability distribution of the spatial variability across CONUS. The

402 relative importance of each variable in determining the spatial variability is calculated as the ratio

403 of the mean |SHAP value| of the variable to the sum of the mean |SHAP value| of all variables.

404 Therefore, the sum of the relative importance of all variables is 100%.

405

406 **3.5 The information loss of water and energy simulations and their drivers**

407 We also evaluated the information loss in simulations when upscaling from 1 km to 12 km

408 resolution and analyzed the drivers of their spatial patterns over CONUS. Four ML models were

409 built to explore the relationships between the $\gamma$ of the simulations and its drivers including the $\gamma$ of

410 the land surface parameters and the mean temperature and precipitation averaged over the 0.5º ×

411 0.5º box. These ML models performed well in predicting the simulations' $\gamma$, with small RMSE and

412 large $R^2$ (Figure S2).

413 Significant information loss ranging from 31% to 54% with maximum values exceeding 90% is

414 observed for SM, LH, ELR, and ASR simulations (Figure 9). Their spatial patterns and drivers

415 show distinct variations. $\gamma_{SM}$ is primarily driven by the information loss of percent clay and sand,

416 mean soil organic matter, and mean temperature, which affects the soil hydraulic properties and

417 soil water balance (Figures 9a and 9b). $\gamma_{LH}$ displays high values in the eastern US and low values

418 in the western US (Figure 9c). It is primarily contributed by the information loss of vegetation

419 properties such as LAI and canopy height, and mean LAI, which influences the partitioning of LH

420 and sensible heat, and the partitioning of transpiration and evaporation (Figure 9d). $\gamma_{ELR}$ exhibits

421 high values in the central and eastern US, particularly in the northeastern US, while $\gamma_{ASR}$ has high

422 values almost all over the US, especially in the eastern regions (Figures 9e and 9g). $\gamma_{ELR}$ and $\gamma_{ASR}$

423 are largely driven by vegetation properties such as LAI and canopy height, which are associated

424    with energy processes such as albedo (Figures 9f and 9h). Additionally, topography factors of

425    standard deviation of elevation and slope also slightly contribute to $\gamma_{ASR}$.

426
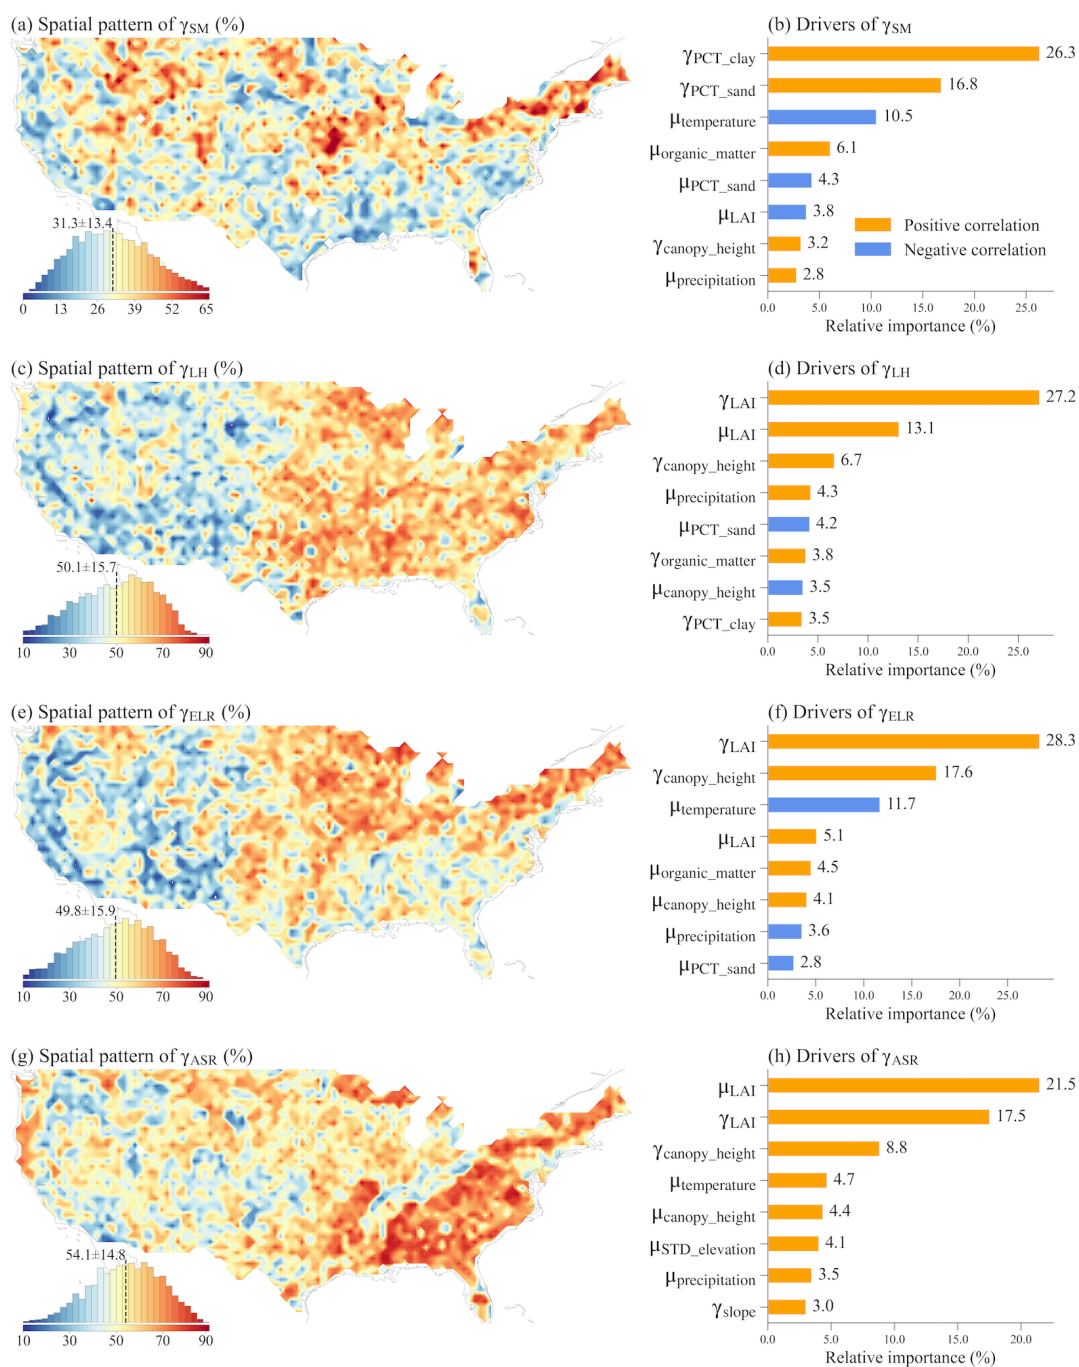

Figure 9. Same as Figure 8 but for information loss.

428 **4. Discussion**

429 The new 1 km land surface parameter datasets developed in this study represent significant

430 improvements over the current datasets. Compared to the two common land surface parameter

431 datasets of CLM5 and K2012, our data are more advanced by utilizing the newest high-resolution

432 data sources, including MODIS PFTs and non-vegetation land units, LAI and SAI, canopy height,

433 soil properties and topography factors. The availability of multi-year data for LULC, LAI, and SAI

434 parameters is advantageous for studies such as LULC changes, including urbanization,

435 deforestation, and agricultural impacts. Incorporating these new 1 km land surface parameters into

436 ESMs will advance the accurate representation and understanding of land surface processes and

437 land–atmosphere interactions. However, certain limitations and opportunities for future

438 development should be noted. The urban extension may differ depending on the data sources,

439 urban definitions, and the algorithms employed, such as those derived from harmonized nighttime

440 lights (Zhao et al., 2022), global artificial impervious area (GAIA, Li et al., 2020b; Gong et al.,

441 2020), urban expansion (Liu et al., 2020; Kuang et al., 2021), which may differ from our urban

442 land units based on MODIS. The urban classification into TBD, HD, and MD in J2010 is based

443 on the global building height. Although there are building height datasets available for specific

444 regions, such as Europe, the US, and China (Yang and Zhao, 2022; Li et al., 2020a; Frantz et al.,

445 2021; Cao and Huang, 2021) , a globally consistent building height dataset is currently not publicly

446 accessible, which hinders the future improvement of urban classification. The multiple-year high-

447 resolution PFT maps developed by the European Space Agency's Climate Change Initiative could

448 be used to further extend this dataset for a longer period (Harper et al., 2023).

449

450  The new 1 km land surface parameters can improve k-scale offline LSMs modeling by better

451  capturing spatial surface heterogeneity. As evidenced by the 1 km ELM simulation over CONUS,

452  soil properties, vegetation properties, and topographic factors contribute to the spatial

453  heterogeneities of ELM water and energy simulations. Upscaling 1 km to a coarser 12 km

454  resolution, we observe significant spatial information loss, with SM experiencing an average loss

455  of 31%, and LH, ELR, and ASR experiencing around 50% information loss on average. This

456  conclusion is in line with the results of Vergopolan et al. (2022), which showed a substantial loss

457  of spatial information in soil moisture when upscaling from 30 m to 1 km resolution, with an

458  average loss of approximately 48% and up to 80% over the CONUS region. The XML analysis

459  reveals that the spatial variability and information loss of ELM2 simulations are influenced by the

460  spatial variability and information loss of the different variables of land surface parameters, as well

461  as the mean precipitation and temperature. Our findings highlight the critical role of land surface

462  parameters in contributing to the spatial variability of water and energy in land surface simulations,

463  showcasing the value of the developed high-resolution datasets. Another implementation example

464  where our 1 km land surface parameters can be beneficial is in hillslope-scale simulations, which

465  are fundamental for organizing water, energy, and biogeochemical processes (Fan et al., 2019).

466  Krakauer et al. (2014) have highlighted the significance of between-cell groundwater flow, which

467  becomes comparable in magnitude to recharge at grid spacings smaller than 10 km. Advancements

468  have been made in ESMs to address hillslope-scale processes, including the representation of intra-

469  hillslope lateral subsurface flow within grid cells in CLM5 (Swenson et al., 2019), the development

470  of explicit lateral flow processes between grid cells (Qiu et al., 2023), and the incorporation of

471  topographic radiation effects within and between grid cells (Hao et al., 2021). Another notable

472  example is the integrated hydrology-land surface model ParFlow-CLM, which incorporates three-

473    dimensional groundwater flow, two-dimensional overland flow, and land surface exchange

474    processes (Maxwell, 2013). ParFlow-CLM has demonstrated remarkable reliability in reproducing

475    hydrologic processes, such as its simulations at 3 km resolution for pan-European and 1 km

476    resolution for CONUS (Naz et al., 2023; O'Neill et al., 2021). More recently, Fang et al. (2022)

477    coupled ParFlow with ELM and the Functionally Assembled Terrestrial Ecosystem Simulator

478    (FATES) to simulate carbon-hydrology interactions at hillslope scale. By incorporating our 1 km

479    datasets and leveraging these advancements, we can improve simulations of hillslope-scale

480    processes and enhance our understanding of water and energy dynamics within ESMs.

481

482    The new land surface parameters are also a timely resource for supporting the emerging need for

483    k-scale Earth system modeling. Representing the impact of spatial heterogeneity on land-

484    atmosphere interaction processes is a major challenge in Earth system modeling. Taking E3SM as

485    an example, researchers have proposed three key approaches to enhance spatial heterogeneity

486    representation to address this challenge. In line with these approaches, our newly developed 1 km

487    land surface parameters offer promising opportunities for improving land-atmosphere coupling

488    within ESMs. The first approach to enhance the representation of spatial heterogeneity is to

489    directly conduct simulations at high resolution. For instance, the Simple Cloud-Resolving E3SM

490    Atmosphere Model (SCREAM) has been used to perform global simulations at 3.25 km (Caldwell

491    et al., 2021), although the land surface parameters were based on coarser resolution datasets. By

492    utilizing the new 1 km land surface parameters, we can enhance the representation of land surface

493    heterogeneity within the ELM component of SCREAM, potentially improving modeling of land–

494    atmosphere coupling. The second and third approaches focus on improving the representation of

495    land surface heterogeneity within ESMs run at a coarse resolution while accounting for subgrid

496    heterogeneity in two different ways. In the second approach, the Cloud Layers Unified By

497    Binormals (CLUBB) has been implemented in E3SM Atmosphere Model (EAM) version 1 (Rasch

498    et al., 2019; Bogenschutz et al., 2013), to better account for subgrid atmospheric heterogeneity of

499    turbulent mixing, shallow convection, and cloud macrophysics. Recently, Huang et al. (2022)

500    developed a novel land-atmosphere coupling scheme in EAM that enables the communication of

501    subgrid land surface heterogeneity information to the atmosphere model with CLUBB,

502    significantly impacting boundary layer dynamics. The new 1km datasets can provide more

503    accurate land surface representations of the variability of individual patches and the inter-patch

504    variability that were used in Huang et al. (2022). The third approach is the Multiple Atmosphere

505    Multiple Land (MAML) approach used in the multiscale modeling framework (MMF) in which a

506    cloud resolving model (CRM) is embedded within each grid cell of the atmosphere (Baker et al.,

507    2019; Lin et al., 2023; Lee et al., 2023). In the MAML approach, each CRM column within the

508    atmosphere grid is coupled directly with its own independent land surface. This enables a more

509    explicit representation of the impact of spatial heterogeneity on land-atmosphere interactions

510    within each grid and has shown notable impacts on water and energy simulations (Baker et al.,

511    2019; Lin et al., 2023). Lee et al. (2023) highlighted the limitation of the current MAML approach,

512    which utilizes the same land surface characteristics for each land surface model interacting with

513    the CRM column within the same grid, which could lead to a weak representation of land-

514    atmosphere interactions. To address this limitation, incorporating the new 1 km land surface

515    parameters within the MAML approach can provide more detailed information about land surface

516    heterogeneity, enabling a more accurate capture of land-atmosphere interactions.

Earth System
Open Access Science
Data Discussions

517   **5. Data availability**

518   The 1 km land surface parameters are publicly available at

519   https://doi.org/10.25584/PNNLDH/1986308 (Li et al., 2023).

520

521   **6. Conclusion**

522   We developed 1 km global land surface parameters using the latest available datasets covering

523   multiple years from 2001 to 2020. These parameters comprise four categories: LULC of PFTs and

524   non-vegetative land cover, vegetation properties, soil properties, and topographic factors. The 1

525   km resolution ELM simulations conducted over CONUS demonstrate the valuable capabilities of

526   the new datasets in enabling k-scale land surface modeling. Through scaling analysis of the 1 km

527   resolution simulations within 0.5º × 0.5º boxes where spatial heterogeneity of the simulations is

528   induced only by spatial heterogeneity of the land surface parameters, we revealed the significant

529   impact of land surface parameters on the spatial variability of water and energy simulations. The

530   spatial information loss of these simulations over CONUS is significant when upscaling from 1

531   km to a coarser 12 km resolution, with an average ranging from 31% to 54% and up to more than

532   90%. The XML analysis reveals that the spatial variability and spatial information loss of ELM2

533   simulations are primarily impacted by the spatial variability and information loss of soil properties,

534   vegetation properties and topography factors, as well as the mean climate conditions of

535   precipitation and temperature. Furthermore, the spatial variability of water and energy in the 1 km

536   simulations is not dominated by the spatial heterogeneity of any land surface parameters,

537   suggesting the usefulness of the multi-parameter high-resolution land surface parameter dataset.

538   The availability of 1 km land surface parameters is a valuable resource that addresses the emerging

539   needs of k-scale LSMs and ESMs modeling. By providing accurate and precise information, these

540     1 km land surface parameters will significantly enhance our understanding of the water, carbon,

541     and energy cycles under global change.
