22 **Abstract.** The oceanic emission of dimethyl sulfide (DMS) plays a vital role in the Earth's climate system and is a significant  
23 source of uncertainty in aerosol radiative forcing. Currently, the widely used monthly climatology of sea surface DMS  
24 concentration cannot meet the requirement for accurately simulating DMS-derived aerosols by chemical transport models.  
25 Thus, there is an urgent need to construct a global sea surface DMS dataset with high time resolution spanning multiple years.  
26 Here we develop an artificial neural network ensemble model based on 9 environmental factors, which demonstrate high  
27 accuracy and generalization in predicting DMS concentrations. Subsequently, a global sea surface DMS concentration and  
28 flux dataset ( $1^\circ \times 1^\circ$ ) with daily resolution covering the period from 1998 to 2017 is established. According to this dataset, the  
29 global annual average concentration was  $\sim 1.82$  nM, and the annual total emission was  $\sim 17.9$  TgS yr<sup>-1</sup>, with  $\sim 60\%$  originating  
30 from the southern hemisphere. While overall seasonal variations are consistent with previous DMS climatologies, notable  
31 differences exist in regional-scale spatial distributions. The new dataset enables further investigation of daily and decadal  
32 variations. During 1998–2017, the global annual average concentration exhibited a slight decrease, while total emissions  
33 showed no significant trend. Benefiting from the incorporation of daily and interannual variation information, the DMS flux  
34 from our dataset showed a much stronger correlation with observed atmospheric methanesulfonic acid concentration compared  
35 to those from previous monthly climatologies. As a result, it can serve as an improved emission inventory of oceanic DMS

36 and has the potential to enhance the simulation of DMS-derived aerosols and associated radiative effects. The new DMS  
37 gridded products are available at <https://zenodo.org/record/10279659> (Zhou et al., 2023).

## 38 **1 Introduction**

39 Dimethyl sulfide (DMS) mostly produced by ocean biota accounts for more than half of natural sulfur emissions and  
40 contributes substantially to sulfur dioxide in the troposphere (Sheng et al., 2015; Andreae, 1990) which can be oxidized to  
41 sulfuric acid and form sulfate aerosols (Barnes et al., 2006; Hoffmann et al., 2016). Sulfate aerosols play an important role in  
42 climate systems by both scattering solar radiation and altering cloud condensation nuclei (CCN) and albedo (Masson-Delmotte  
43 et al., 2021). Recent studies have proven that CCN over remote oceans and polar regions are primarily composed of non-sea-  
44 salt sulfate ( $\text{nss-SO}_4^{2-}$ ) (Quinn et al., 2017; Park et al., 2021). Given 70% coverage of the Earth's surface by the ocean and the  
45 weak influence of anthropogenic  $\text{SO}_2$  over open oceans, marine biogenic DMS can be the most important source of  $\text{nss-SO}_4^{2-}$   
46 and regulates regional and global climate (McCoy et al., 2015). Accordingly, DMS has been suggested to be the key substance  
47 in the postulated feedback of marine phytoplankton to climate warming (the "CLAW" hypothesis) (Charlson et al., 1987).  
48 However, there are still many controversies surrounding the CLAW hypothesis (Quinn and Bates, 2011). To address these  
49 controversies, we need to accurately simulate the global climate effects of DMS-derived aerosols. This requires further  
50 exploration of complex atmospheric chemistry and climate processes (Hoffmann et al., 2016; Novak et al., 2021), as well as  
51 high-fidelity and high-resolution sea surface DMS concentrations and emission fluxes as emission inventories. According to  
52 the uncertainty estimation by Carslaw et al. (2013), the uncertainty in DMS emission flux is the second largest contributor to  
53 the overall uncertainty in the radiative forcing of natural aerosols. Therefore, improving the understanding of the  
54 spatiotemporal variations of DMS in global oceans is currently an important task.

55 There are complex production and consumption mechanisms of DMS in the upper ocean, which makes it difficult to well  
56 capture the dynamics and distributions of sea surface DMS across different oceanic regions. Dimethylsulfoniopropionate  
57 (DMSP), the major precursor of DMS, is synthesized mainly by phytoplankton in the photic zone and plays a variety of  
58 physiological functions in algal cells (Stefels, 2000; Sunda et al., 2002; McParland and Levine, 2018). The DMSP yield differs  
59 dramatically among algal species (Stefels et al., 2007; Keller et al., 1989), and DMS can be produced through DMSP  
60 intracellular and extracellular cleavage by both algae and bacteria (Alcolombri et al., 2015; Zhang et al., 2019). Therefore, the  
61 oceanic DMS produced via multiple pathways can be affected by many biotic and abiotic factors, including temperature,  
62 salinity, solar radiation, mixed layer depth, nutrients, oxygen, acidity, etc. (Simó and Pedrós-Alió, 1999b; Vallina and Simó,  
63 2007; Stefels, 2000; Zindler et al., 2014; Six et al., 2013; Omori et al., 2015; Stefels et al., 2007). In addition, seawater DMS  
64 has multiple removal pathways (bacterial consumption, photodegradation, sea-to-air ventilation, etc.), further complicating the  
65 DMS cycling (Stefels et al., 2007). Therefore, although previous studies have developed several empirical algorithms (Simó  
66 and Dachs, 2002; Belviso et al., 2004b; Vallina and Simó, 2007) and process-embedded prognostic models (Kloster et al.,

67 2006; Vogt et al., 2010; Belviso et al., 2011; Wang et al., 2015) based on relevant variables (mixed layer depth, chlorophyll *a*,  
68 nutrients, radiation, phytoplankton group, etc.) to estimate the distribution of DMS, their results showed significantly different  
69 distribution patterns and obvious inconsistency with observations in many regions (Tesdal et al., 2016; Belviso et al., 2004a).  
70 Recently, Galí et al. (2018) developed a new empirical algorithm following a parameterization of DMSP (Galí et al., 2015).  
71 The estimated DMS field exhibited a generally higher consistency with observations than those derived from the previous two  
72 algorithms SD02 (Simó and Dachs, 2002) and VS07 (Vallina and Simó, 2007), but this method did not consider the influences  
73 of nutrients and there are still great biases in certain regions (e.g., near the Antarctic).

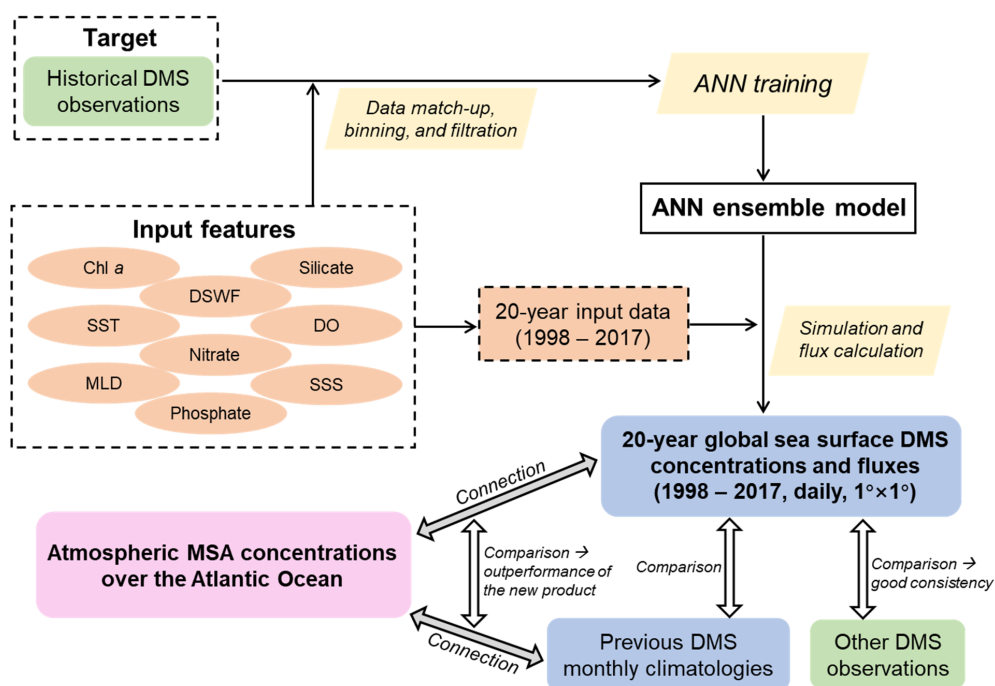

74 Since Lovelock et al. (1972) first discovered the ubiquitous presence of DMS in seawater, numerous observations of sea  
75 surface DMS have been conducted worldwide, accumulating a large amount of observational data to date. Based on these  
76 worldwide measurements, monthly climatology of global DMS can be generated through interpolation and extrapolation  
77 (Hulswar et al., 2022; Kettle et al., 1999; Lana et al., 2011). The latest version incorporated 873,539 raw observations (48,898  
78 after data filtration and unification for climatology development), and the estimated global annual mean concentration and  
79 total flux are 2.26 nM and 27.1 TgS yr<sup>-1</sup>, respectively (Hulswar et al., 2022). However, despite the large data volume, there  
80 are still considerable spatial and temporal disparities, which may lead to large uncertainties for the regions or periods with  
81 sparse observations. In addition, the observational data from different years were equally combined and the interannual  
82 variations cannot be addressed by this approach.

83 In recent years, the application of data-driven approaches like machine learning to Earth system science has drawn more and  
84 more attention. Compared with traditional approaches and process models, machine learning explores larger function space  
85 and captures more hidden information from the big data, hence it often provides a better simulation and prediction performance  
86 (Reichstein et al., 2019; Zheng et al., 2020; Bergen et al., 2019). A recent study has demonstrated that artificial neural network  
87 (ANN) can capture much more (~66%) of the raw data variance than multilinear regression (~39%), and a global monthly  
88 climatology of DMS has been developed based on ANN (Wang et al., 2020). The machine learning techniques have also been  
89 used to simulate the distribution of DMS in the Arctic (Galí et al., 2021), North Atlantic Ocean (Bell et al., 2021; Mansour et  
90 al., 2023), and East Asia (Zhao et al., 2022).

91 However, to our best knowledge, there is no global-scale sea surface gridded DMS dataset with both high time resolution  
92 (daily) and long-term coverage (> 10 years), which is urgently needed for modeling the atmospheric processes and climatic  
93 implications of oceanic DMS. Since the sea surface concentration and sea-to-air emission flux of DMS can vary greatly from  
94 day to day (Simó and Pedrós-Alió, 1999a) and the emitted DMS makes effects on the atmosphere in a time scale of several  
95 hours to days, just using monthly climatology of DMS as the emission inventory cannot capture the details and may lead to  
96 large modeling biases compared with observed concentrations of atmospheric DMS or its oxidation products (Chen et al., 2018;  
97 Fung et al., 2022).

98 Here, we build a 20-year (1998 – 2017) global sea surface DMS gridded dataset ( $1^\circ \times 1^\circ$ ) with a daily resolution based on a  
 99 data-driven machine learning approach (ANN ensemble). This product can improve our understanding of the spatiotemporal  
 100 variations of oceanic DMS. More importantly, it can serve as an updated emission inventory of marine biogenic DMS for  
 101 chemical transport models, which is very beneficial for improving the simulation of atmospheric processes of DMS and lower  
 102 down the uncertainties in marine aerosol's climate effects. The paper consists of the following main parts which are  
 103 demonstrated in Fig. 1: (1) the development of the machine learning model based on global DMS measurements and 9 ancillary  
 104 environmental variables; (2) the derived spatial and temporal distributions of DMS and comparisons with previous estimates;  
 105 (3) an example showing the superiority of our newly developed DMS field in linking atmospheric biogenic sulfur; and (4) the  
 106 uncertainties and limitations of our approach and the resulting data product.

107  
 108 **Figure 1.** Flowchart of this study, including the construction of the new DMS gridded dataset and subsequent analyses of the  
 109 validity and superiority of this product.

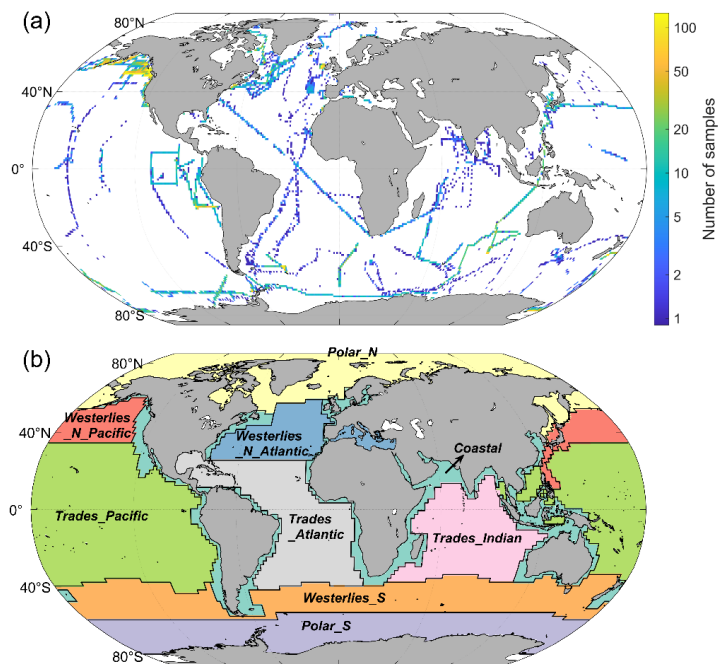

## 110 2 Methodology

### 111 2.1 Input datasets

112 The in-situ DMS measurement data used for training the machine learning model was obtained from the Global Surface  
113 Seawater DMS (GSSD) database (Kettle et al., 1999). The GSSD database contains a total of 87,801 DMS measurements  
114 obtained from 266 cruises and fixed-site observation campaigns from 11 March 1972 to 27 August 2017  
115 (<https://saga.pmel.noaa.gov/dms/>, last access: 1 April 2020). The spatial distribution of these in-situ observational data is  
116 shown in Fig. S1, which covers all major regions of the global ocean.

117 We selected 9 environmental variables related to DMS biogeochemical processes as input features, including chlorophyll *a*  
118 (Chl *a*), sea surface temperature (SST), mixed layer depth (MLD), nitrate, phosphate, silicate, dissolved oxygen (DO),  
119 downward short-wave radiation flux (DSWF), and sea surface salinity (SSS). The data sources and relevant information of 9  
120 input variables and DMS are listed in Table 1. Chl *a* was obtained from both in-situ observations accompanied by DMS data  
121 and satellite remote sensing products (SeaWiFS and Aqua-MODIS,  $0.083^{\circ} \times 0.083^{\circ}$ ). Daily SST data ( $0.25^{\circ} \times 0.25^{\circ}$ ) was from  
122 the NOAA OI SST V2 high-resolution blended reanalysis dataset (Huang et al., 2021). Daily MLD, DSWF, and SSS were  
123 from the modeling outputs of NASA's "Estimating the Circulation and Climate of the Ocean" (ECCO) consortium, Version 4  
124 Release 4 (V4r4) (Forget et al., 2015). The LLC90 (Lat-Lon-Cap 90) grid is a native grid used for ECCO data, which has 5  
125 faces containing 13 regional tiles covering the global ocean, with spatial resolution varying from 22 km to 110 km (Forget et  
126 al., 2015). As for the concentrations of nitrate, phosphate, silicate, and DO, the monthly climatologies ( $1^{\circ} \times 1^{\circ}$ ) of World Ocean  
127 Atlas 2018 (WOA18) based on the historical observational data from the World Ocean Database (WOD) were used (Garcia et  
128 al., 2019b, a). The surface wind speed (WS) and sea ice fraction (SI) data are also needed in the calculation of sea-to-air flux.  
129 Here we utilized the daily 10-meter WS data from ECCO V4r4 and the daily SI data from NOAA OI SST V2. Since there are  
130 multiple different spatial grids and temporal resolutions among all datasets, the data match-up has been conducted as described  
131 in the next section.

132  
133 **Figure 2.** (a) The distribution of 34,118 DMS observational data after matchup, filtration, and binning for constructing the  
134 ANN model. The grid size is  $1^\circ \times 1^\circ$ . (b) Nine oceanic regions separated based on Longhurst's biomes (Longhurst, 1998).

138

139 **2.2 Data preprocessing for model development**

140 The data extraction and match-up were performed according to the sampling location and time in the GSSD database, as well  
141 as the time range and grid distribution of each variable. For satellite-retrieved Chl *a* concentration, the data of the grids covering

142 DMS sampling points were extracted and matched. If one grid data is missing, the average value of the 5×5 grids nearby will  
143 be extracted. The SeaWiFS and Aqua-MODIS data during their overlapping periods were averaged. For other variables, only  
144 values in the grids matching the DMS sampling locations were extracted.

145 There are in-situ Chl *a* measurements accompanied by some of the GSSD data, which were used along with satellite-retrieved  
146 Chl *a*. The in-situ Chl *a* have many low-precision values (defined as  $< 0.1 \text{ mg m}^{-3}$ , and the number of significant digits is 1),  
147 and we removed those values. For a certain in-situ observation campaign, if the number of low-precision values is larger than  
148 10 and accounts for more than half, all in-situ Chl *a* data from this campaign will be removed. In addition, the in-situ Chl *a*  
149 data in the GSSD database are measured by two different methods, i.e., Turner fluorometry and high-performance liquid  
150 chromatography (HPLC). In order to improve mutual consistency, a conversion between the data from these two methods was  
151 applied and then the in-situ Chl *a* concentrations were adjusted to match up with satellite Chl *a* following the functions  
152 described in Galí et al. (2015). After that, the statistical outliers for all  $\log_{10}(\text{Chl } a)$  (outside the range of average  $\pm 3$  standard  
153 deviations) were eliminated. The  $\log_{10}$  transformation was applied to make the data distribution close to normal distribution.  
154 When finally selecting the  $\log_{10}(\text{Chl } a)$  corresponding to each DMS data, the precedence order of the various datasets is as  
155 follows: in-situ data, daily satellite data, 8-day averaged satellite data, and monthly averaged satellite data. The comparison  
156 between in-situ and different satellite-retrieved Chl *a* data is shown in Fig. S2. There is a good consistency between in-situ  
157 and daily satellite Chl *a* data ( $R^2 > 0.5$ , RMSE  $< 0.4$ ), indicating it is rational to combine the in-situ and satellite Chl *a* data  
158 together.

159 DMS and extracted MLD and three nutrients (nitrate, phosphate, silicate) were also performed  $\log_{10}$  transformation. Together  
160 with SST, DO, DSWF, and SSS, their statistical outliers were excluded as mentioned above. After data filtration, a total of  
161 54,191 DMS measurements can be matched by all variables. To avoid multi-data points gathering in a certain time (the same  
162 day) and a small region ( $< 0.05^\circ \times 0.05^\circ$ ), these data points were averaged, and finally the number of binned samples used for  
163 model development is 34,118. The spatial distribution of these binned samples is shown in Fig. 2a.

### 164 2.3 Artificial neural network training and validation

165 The 34,118 binned samples after the previously mentioned data preprocessing were used to develop the artificial neural  
166 network (ANN) model. The target feature is  $\log_{10}(\text{DMS})$ , and the input features are  $\log_{10}(\text{Chl } a)$ , SST,  $\log_{10}(\text{MLD})$ ,  
167  $\log_{10}(\text{nitrate})$ ,  $\log_{10}(\text{phosphate})$ ,  $\log_{10}(\text{silicate})$ , DO, DSWF, and SSS. The data of all variables were standardized before  
168 training. We randomly selected 5% of the samples ( $n = 1706$ ) to be entirely excluded from training, as a subset for global  
169 validation and overfitting test. Then, the remaining samples ( $n = 32,412$ ) were randomly split into three parts, that is, 70% for  
170 training, 15% for validation, and 15% for testing. Our feed-forward back-propagation (BP) neural network contains one hidden  
171 layer with 20 nodes, and the training algorithm is the Levenberg-Marquardt algorithm. Rooted mean squared error (RMSE) is  
172 chosen as the indicator for performance evaluation during training, and the upper limit of the number of iterations in each

173 training session is 1000. The training processes were carried out with Neural Network Toolbox on Matlab R2014b. We have  
174 trained the ANN 100 times and each training session started independently with a new random partition of those 32,411  
175 samples. The average output of 100 trained ANNs showed an obviously higher consistency with the target than individual  
176 ANN. But as the number of training sessions ( $N_{\text{training}}$ ) is larger than 80, the simulation performance tends to be stable (Fig.  
177 S3). Therefore, we used the average of 100 ANN outputs as our final model output. This kind of multiple-training approach is  
178 also called “ANN ensemble” or “Monte Carlo cross-validation”, which has been widely used to improve the model  
179 generalization and performance (Sigmund et al., 2020; Holder et al., 2022) as well as get a better model evaluation (Dubitzky  
180 et al., 2007).

181 To evaluate whether there is a spatial preference for DMS simulation, the comparisons of simulated and observed DMS  
182 concentrations in different types of oceanic regions were conducted. We divided the global ocean into 9 regions based on  
183 Longhurst’s biomes (Longhurst, 1998). There are 6 biomes in Longhurst’s definition, including Coastal, Polar\_N, Polar\_S,  
184 Westerlies\_N, Westerlies\_S, and Trades (the .shp file of Longhurst’s biomes and provinces was downloaded from  
185 <https://www.marineregions.org/downloads.php#longhurst>). We further divided Westerlies\_N into Westerlies\_N\_Pacific and  
186 Westerlies\_N\_Atlantic, and divided Trades into Trades\_Pacific, Trades\_Indian, and Trades\_Atlantic by different basins as  
187 shown in Fig. 2b.

## 188 2.4 Deriving the 20-year global DMS distributions

### 189 2.4.1 Simulation of sea surface DMS concentrations

190 First, we constructed the daily gridded dataset of input variables with a spatial resolution of  $1^\circ \times 1^\circ$  from 1998 to 2017 using  
191 the data sources listed in Table 1 (except in-situ Chl *a* data). For those datasets with a higher spatial resolution than  $1^\circ \times 1^\circ$ ,  
192 values in each  $1^\circ \times 1^\circ$  grid were averaged. As for satellite Chl *a* data, the priority level was the same as mentioned in Section  
193 2.2, and SeaWiFS and Aqua-MODIS datasets were combined. As for nutrients and DO, only monthly climatologies were  
194 provided in WOA18 and the same value was used for all the days of each month. Hence, these variables lack information on  
195 inter-annual and day-to-day variations, but the spatial and monthly variations are well captured. The potential uncertainties in  
196 predicted DMS fields associated with this issue are discussed in Section 4. Then, the obtained gridded dataset was fed into the  
197 ANN ensemble model, and the 20-year global distribution of sea surface DMS concentration with the daily resolution was  
198 simulated.

### 199 2.4.2 Calculation of sea-to-air fluxes

200 The sea-to-air fluxes of DMS were calculated on the basis of simulated surface DMS concentrations following equation (1):

$$201 \quad DMS \text{ flux} = Kt \times \left( DMS_w - \frac{DMS_a}{H} \right) \quad (1)$$

202 Here  $DMS_w$  and  $DMS_a$  are DMS concentrations in surface seawater and air, respectively.  $H$  is Henry's law constant of DMS.

203 Since  $\frac{DMS_a}{H}$  is usually  $\ll DMS_w$ , this term was omitted in the calculation.  $Kt$  is the total transfer velocity considering the sea

204 ice coverage fraction ( $SI$ ):

$$205 \quad Kt = k_t \times (1 - SI) \quad (2)$$

206  $k_t$  is the total transfer velocity without considering sea ice which is calculated by equation (3):

$$207 \quad \frac{1}{k_t} = \frac{1}{k_w} + \frac{1}{k_a \times H} \quad (3)$$

208 Here  $k_w$  and  $k_a$  are the water-side transfer velocity and air-side transfer velocity, respectively. We used the same approach as

209 Galí et al. (2019) to obtain  $k_w$ ,  $k_a$ , and  $H$  for DMS, where the effect of wind speed was considered for  $k_a$ , and the influences of

210 SST and SSS were considered for  $H$ . The calculations of  $k_a$  and  $H$  followed the parameterizations put forward by Johnson

211 (2010). As for  $k_w$  calculation, we adopted the bubble scheme (Woolf, 1997), which divided the sea-to-air mass transfer process

212 into turbulence- and bubble-mediated gas exchange. The calculated  $k_w$  based on the bubble scheme is lower than that of

213 Nightingale's scheme (Nightingale et al., 2000) under the condition of high wind speed and has a smaller deviation from the

214 actual value (Beale et al., 2014; Galí et al., 2019). Before calculation, WS and SI data were also binned by  $1^\circ \times 1^\circ$  grid. By

215 using WS and SI together with SST and SSS datasets, we obtained the daily gridded  $Kt$  and then calculated the sea-to-air DMS

216 fluxes (daily, 1998–2017) by multiplying simulated DMS concentrations by  $Kt$  values.

## 217 3 Results

### 218 3.1 Model performance

219 As shown in Fig. 3a, the newly-developed ANN ensemble model captures a substantial part of data variance globally ( $\log_{10}$

220 space  $R^2 = 0.624$  and  $RMSE = 0.267$ ). 92.3% of ANN simulated concentration values fall within 1/3 to 3 times of corresponding

221 true values. The simulation performance for 5% of the dataset not used in training ( $R^2 = 0.604$ ,  $RMSE = 0.274$ , and 91.6% of

222 data within the range of 1/3 to 3 times of observations) is very close to that for the training dataset (Fig. 3b), suggesting no

223 obvious overfitting. The ANN model exhibits much better performance compared to previous empirical and process-based

224 models ( $R^2 = 0.01\text{--}0.14$ ) (Tesdal et al., 2016) as well as the satellite-based algorithm ( $R^2 = 0.50$ ) (Galí et al., 2018). The ANN

225 model developed by Wang et al. (2020) showed a slightly higher performance ( $R^2 = 0.66$ ,  $RMSE = 0.264$  for training dataset)

226 than our model, likely due to their more complex ANN configuration (two hidden layers with 128 nodes each) and the including

227 of sample location and time into input features. However, the more complex model will significantly increase the

228 computational cost, and the incorporation of location and time information may weaken the physical interpretability. On the

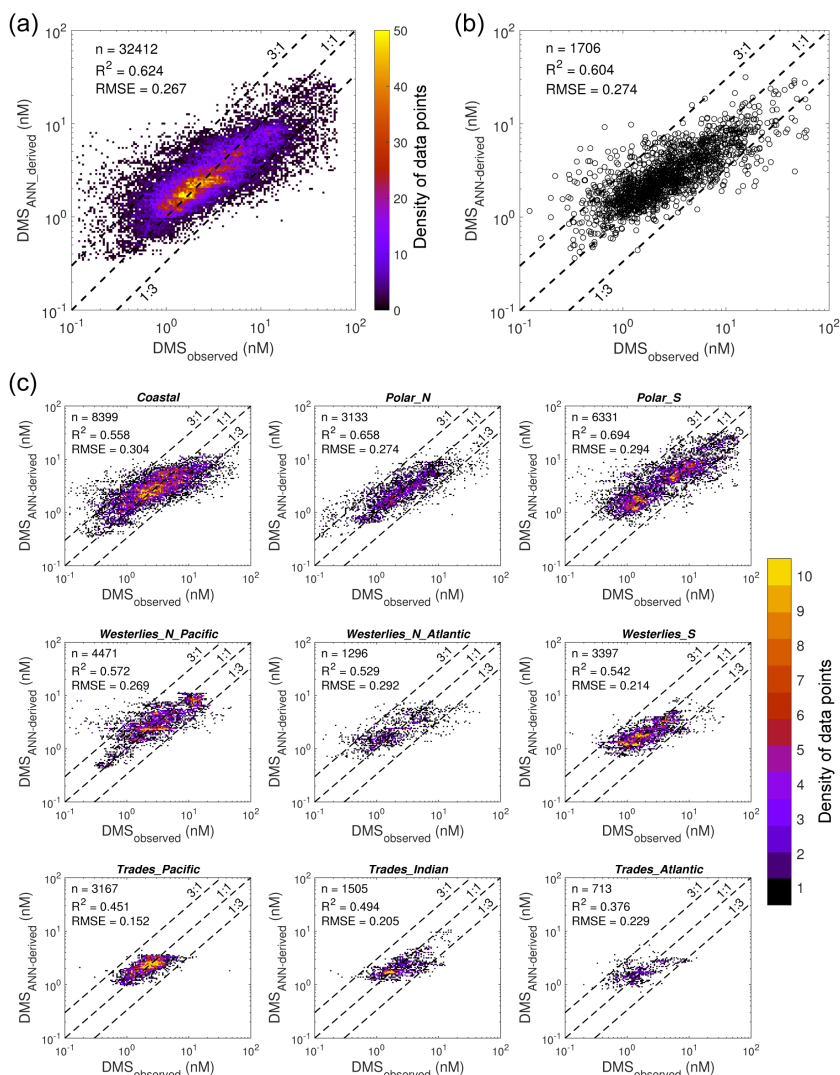

229 other hand, the performance improvement is very limited. Therefore, we keep the simpler model configuration. It should be

230 noted the ANN model may not reproduce the extreme DMS concentrations ( $> 20$  nM or  $< 0.2$  nM) well, but the fraction of

231 these values is less than 3% and has little impact on the overall performance.

232 Our ANN model also shows good performance in each of the 9 separated oceanic regions without harmful spatial preference.  
233 As illustrated in Fig. 3c, the  $\log_{10}$  space RMSEs are all below 0.3 except for the Coastal region (RMSE = 0.304). The percentage  
234 of simulated values within the 1:3 and 3:1 lines ranges from 88.7% to 99.4%. Although the  $R^2$  values in 3 Trades regions are  
235 lower than 0.5, which is related to the relatively small variation range of the DMS, the RMSEs in these regions are quite low  
236 and not inferior to those of other regions.

237

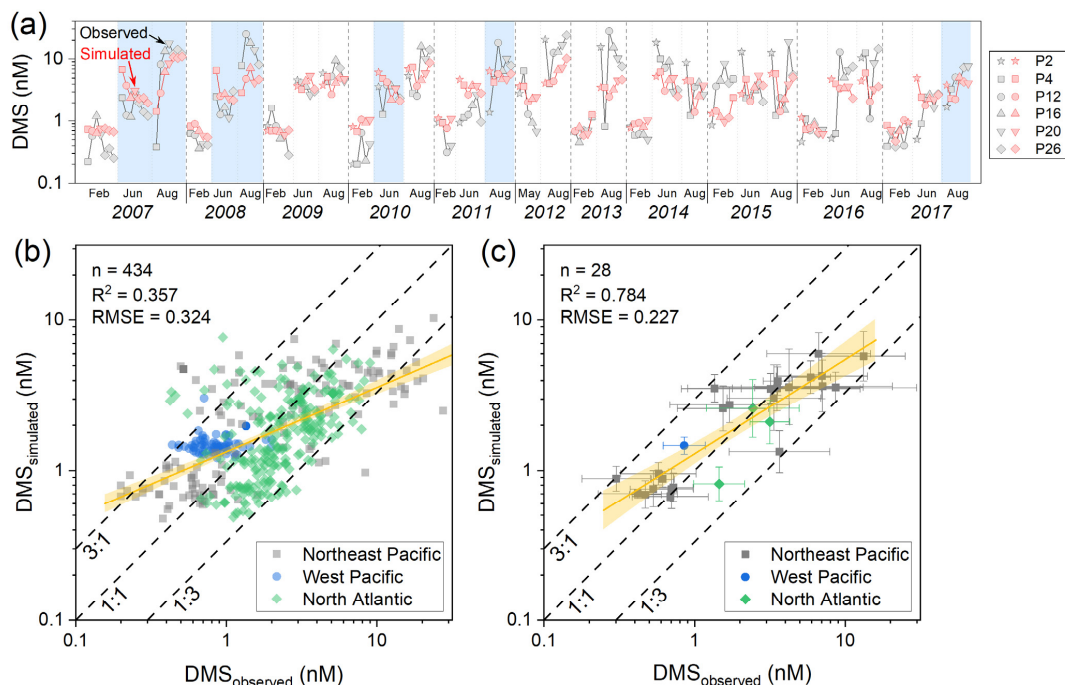

238 **Figure 3.** Comparisons between ANN-simulated and observed DMS concentrations in the GSSD database. (a) Scatter density  
 239 for all simulated versus observed DMS concentration data used in ANN training. (b) Comparison between the simulation  
 240 results and the 5% of GSSD observational data not used for training. (c) Scatter density for simulated versus observed DMS  
 241 concentration data in each of the 9 regions. The number of data ( $n$ ), the  $\log_{10}$  space  $R^2$  and the root mean squared error (RMSE)  
 242 are also displayed.

243

244 It is worth noting that there may be intrinsic connections between the 5% excluded DMS subset and trained dataset both from  
245 the GSSD database, because the data from the same cruise or fixed-site campaign have certain continuity. To further evaluate  
246 the reliability of the ANN model, we compared the simulated DMS concentrations with the observational data not archived in  
247 the GSSD database, which are obtained from 35 cruises in Northeast Pacific, West Pacific, and North Atlantic (number of data  
248 = 6,478). These data include (1) off-line sampling and measurement data of 31 cruises of *Line P Program* in Northeast Pacific  
249 (Steiner et al., 2011) (9 February 2007 – 26 August 2017, number of data = 177,  
250 <https://www.waterproperties.ca/linep/index.php>, last access: 23 November 2020), (2) underway measurements during *SONNE*  
251 *cruise 202/2 (TRANSBROM)* in West Pacific (Zindler et al., 2013) (9 – 23 October 2009, number of data = 115,  
252 <https://doi.org/10.1594/PANGAEA.805613>, last access: 23 November 2020), (3) underway measurements during 3 cruises of  
253 the *North Atlantic Aerosols and Marine Ecosystems Study (NAAMES)* (Behrenfeld et al., 2019; Bell et al., 2021) (11 – 30  
254 November 2015, 14 May – 4 June 2016, 6 – 24 September 2017, number of data = 6,186, <https://seabass.gsfc.nasa.gov/naames>,  
255 last access: 27 November, 2020). Before the comparison, the data measured within a  $1^{\circ} \times 1^{\circ}$  grid and at the same day were  
256 binned by arithmetic average.

257 The comparisons between these observed DMS concentrations and ANN simulation are shown in Fig. 4. As for the *Line P*  
258 *Program*, it should be noted that there are 7 cruises included in the GSSD database, but those data were obtained by underway  
259 measurements, different from the off-line data used here. Hence, these cruises were retained and marked in Fig. 4a but  
260 eliminated in subsequent statistical analysis (Fig. 4b-c). It can be seen that the simulation well captures the seasonal variation,  
261 which is generally August > June > February. In addition, the simulation can also partially reproduce the changes between  
262 different stations, though the performance is not as good as the overall comparison between different cruises. As for underway  
263 measurements, although a certain degree of overestimation in the West Pacific and underestimation in North Atlantic was  
264 observed, most of the simulated values (88.4%) are within the range of 1/3 to 3 times of observations. If all of the above data  
265 are binned by each cruise, the simulations will demonstrate high consistency with observations as shown in Fig. 4c ( $R^2 = 0.784$ ,  
266 RMSE = 0.227). These results further evidence the validity of our ANN model in simulating the concentrations of sea surface  
267 DMS.

268

269 **Figure 4.** Comparisons between the ANN model simulation results and DMS observational data not archived in the GSSD  
 270 database. (a) Time series of simulation results and DMS observational data obtained from *Line P Program*. The different  
 271 markers represent different stations of *Line P*. The blue shades cover the data obtained from the cruises included in the GSSD  
 272 database but with a different method. (b) Scatter plot of simulated versus observed DMS concentrations. (c) The same as panel  
 273 b but for averaged data of each cruise. The yellow lines and shaded bands are linear fittings and corresponding 95% confidence  
 274 intervals for  $\log_{10}$  space data. The  $R^2$  and RMSE displayed in the figure also correspond to  $\log_{10}$  space data.

## 275 3.2 DMS distribution

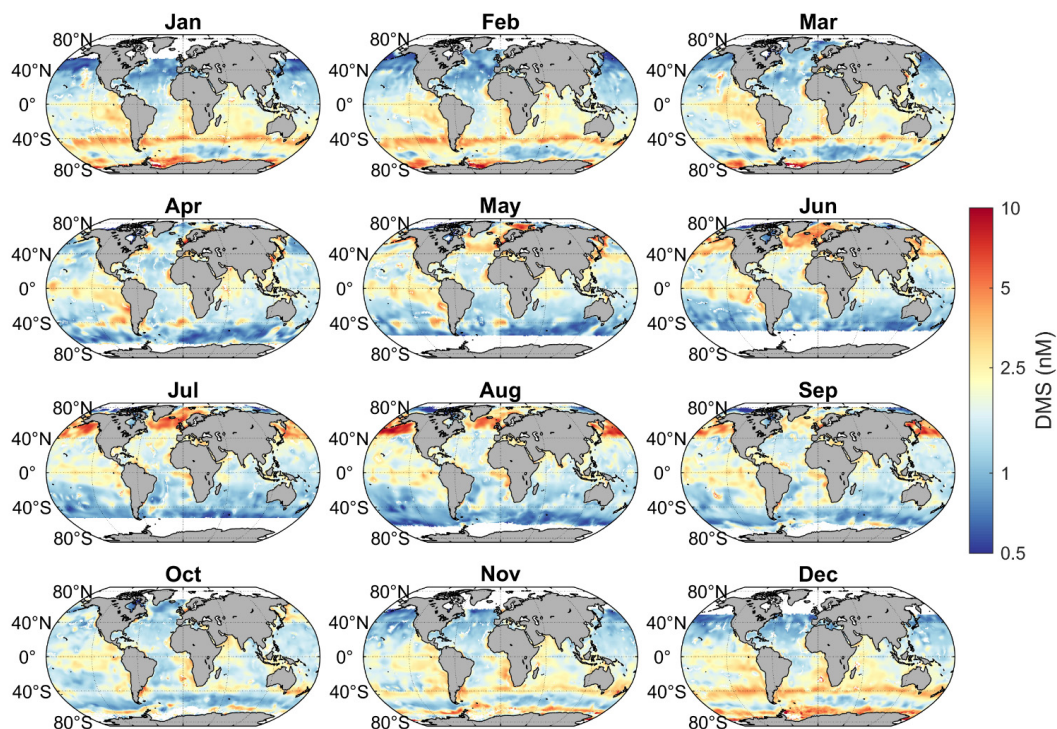

### 276 3.2.1 Spatial and seasonal variations

277 The monthly climatology of ANN-simulated DMS concentrations in the global sea surface from 1998 to 2017 is shown in Fig.  
 278 5. Overall, the DMS concentrations in mid-high latitude regions exhibit a seasonal variation of high in summer and low in  
 279 winter, which is consistent with the results of many previous observational studies. In the northern hemisphere, high DMS  
 280 concentrations ( $>2.5$  nM) in summer mainly occur in two regions. One is the North Pacific ( $40^{\circ}$ – $60^{\circ}$  N) extending from the  
 281 coast of Japan and Russia to the coast of Alaska and Canada, where the concentration generally peaks in August (Fig. 6). The

282 other is the subarctic North Atlantic ( $50^{\circ}$ – $80^{\circ}$  N), where a significant increase of DMS concentration firstly occurs in the  $45^{\circ}$ –  
283  $50^{\circ}$  N in May and then gradually shifts to the north of  $50^{\circ}$  N in July, consistent with the spatiotemporal evolution of solar  
284 radiation intensity. The peak concentration date at the same latitude in the North Atlantic is generally earlier than in the North  
285 Pacific (Fig. 6). In the southern hemisphere, there is a clear DMS-rich area near  $40^{\circ}$  S (where the Subtropical Convergence  
286 lies) in summer, forming a ring-shaped high-concentration band nearly parallel to the latitude. The highest seasonal mean  
287 concentration (December–February) at a specific latitude is 3.58 nM, taking place at  $41.5^{\circ}$  S (Fig. 8). Southward from this  
288 region, there is a low-DMS area in the  $51^{\circ}$ – $61^{\circ}$  S, where the average concentration is below 2.0 nM in all seasons. However,  
289 in the coastal waters of Antarctica (south of  $60^{\circ}$  S), significantly high concentrations also appear in summer, reaching over 4.0  
290 nM, even higher than the region near  $40^{\circ}$  S (Fig. 4 and 8). In addition to the above regions, some typical upwelling zones also  
291 exhibit relatively higher DMS concentrations, such as the eastern Pacific and the Southeast Atlantic. The former is at low  
292 latitudes with no obvious seasonal variation, while the latter exhibits higher concentrations from October to February. The  
293 high nutrient concentrations in upwelling areas could support higher primary productivity, leading to more intense biological  
294 activities including the production of biogenic sulfur.

295

296

297 **Figure 5.** Monthly climatology of global sea surface DMS concentration during 1998 to 2017.

298

299

300 **Figure 6.** The day of the year with the highest sea surface DMS concentration for each grid.

301

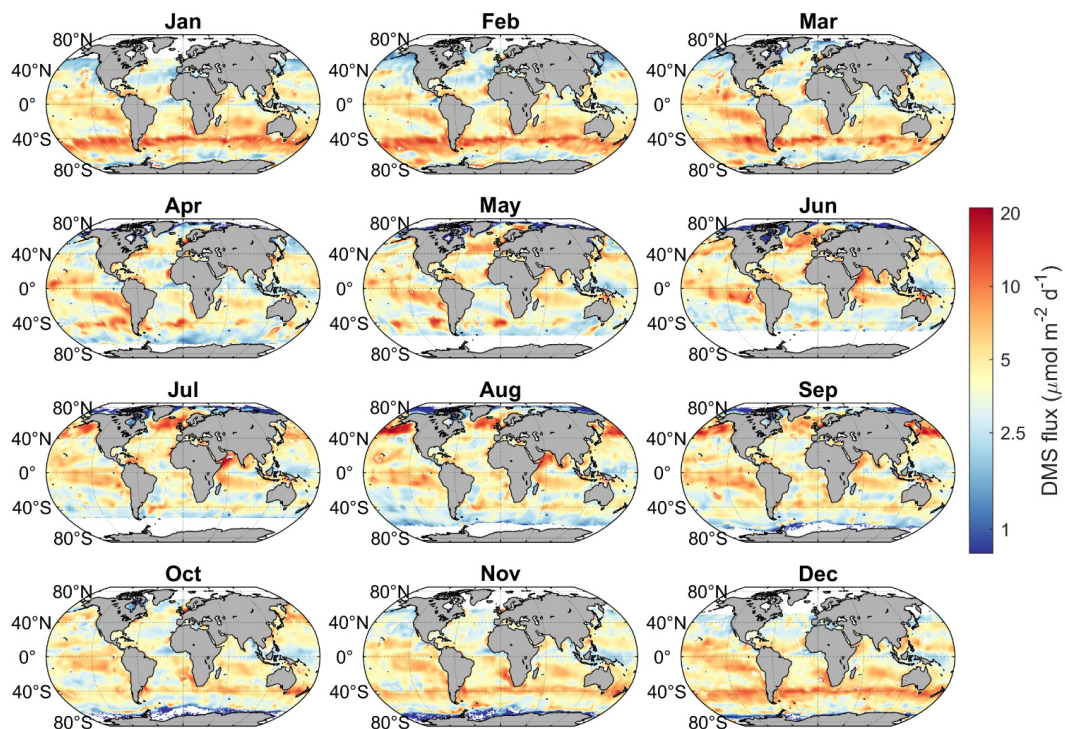

302 The spatiotemporal variation of DMS emission flux is generally consistent with that of concentration. As shown in Fig. 7,  
303 DMS fluxes are also significantly higher in summer in most mid-high latitude regions, and the high-flux regions generally  
304 overlap with the hot spots of DMS concentration. This indicates that the distribution of sea surface DMS concentration is the  
305 main factor controlling the distribution pattern of DMS emissions at the global scale, and the effect of transfer velocity is  
306 secondary. However, in certain specific regions, the variations of DMS flux and concentration may be inconsistent. For  
307 example, in the Arabian Sea and the central Indian Ocean, the high transfer velocities (Fig. S4) caused by higher wind speeds  
308 during the period from June to September can significantly uplift the emission fluxes, although the concentrations are relatively  
309 lower than in other months. In the polar regions, especially along the coast of Antarctica, although the DMS concentration is  
310 high in summer, the sea ice coverage will greatly hinder the release of DMS, thus the emission flux remains at a lower level.

311 As shown in Fig. 8, the higher wind speeds in autumn and winter at mid to high latitudes result in higher total transfer velocities,  
312 leading to smaller summer-to-winter ratios of DMS emission flux compared to that of DMS concentration. In low latitudes,  
313 the existence of the trade wind zones in both hemispheres further differentiates two high-flux bands compared to concentration,  
314 located between 5° to 20°. The emission fluxes in the equatorial region between these two trade zones are significantly lower.  
315 Although the latitudinal distributions of mean DMS emission fluxes in the southern and northern hemispheres are almost  
316 symmetrical, the huge difference in ocean area between the two hemispheres results in a significantly higher total emission  
317 from the southern hemisphere. Since anthropogenic SO<sub>2</sub> emissions are mainly concentrated in the northern hemisphere,  
318 oceanic DMS plays a much more important role in the southern hemisphere, especially over the regions south of 40° S where  
319 the DMS emission is high and the perturbation of anthropogenic pollution is low.

320 According to our newly built DMS gridded dataset, the global area-weighted annual mean concentration of DMS at the sea  
321 surface from 1998 to 2017 was ~1.82 nM (1.80–1.84 nM), which is at an intermediate level among the values (1.6 to 2.4 nM)  
322 obtained by various methods in previous studies (Tesdal et al., 2016). The global annual mean DMS emission to the atmosphere  
323 was 17.9 TgS yr<sup>-1</sup> (17.7–18.4 TgS yr<sup>-1</sup>), with 10.7 TgS yr<sup>-1</sup> (59.4%) from the southern hemisphere and 7.3 TgS yr<sup>-1</sup> (40.6%)  
324 from the northern hemisphere. It is worth noting that there is no valid satellite Chl *a* data in high latitudes in winter, and the  
325 Chl *a* data missing also exists in other regions, thus the simulated DMS concentrations are missing under these circumstances.  
326 This part of missing data was filled in the calculation of global mean DMS concentration and total emission. The specific  
327 method is shown in Appendix B. Without filling in the missing data, the global annual mean concentration and total emission  
328 are 1.86 nM (1.84–1.88 nM) and 16.8 TgS yr<sup>-1</sup> (16.6–17.2 TgS yr<sup>-1</sup>), respectively.

329

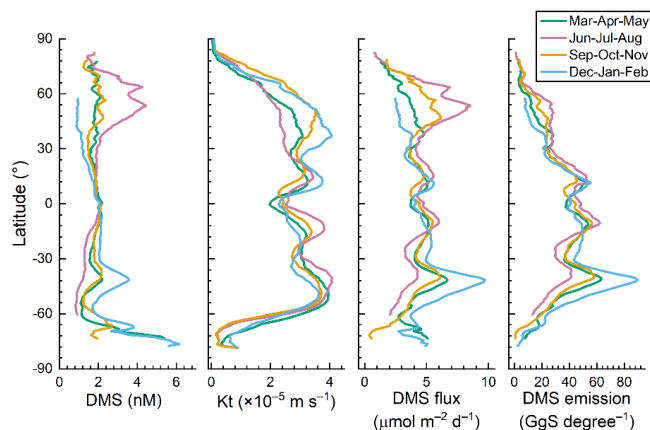

330

331 **Figure 7.** Monthly climatology of global DMS sea-to-air flux from 1998 to 2017.

332

333

334

335 **Figure 8.** The latitudinal distributions of sea surface DMS concentration, total transfer velocity (Kt), sea-to-air flux, and total  
 336 emission in different seasons during 1998–2017. Only the latitudes in a season with no more than 75% of data missing are  
 337 shown in the figure.

### 338 3.2.2 Comparisons with other global DMS climatologies

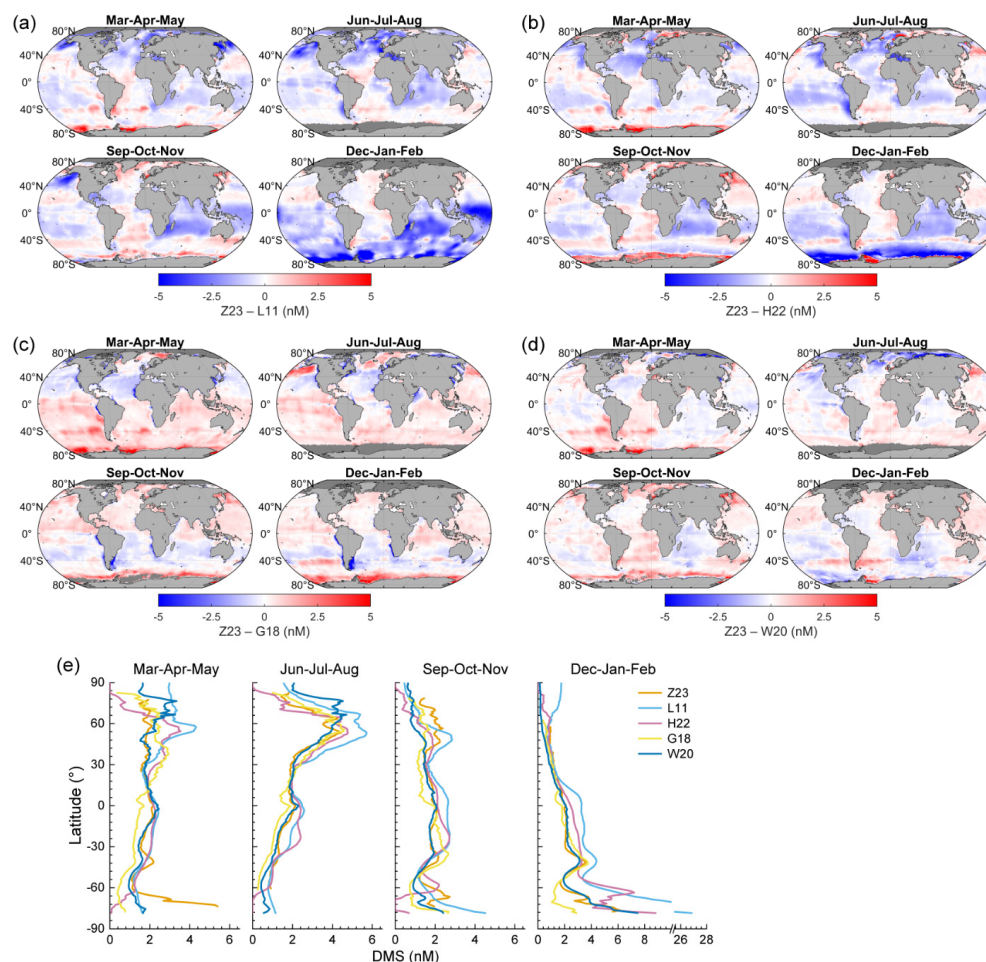

339 Here we compare the distributions of DMS concentration derived from our ANN simulation (referred to as Z23) with four  
 340 previously constructed climatologies, including (1) L11: the widely used second version of interpolation/extrapolation-based  
 341 climatology established by Lana et al. (2011), (2) H22: an updated version of L11 incorporating much more DMS  
 342 measurements and using dynamic biogeochemical provinces (Hulswar et al., 2022), (3) G18: the DMS concentration field  
 343 estimated by a two-step remote sensing algorithm (Galí et al., 2018), and (4) W20: the previous DMS climatology simulated  
 344 by ANN (Wang et al., 2020).

345 In general, all datasets can reflect the basic pattern of high DMS concentration in summer and low concentration in winter, but  
 346 there are significant differences in their specific distributions. Due to the limitation of the method used, DMS<sub>L11</sub> exhibits  
 347 relatively lower spatial heterogeneity (i.e., higher patchiness), which may not well capture the detailed spatial variability on a  
 348 regional scale. Compared with DMS<sub>L11</sub>, DMS<sub>Z23</sub> is significantly lower at high latitudes in summer and in the South Indian  
 349 Ocean and Southwest Pacific Ocean from December to February (Fig. 9a). Particularly in the southern polar region (Polar\_S),  
 350 DMS<sub>L11</sub> can reach > 10 nM in summer, which is 1–3 times higher than DMS<sub>Z23</sub> (Fig. 9e). However, DMS<sub>Z23</sub> around the  
 351 Antarctic in March remains the similar level as in summer, and it is significantly higher than DMS<sub>L11</sub> as well as the other three  
 352 climatologies. DMS<sub>H22</sub> shows fewer differences with DMS<sub>Z23</sub> in northern high latitudes, the South Indian Ocean, and the  
 353 Southwest Pacific Ocean, but the summertime concentrations in most of Polar\_S region are also > 2 nM higher than DMS<sub>Z23</sub>

354 (Fig. 9b). The global annual mean DMS concentrations in L11 and H22 are 2.43 nM and 2.26 nM, about 33.5% and 24.2%  
355 higher than Z23, respectively.

356 G18 exhibits the lowest global annual mean concentration (1.63 nM) among these climatologies, about 10.4% lower than Z23.  
357 There are more than 60% of global oceans with higher  $DMS_{Z23}$  than  $DMS_{G18}$  in all seasons, which is especially obvious in  
358 autumn and winter for both hemispheres (Fig. 9c). In addition,  $DMS_{Z23}$  is  $> 2$  nM ( $> 100\%$ ) higher than  $DMS_{G18}$  in North  
359 Pacific during boreal summer and near the Antarctic during austral summer and autumn. However, there are extremely high  
360 DMS concentrations ( $> 5$  nM) in some coastal seas (such as the coast of Patagonia and Peru, the southwestern coast of Africa,  
361 the western coast of North America, and the Sahara Desert) based on the G18 estimate, and this characteristic was not  
362 completely reproduced by other DMS fields. W20 exhibits the highest consistency with Z23 in spatiotemporal distribution  
363 patterns as well as the lowest difference in global annual mean concentration (1.74 nM, only 4.4% lower than Z23). But in  
364 specific regions, there are also obvious disagreements. For example, the summertime  $DMS_{Z23}$  is  $> 1$  nM ( $> 40\%$ ) lower than  
365  $DMS_{W20}$  in more than half of the Arctic area, but in the southeastern Pacific and South Atlantic during austral summer and  
366 autumn  $DMS_{Z23}$  is significantly higher than  $DMS_{W20}$  (Fig. 9e). Moreover, only  $DMS_{Z23}$  forms a nearly complete high-  
367 concentration annular band at  $\sim 40^\circ$  S during austral summer.

368

369 **Figure 9.** (a–d) The spatial distributions of DMS concentration differences between Z23 and four previously estimated fields  
370 in different seasons: (a) L11, (b) H22, (c) G18, and (d) W20. Dark gray regions in the ocean represent data missing in at least  
371 one field. (e) Comparisons between the latitudinal distributions of Z23 and four previous DMS fields in different seasons.

372

### 373 3.2.3 Decadal changes

374 One of the advantages of our ANN-derived DMS dataset is that it contains information on interannual variations. Here we  
375 present the decadal trends of DMS concentration, Kt, and emission flux during 1998–2017 at global and regional scales.

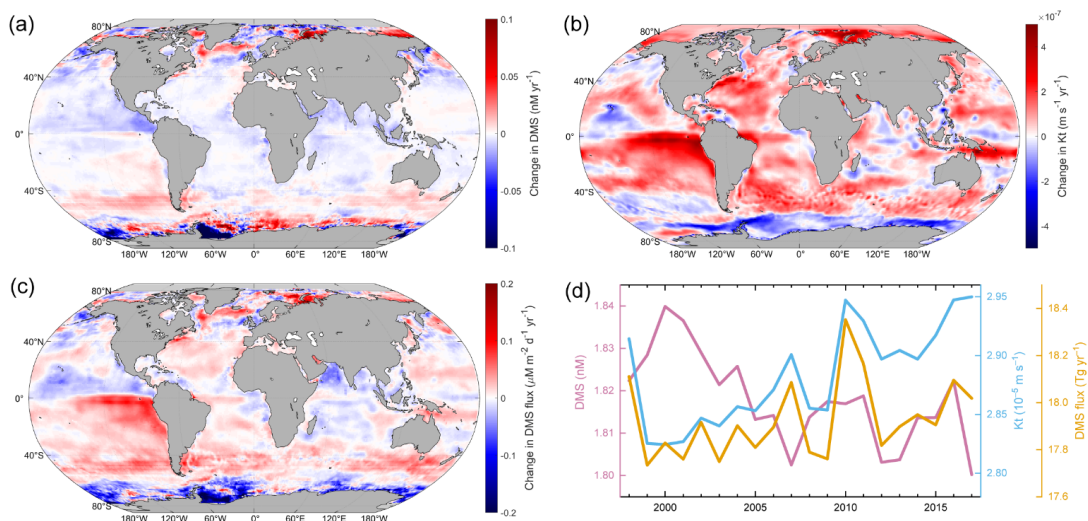

376 Overall, the interannual variability of DMS concentration in most global oceanic regions is relatively small. 90% of the global  
377 oceanic area exhibited a difference of less than 1 nM between the maximum and minimum annual average concentrations  
378 during this 20-year period. As for the relative variation range ((maximum – minimum)/mean) of the annual average  
379 concentration, it was lower than 0.2 in 66% of the global oceanic area, mainly distributed between the latitude 40° S and 40°  
380 N. The annual mean concentration in the polar regions varied greatly (Fig. 10a). In particular, the Labrador Sea, Baffin Bay,  
381 Barents Sea, Kara Sea, East Siberian Sea, and Chukchi Sea in the Arctic showed a significant increasing trend ( $> 0.03 \text{ nM yr}^{-1}$ ,  $P < 0.05$ ). In contrast, some areas around the Antarctic showed a significant decreasing trend, such as the inner Weddell Sea  
382 and Ross Sea ( $> 0.05 \text{ nM yr}^{-1}$ ), but the annual means in marginal seas of the Antarctic between 0°–180° E increased. In addition,  
383 there was a significant increasing trend at ~50° S, but the rate of increase was relatively slow ( $< 0.02 \text{ nM yr}^{-1}$ ). In the low-mid  
384 latitude regions where the variation range of DMS was small, the overall trend was decrease, and the large area of these regions  
385 resulted in a mild decrease in global average concentration, with a rate of  $\sim 0.0012 \text{ nM yr}^{-1}$  (Fig. 10d). The highest concentration  
386 (1.84 nM) occurred in 2000, while the lowest concentration (1.80 nM) occurred in 2017. Due to the increasing SST and WS  
387 in most mid-low latitude regions (Fig. S5), the Kt of DMS also showed an overall increasing trend, especially in the eastern  
388 equatorial Pacific (Fig. 10b). The increase in Kt can offset the decrease in DMS concentration to some extent, resulting in no  
389 significant trend in global DMS fluxes during this 20-year period (Fig. 10d).

391 In the Arctic region, which is the most sensitive to climate warming (Screen et al., 2012; Serreze and Barry, 2011), the sea ice  
392 coverage has significantly decreased over the past 2 decades, particularly in the Barents Sea and Kara Sea and further north ( $>$   
393  $1\% \text{ yr}^{-1}$  for annual mean SI, Fig. S5). The retreat of summertime sea ice leads to an expansion of open-sea surface, further  
394 promoting the increase in DMS emission, which is consistent with the results of Galí et al. (2019). As shown in Fig. 11, the  
395 annual DMS emission flux in the Polar\_N region increased from 0.48 TgS  $\text{yr}^{-1}$  before 2002 to 0.58 TgS  $\text{yr}^{-1}$  in 2016. If we  
396 just consider the fluxes during May–August north of 70° N, as in Galí et al. (2019), the lowest value was 37 GgS in 2003 and  
397 the highest was 64 GgS in 2016. In contrast, the sea ice fraction in the Southern Ocean has significantly increased (Fig. S5),  
398 leading to a significant decrease in the Kt and DMS emission flux (Fig. 10b-c). The highest annual total emission flux in the  
399 Polar\_S region occurred in 1999 (0.85 TgS) and the lowest occurred in 2013 (0.63 TgS), which decreased by  $\sim 26\%$ . For other  
400 oceanic regions, the average DMS concentrations in the Coastal, Westerlies\_N\_Pacific, and all 3 Trades regions exhibit  
401 decreasing trends over the past 20 years, while the concentration in Westerlies\_S has increased ( $P < 0.05$ , Fig. 11). As for the  
402 DMS flux, only the Westerlies\_N\_Atlantic and Trades\_Pacific regions showed a slight increase, while there was no significant  
403 trend in other low-mid latitude regions.

404

405

414 1998 to 2017.

### 415 3.3 Connection with atmospheric biogenic sulfur

416 One of the main aims of developing this daily gridded DMS dataset (Z23) covering multiple years is to provide a better  
417 emission inventory of marine biogenic DMS and effectively improve the modeling performance for atmospheric sulfur  
418 chemistry, especially for simulating sulfur aerosols. In order to investigate whether our newly constructed DMS dataset can  
419 reach this goal, we employed a backward trajectory-based method to establish the connection between sea surface DMS  
420 emissions and DMS's oxidation products in the atmosphere. The correlation was compared to those calculated by applying  
421 previously reported DMS climatologies ( L11, H22, G18, and W20).

422 Here we use the observed concentrations of particulate methanesulfonic acid (MSA) over the Atlantic Ocean as a reference.  
423 MSA is one of the major end-products of DMS in the atmosphere and is solely from the oxidation of marine biogenic DMS  
424 over remote oceans (Saltzman et al., 1983; Savoie et al., 2002; Osman et al., 2019). Therefore, there is likely to be a dependence

425 of the variation of MSA concentration on the DMS emission fluxes. During four transection cruises in the Atlantic conducted  
426 by *R/V Polarstern* (20 April – 20 May 2011, 28 October – 1 December 2011, 10 April – 15 May 2012, and 27 October – 27  
427 November 2012), the MSA concentrations in submicron aerosols were measured online using a High-Resolution Time-of-  
428 Flight Aerosol Mass Spectrometer with the time resolution of 20 min. We applied 1-h averaged data to match the air mass  
429 backward trajectories calculated every hour. The ship tracks are shown in Fig. S6, and detailed information about the cruises  
430 and measurement method was given by Huang et al. (2016). The 72-hour air mass backward trajectories reaching the ship  
431 position were calculated every hour by the HYSPLIT model with the start height of 100 m (Stein et al., 2015), and then the air  
432 mass exposure to DMS emission (AEDMS), i.e., the weighted average of DMS emission flux along the trajectory path was  
433 calculated following the approach of Zhou et al. (2021). We used 5 different DMS gridded datasets, including Z23, L11, H22,  
434 G18, and W20. For Z23, the calculated daily DMS fluxes were used. For the other 4 monthly climatologies, we applied the  
435 daily Kt data from Z23 to calculate the DMS fluxes to exclude the confounding influences by different Kt parameterizations.  
436 In this calculation, the same concentration was assigned to all days in a month without interpolation. The detailed calculation  
437 procedures for AEDMS are illustrated in Appendix C.

438 MSA concentrations were significantly higher in late spring than those in autumn for both North and South Atlantic Oceans  
439 (Fig. 12a). For example, during the boreal spring cruise in 2011, the average MSA concentration over the North Atlantic ( $0.068$   
440  $\mu\text{g m}^{-3}$ , north of  $25^\circ\text{N}$ ) was about an order of magnitude higher than the average concentration over the South Atlantic ( $0.006$   
441  $\mu\text{g m}^{-3}$ , south of  $5^\circ\text{S}$ ). In contrast, during the boreal autumn cruise in 2011, the average concentration over the South Atlantic  
442 ( $0.034 \mu\text{g m}^{-3}$ , south of  $5^\circ\text{S}$ ) was  $\sim 5$  times higher than that over the North Atlantic ( $0.006 \mu\text{g m}^{-3}$ , north of  $25^\circ\text{N}$ ). In addition  
443 to this major seasonal pattern, there was also a minor MSA concentration peak between  $5^\circ$ – $15^\circ\text{N}$  in both seasons. The spatial  
444 and seasonal variations of AEDMS based on the Z23 dataset (referred to as AEDMS\_Z23) largely coincided with these MSA  
445 concentration patterns (Fig. 12a). It should be noted that the AEDMS/MSA ratio between  $5^\circ$ – $15^\circ\text{N}$  was significantly higher  
446 than those in other high-MSA regions, which may result from the DMS simulation biases near the coast of West Africa or the  
447 lower DMS-to-MSA conversion yields related with air temperature and oxidant species (Barnes et al., 2006; Bates et al., 1992).  
448 There were also several AEDMS peaks in North Atlantic during November 2012, inconsistent with the continuously low MSA  
449 concentrations. Given the high precipitation rates along the trajectory, a strong wet scavenging process might significantly  
450 reduce aerosol concentrations (Wood et al., 2017).

451 The AEDMS derived from other DMS concentration fields showed similar variations as AEDMS\_Z23 (Fig. 12a). It was not  
452 surprising since all DMS concentration fields exhibit similar large-scale spatiotemporal patterns, and the same air mass  
453 transport path and Kt were applied in different AEDMS calculations. However, because those DMS monthly climatologies  
454 have low temporal resolutions and lack interannual changes, the resulting AEDMS was less effective in capturing the  
455 variability in fine scale or among different years. Here we focus on the high-MSA periods to elaborate on this issue, which  
456 corresponds to the latitudes north of  $25^\circ\text{N}$  in boreal spring (S1 and S2 in Fig. 12a) and south of  $5^\circ\text{N}$  in boreal autumn (A1

457 and A2 in Fig. 12a). As shown in Fig. 12b–c, hourly MSA concentrations exhibited significantly stronger correlations with  
458 AEDMS\_Z23 than with other AEDMS time series in both seasons, which means AEDMS\_Z23 can explain much more (0.78–  
459 2.71 times higher) variance of MSA concentration. It was even more obvious for 6-h averaged data, as AEDMS\_Z23 can  
460 explain ~70% of the variance during S1 and S2, while others can only explain ~30% (Fig. S7). These remarkably stronger  
461 connections between Z23 and atmospheric DMS-derived aerosols mainly benefited from the combined effects of higher time  
462 resolution and accuracy of DMS concentrations as well as the incorporation of interannual variations. For example, the ratio  
463 of average MSA concentration during S1 to that during S2 (S1-to-S2 ratio) was 1.89, and the A2-to-A1 ratio was 1.58.  
464 AEDMS\_Z23 exhibited a slightly lower but still significant interannual variation degree, where the S1-to-S2 ratio and A2-to-  
465 A1 ratio were 1.59 and 1.34, respectively. However, this interannual variation cannot be reproduced by other datasets, where  
466 the S1-to-S2 ratio and A2-to-A1 ratio were in the range of 1.09–1.32 and 1.05–1.11, respectively. The results further prove the  
467 fidelity of our newly developed DMS gridded data product, which has the prospect of greatly improving the modeling  
468 performance for atmospheric DMS processes compared with previously reported climatologies. Of course, the AEDMS  
469 method used here is a highly simplified approach without considering the complex DMS chemistry in the atmosphere, and the  
470 intercomparisons based on chemical transport models can be used in the future to obtain a more straightforward conclusion.

471

472  
 473 **Figure 12.** (a) Time series of observed MSA concentration, AEDMS calculated based on different DMS concentration datasets,  
 474 and average precipitation along the backward trajectory (Precipitation\_traj) during four Atlantic cruises in 2011–2012. (b–c)  
 475 Correlations between hourly MSA concentration and AEDMS based on different DMS concentration datasets (b) in the region  
 476 north of  $25^{\circ} \text{N}$  in boreal spring (the shaded area S1 and S2 in panel a) and (c) in the region south of  $5^{\circ} \text{N}$  in boreal autumn (the

477 shaded area A1 and A2 in panel a). Data points during the periods with air mass time fraction within the boundary layer less  
478 than 90% were removed.

#### 479 **4 Uncertainties and limitations**

480 Although our ANN ensemble model and derived DMS dataset demonstrate certain advantages compared to previous studies,  
481 as discussed in Section 3.3, there are still notable uncertainties and limitations, which result in the ~38% uncaptured variance  
482 (Figure 3a) and non-negligible simulation biases. First, the input factor datasets from different sources and the observed sea  
483 surface DMS concentrations inherently possess certain uncertainties, which can introduce biases in the ANN learning process.  
484 Second, ANN models may not fully capture all intricate data features, and the outcomes obtained from each training can exhibit  
485 certain randomness. In this study, the average standard deviation of simulated  $\log_{10}$ DMS values from 100 neural networks was  
486 0.256, and the 5%-95% range of the coefficient of variation for DMS concentration was 0.36–1.96, with a mean of 1.06. If the  
487 detailed uncertainties associated with each data source are known, future investigations could employ Monte Carlo methods  
488 to estimate the uncertainties of final results arising from the aforementioned two factors (Abdar et al., 2021; Moradkhani et al.,  
489 2012). Third, while the DMS observational data covers all major oceanic basins, certain regions such as the Southeast Pacific  
490 remain underrepresented. Advances in online measurement technologies offer promising opportunities for acquiring more  
491 extensive and convenient observational data (Hulswar et al., 2022). In the future, more observations are needed for these  
492 underrepresented regions, and the model can be retrained and updated accordingly.

493 The ideal scenario for this study would entail having all input datasets covering a 20-year period with a daily resolution.  
494 However, this is not the case for the nutrients and DO datasets utilized here, and only a portion of the Chl *a* datasets are  
495 available at a daily resolution, potentially impacting the model performance to some extent. Nevertheless, machine learning  
496 techniques can capture the interactions among various input factors. Two key factors, SST and MLD, influence the surface  
497 concentration of these species, and we provided the multi-year daily datasets of SST and MLD. Therefore, during the training  
498 process, the model can learn some of the daily and interannual variation information regarding nutrients and DO, as well as  
499 their impact on DMS concentration, thereby partially compensating for the model performance. Of course, in the future, the  
500 utilization of accurate daily resolution data instead of monthly climatologies may yield improved simulation results.  
501 Additionally, apart from the 9 variables incorporated in this study, other environmental parameters, such as trace metal  
502 elements (Li et al., 2021), can also influence the DMS concentration. Not incorporating these factors may introduce potential  
503 biases. Thus, further field measurements of these factors are necessary to comprehend their spatiotemporal distributions, which  
504 are likely to enhance the model's ability to simulate sea surface DMS concentrations.

505 When using our newly developed DMS dataset, two issues should be aware of. First, there is a notable amount of missing data  
506 during winter in polar regions due to the unavailability of satellite Chl *a*, which restricts the investigation of subsequent DMS  
507 atmospheric processes related to DMS. Nevertheless, given the low phytoplankton biomass and extensive sea ice coverage

508 during winter, DMS emissions are typically at the lowest level of the year, thus the data missing has a relatively small impact.  
509 Second, the ANN ensemble model exhibits limited capacity in accurately reproducing extremely high and low concentrations  
510 of DMS (Fig. 3a). Therefore, in some nearshore areas with intensive biological activity, this dataset may potentially  
511 underestimate the actual DMS concentrations.

## 512 **5 Code and data availability**

513 The generated gridded datasets of DMS concentration, total transfer velocity, and flux have been deposited at  
514 <https://zenodo.org/record/10279659> (Zhou et al., 2023) and can be downloaded publicly. The ANN model code and the Matlab  
515 scripts for data analysis are available from <https://zenodo.org/record/8077751> (Zhou, 2023).

## 516 **6 Conclusion**

517 Based on the global sea surface DMS observations and associated data of 9 relevant environmental variables, an ANN  
518 ensemble model was trained. The ANN model effectively captures the variability of DMS concentrations and demonstrates  
519 good simulation accuracy. Leveraging this ANN model, a global sea surface DMS gridded dataset with a daily resolution  
520 spanning 20 years (1998–2017) was constructed. The global annual average concentration was  $\sim 1.82$  nM, falling within the  
521 range of previous estimates, and the annual total emission was  $\sim 17.9$  TgS yr<sup>-1</sup>. High DMS concentrations and fluxes took place  
522 in summer in North Pacific (40°–60° N), North Atlantic (50°–80° N), the annular band of  $\sim 40^\circ$  S, and the Southern Ocean.  
523 With this newly developed dataset, the day-to-day changes and interannual variations can be investigated. The global annual  
524 average concentration shows a mild decreasing trend ( $\sim -0.0012$  nM yr<sup>-1</sup>), while the total emission remains stable. There were  
525 more significant decadal changes in certain regions. Specifically, the annual DMS emission in the Arctic and Antarctic regions  
526 showed opposite trends.

527 To further validate the robustness and advantages of our new dataset, an air mass trajectory-based approach was applied to link  
528 the DMS flux and atmospheric MSA concentration. Compared to previous monthly climatologies, the air mass exposure to  
529 DMS calculated using our new dataset explains a greater amount of variance in atmospheric MSA concentration over the  
530 Atlantic Ocean. Therefore, despite the presence of uncertainties and limitations, the new dataset serves as an improved DMS  
531 emission inventory for atmospheric models and holds the potential to significantly enhance the simulation of DMS-induced  
532 aerosols and their associated climatic effects.

533

## 534 **Appendix A: Acronyms**

535	AEDMS	Air mass exposure to DMS emission
536	ANN	Artificial neural network
537	BLH	Boundary layer height

538	CCN	Cloud condensation nuclei
539	Chl <i>a</i>	Chlorophyll <i>a</i>
540	DMS	Dimethyl sulfide
541	DMSP	Dimethylsulfoniopropionate
542	DO	Dissolved oxygen
543	DSWF	Downward short-wave radiation flux
544	ECCO	Estimating the Circulation and Climate of the Ocean
545	GSSD database	Global Surface Seawater DMS database
546	K <sub>t</sub>	Total transfer velocity
547	MLD	Mixed layer depth
548	MSA	Methanesulfonic acid
549	MSE	Mean squared error
550	NAAMES	North Atlantic Aerosols and Marine Ecosystems Study
551	RMSE	Rooted mean squared error
552	SI	Sea ice fraction
553	SST	Sea surface temperature
554	SSS	Sea surface salinity
555	WOA18	World Ocean Atlas 2018
556	WOD	World Ocean Database
557	WS	Wind speed

558

559 **Appendix B: Filling the missing DMS concentration data**

560 In the calculation of global mean DMS concentration and total emission flux, the missing data was complemented based on  
561 the adjacent valid values. First, for a certain global DMS gridded dataset, we calculated the proportion of missing data for each  
562 latitude and identified the absolute minimum latitudes with missing proportions above 0.5 for the southern and northern  
563 hemispheres, denoted as *Lat1* and *Lat2*, respectively (assuming *Lat1* is for the southern hemisphere with negative value, and  
564 *Lat2* is for the northern hemisphere with positive value). Next, for latitudes outside the range of *Lat1* and *Lat2* (including *Lat1*  
565 and *Lat2*), the missing data were replaced by the average of all valid values with latitude  $< Lat1 + 10^\circ$  or  $> Lat2 - 10^\circ$ . For the  
566 latitudes between *Lat1* and *Lat2*, the missing data at a certain grid was replaced by the average value of all adjacent grid points  
567 within  $5^\circ$  differences in both longitude and latitude. This operation was iterated until all such missing values were filled.

568

569 **Appendix C: The calculation of air mass exposure to DMS emission (AEDMS)**

570 Here the AEDMS index followed the similar calculation of the air mass exposure to Chl *a* (AEC) in previous studies (Arnold  
571 et al., 2010; Park et al., 2018; Zhou et al., 2021). We adopted the same approach presented in Zhou et al. (2021), only replacing  
572 the Chl *a* concentration by DMS flux, as shown in the following equation (A2):

$$573 \quad AEDMS = \frac{\sum_{i=0}^{72} DMS \text{ flux}_i e^{-\frac{t_i}{72} \frac{600}{BLH}}}{n} \quad (A2)$$

574 Here *i* represents the *i*-th trajectory point of the 72-hour backward trajectory (0-th for the receptor point). *DMS flux<sub>i</sub>* represents  
575 the mean DMS flux within a radius of 20 km at the location of *i*-th trajectory point. *DMS flux<sub>i</sub>* is set to zero if the point locates  
576 on land or the air mass pressure is below 850 hPa (usually in the free troposphere with little influence of surface emission). *t<sub>i</sub>*  
577 is the tracking time of the trajectory point (unit: hour) and  $e^{-\frac{t_i}{72}}$  is the weighting factor to assign higher values for regions  
578 closer to the receptor point. *n* is the total number of trajectory points with valid DMS flux (including 0). To better connect with  
579 the atmospheric concentrations in the marine boundary layer, the normalization by boundary layer height (BLH) is added by  
580 the  $\frac{600}{BLH}$  term. The BLH below 50 m is replaced by 50 m.

#### 581 **Author contributions.**

582 SZ and YC designed the research. SZ, FW, ZX, and KY collected the data and did the data preprocessing. SZ implemented  
583 the model development and performed the simulation with assistance from GY, HZ, and YZ. SH, HH, AW, and LP provided  
584 the measurement data of atmospheric MSA over the Atlantic Ocean. SZ conducted the data analysis and visualization with  
585 advice from YC and XG. SZ and YC wrote the manuscript with inputs from all authors.

#### 586 **Competing interests.**

587 The authors declare that they have no conflict of interest.

#### 588 **Acknowledgements.**

589 We greatly thank National Oceanic and Atmospheric Administration's Pacific Marine Environmental Laboratory for  
590 maintaining the Global Surface Seawater DMS Database. We acknowledge Dr. Chenzhao Li for sharing the code of global  
591 sensitivity analysis and Dr. Martin Johnson for sharing the code of DMS transfer velocity calculation. We also thank Dr. Rich  
592 Pawlowicz for developing and sharing the M\_Map toolbox for Matlab (<https://www.eoas.ubc.ca/~rich/map.html>), which was  
593 used in the mapping of this study. XG was supported by the Research Center for Industries of the Future (RCIF) at Westlake  
594 University and Westlake University Education Foundation.

595 **Financial support.**
