Abstract

Our understanding and predictive capability of streamflow processes largely rely on high-quality datasets that depict a river's upstream basin characteristics. Recent proliferation of large sample hydrology (LSH) datasets has promoted model parameter estimation and data-driven analyses of the hydrological processes worldwide, yet existing LSH is still insufficient in terms of sample coverage, uncertainty estimates, and dynamic descriptions of anthropogenic activities. To bridge the gap, we contribute the Synthesis of Global Streamflow characteristics, Hydrometeorology, and catchment Attributes (GSHA) to complement existing LSH datasets, which covers 21,568 watersheds from 13 agencies for as long as 43 years based on discharge observations scraped from web. In addition to annual and monthly streamflow indices, each basin's daily meteorological variables (i.e., precipitation, 2 m air temperature, longwave/shortwave radiation, wind speed, actual and potential evapotranspiration), daily-weekly water storage terms (i.e., snow water equivalence, soil moisture, groundwater percentage), and yearly dynamic descriptors of the land surface characteristics (i.e., urban/cropland/forest fractions, leaf area index, reservoir storage and degree of regulation) are also provided by combining openly available remote sensing and reanalysis datasets. The uncertainties of all meteorological variables are estimated with independent data sources. Our analyses ~~revealed~~ reveal the following insights: (i) the meteorological data uncertainties vary across variables and geographical regions, and the ~~prominent patterns~~ revealed pattern should be accounted for by LSH users, (ii) ~6% watersheds shifted between human managed and natural states during ~~the GSHA time span~~ 2001-2015, e.g., basins with environmental recovery projects in Northeast China, which may be useful for hydrologic analysis that takes the changing land surface characteristics into account, and (iii) GSHA watersheds ~~observed~~ showed a more widespread declining trend in runoff coefficient than an increasing trend, pointing towards critical water availability issues. Overall, GSHA is expected to serve hydrological model parameter estimation

41 and data-driven analyses as it continues to improve. ~~GSHA v1.0 can be accessed at~~
42 ~~<https://doi.org/10.5281/zenodo.8090704>~~GSHA v1.1 can be accessed at
43 ~~<https://doi.org/10.5281/zenodo.8090704>~~ and ~~<https://doi.org/10.5281/zenodo.10127757>~~. (Yin et al.,
44 2023).

45 1 Introduction

46 Climate change has posed profound challenges to the management of freshwater resources,
47 specifically riverine floods or water shortages (AghaKouchak et al., 2020; Thackeray et al., 2022).
48 The urgent need for flood and drought forecasting, water resources planning and management, all
49 call for high-quality streamflow predictions for basins worldwide to analyse global terrestrial water
50 conditions in a systematic view (Burgess, 1998). The scarcity of hydrological observations has
51 brought challenges to these predictions (Belvederesi et al., 2022; Hrachowitz et al., 2013), thus the
52 development of computer models that allow for “modelling everything everywhere” (Beven &
53 Alcock, 2012) constitutes the backbone of hydrological studies. Existing studies have used
54 physically-based and data-driven models for streamflow simulation (Lin et al., 2018; Nandi &
55 Reddy, 2022; Zhang et al., 2020), with efforts to improve accuracy of prediction by combining both
56 (Cho & Kim, 2022; Razavi & Coulibaly, 2013). Yet the prediction of the magnitude, timing, and
57 trend of critical streamflow characteristics are still subject to multiple sources of errors and
58 uncertainties (Bourdin et al., 2012; Brunner et al., 2021).

59 Streamflow (Q) can be represented by the simple water balance equation involving
60 precipitation (P), evapotranspiration (ET), and water storage terms (S) denoted as $Q = P - ET - \Delta S$,
61 yet influencing factors of these components could bring uncertainties that ~~will~~ cascade downstream.
62 Starting from the model assumptions to the data used to represent climate, soil water, ice cover,
63 topography and land use, as well as ~~to~~ the less well-known processes such as human perturbations
64 and sub-surface flows (Benke et al., 2008; Wilby & Dessai, 2010), these complications impede our
65 understanding of streamflow processes across scales, which also limits the modelling and predictive
66 capability for streamflow. Thus, reducing the predictive uncertainties ~~require~~requires high-quality
67 data with massive samples capable of depicting each of the water balance components, as well as
68 the natural and anthropogenic factors involved (Gupta et al., 2014).

69 Efforts have been made to address the need ~~effor~~ for such kind of high-quality datasets on
70 watershed-scale hydro-climate and environmental conditions during the past couple of decades. One
71 of the earliest was the most widely used dataset generated for the Model Parameter Estimation
72 Experiment (MOPEX) project aimed at better hydrological modelling (Duan et al., 2006). Historical
73 hydro-meteorological data and land surface characteristics for over 400 hydrologic basins in the
74 United States were provided, which was fundamental to the progress in large sample hydrology
75 (LSH) (Addor et al., 2020; Schaake et al., 2006). Later the dataset was expanded to 671 catchments
76 in the contiguous United States (CONUS) and benchmarked by model results (Newman et al., 2015).
77 Based on these studies, the Catchment Attributes and Meteorology for Large-sample Studies
78 (CAMELS) dataset was developed, providing comprehensive and updated data on topography,
79 climate, streamflow, land cover, soil, and geology attributes for each catchment (Addor et al., 2017).

80 The CONUS CAMELS dataset soon became influential in LSH and has since inspired researchers
81 from Australia (Fowler et al., 2021), Europe (Coxon et al., 2020; Delaigue et al., 2022; Klingler et
82 al., 2021), South America (Alvarez-Garreton et al., 2018; Chagas et al., 2020), and China (Hao et
83 al., 2021) to contribute their regional CAMELS. Another comprehensive regional LSH dataset for
84 North America named the Hydrometeorological Sandbox - École de Technologies Supérieure
85 (HYSETS) dataset, ~~is~~was also developed with larger sample size (14425 watersheds) and richer data
86 sources compared with the CAMELS (Arsenault et al., 2020).

87 While these datasets are reliable data sources for regional studies, attempts on building global
88 datasets ~~has~~have become the new norm in the era of big data to boost our analytical and modelling
89 capability for the terrestrial hydrological processes. The HydroATLAS dataset ~~integrates~~integrated
90 indices of hydrology, physiography, climate, land cover, soil, geology, and anthropogenic activity
91 attributes for 8.5 million global river reaches (Lehner et al., 2022; Linke et al., 2019). A recent work
92 combined a series of CAMELS ~~dataset~~datasets with HydroATLAS attributes into a new global
93 community dataset on the cloud named Caravan, with dynamic hydro-climate variables and
94 comprehensive static catchment attributes extracted on 6830 watersheds (Kratzert et al., 2023),
95 which represents by far the most comprehensive synthesis of existing CAMELS. Another global-
96 scale effort, the Global Streamflow Indices and Metadata archive (GSIM), incorporated dynamic
97 streamflow indices and attribute metadata for topography, climate type, land cover, etc., for over
98 35000 gauges (Do et al., 2018; Gudmundsson et al., 2018), and the streamflow indices ~~are~~were
99 updated to allow for trend analysis (Chen et al., 2023). A recent study filled in the discontinuity and
100 latency of gauge records, and provided streamflow for over 45,000 gauges with improved data
101 quality (Riggs et al., 2023). These global-scale datasets have been widely used in data-driven
102 machine learning models (Kratzert et al., 2019a, 2019b; Ren et al., 2020), physical hydrological
103 models (Aerts et al., 2022; Clark et al., 2021), and parameter estimation and regionalization studies
104 (Addor et al., 2018; Fang et al., 2022).

105 Although the flourishing of LSH datasets has promoted comparative hydrological studies
106 (Kovács, 1984) and large-scale hydrological modeling and ~~analyses~~analysis efforts, several
107 challenges are still standing in the way ~~to realize~~of realizing the full potential of LSH. As briefly
108 outlined in a recent review by Addor et al. (2020), current LSH datasets lack common standards,
109 metadata and uncertainty estimates, and are insufficient in characterising human interventions. More
110 specifically, the following major critical aspects still need ~~attentions~~attention from the LSH
111 developers, which we attempt to address with GSHA (Yin et al., 2023). First, the majority of current
112 datasets (especially those at a global scale) ~~incorporate~~incorporated only one data source for each
113 variable, while earth observations, reanalysis, satellite-based estimates are subject to uncertainties
114 (Merchant et al., 2017; Ukhurebor et al., 2020). These uncertainties were rarely represented and
115 may bring difficulties to the regionalization of model parameters (Beck et al., 2016), while also
116 resulting in inconsistent conclusions. Second, anthropogenic activities including land use and land
117 cover (LULC) changes, dam and reservoir building, etc., are critical drivers of shifts in streamflow
118 statistical moments (Niraula et al., 2015). However, historical time series of watershed human
119 modifications ~~have~~were rarely ~~been~~ included in LSH datasets, which is particularly problematic for
120 regions with rapid economic growth. Finally, although the most recent Caravan ~~has~~ provided
121 hydroclimate data for global watersheds, the samples are limited to the existing regional CAMELS
122 which Caravan synthesizes. Therefore, plenty of room is left to increase data sample size and spatial
123 coverage by revisiting the streamflow data acquisition process in a more comprehensive way.

124 To complement existing LSH datasets, we contribute the first version of a synthesis of Global
 125 Streamflow characteristics, Hydrometeorology, and catchment Attributes (GSHA v_1.0) for large-
 126 sample river-centric studies. GSHA features the following characteristics:

- 127 ● Updated physical and anthropogenic descriptors of global rivers, covering streamflow
 128 characteristics, hydrometeorological variables, and land use land cover changes for 21568
 129 watersheds derived from gauged streamflow records from 13 agencies.
- 130 ● Streamflow indices for data scarce regions, including those derived from 263 gauges in
 131 China, are included.
- 132 ● Extended temporal coverage for as long as 43 years (1979-2021), which varies regionally.
- 133 ● Uncertainty estimates for the meteorological variables.
- 134 ● Dynamic descriptors for the urban, forest, and cropland fractions, as well as reservoir
 135 storage capacity to improve the representation of human activities in the basin.

136 With the above features, we expect GSHA to support hydrological model parameter estimation
 137 and data-driven analysis of global streamflow as one of the most comprehensive LSH datasets
 138 regarding sample size, variable dynamics, and uncertainty estimates. **Table 1** summarizes the
 139 differences between GSHA and other prominent LSH datasets. Our paper is organized as follows.
 140 Section 2 expands on **Table 1** and provideprovides more details of the data included for GSHA.
 141 Section 3 introduces the data sources and methodologies involved in creating GSHA. Section 4
 142 highlights the key features of GSHA by conducting some analyses, followed by conclusions reached
 143 in Section 5.

144
 145 **Table 1 Comparison of GSHA with other LSH datasets.** Note that we only include the CONUS
 146 CAMELS dataset to represent regional LSH datasets for this comparison, as other regional CAMELS
 147 share large similarity with CONUS CAMELS.

Factors	CAMELS (eg. US)	HydroATLAS	Caravan	GSIM	GSHA
Spatial extent	Regional	Global	Global	Global	Global
Sample size	671	8.5 million	6830	35002	21568
Time span	1980–2015	Static	1981–2020	1806-2016	1979-2021
Streamflow dynamics	Yes	No	Yes	Yes (statistical indices)	Yes (<u>monthly and yearly</u> statistical indices)
Meteorological time series	Yes	No	Yes	No	Yes
Multi data sources for meteorological variables	Yes	No	No	No	Yes (with uncertainty estimates)
Water storage dynamics	No	No	Only soil water dynamics	No	Yes
Land cover dynamics	No	No	No	No	Yes

Reservoir dynamics	No	No	No	No	Yes
Static attributes	Yes	Yes	Yes (from HydroATLAS)	Yes	Yes (from HydroATLAS)

148 2 Dataset content of GSHA v1

149 In this section, the data fields, variables, and attributes included in GSHA are described in more
150 details and summarized in **Table 2**. For the instructions of the data format, we ~~provided~~provide a
151 user manual along with the dataset (see readme.docx). GSHA includes yearly and monthly
152 streamflow characteristics derived from daily discharge observations, meteorological variables
153 (including precipitation, 2-m air temperature, long- and shortwave radiation, wind speed, actual and
154 potential evapotranspiration (AET and PET)), daily or weekly water storage terms (4 layers of soil
155 moisture, groundwater, and snow depth water equivalence), daily vegetation index (leaf area index
156 (LAI)), yearly LULC characteristics (urban, cropland, and forest fraction), and yearly reservoir
157 information (degree of regulation (DOR) and reservoir capacity). For each meteorological variable,
158 multiple independent data sources are incorporated to provide uncertainty estimates. Static attributes
159 like land physiography, soils, and geology are not additionally extracted, as similar efforts have been
160 made by other researchers, so we directly matched our gauge locations to the HydroATLAS dataset
161 (Lehner et al., 2022; Linke et al., 2019) by providing the river ID match table. Users can link the
162 two to obtain these attributes.

163 **Watershed polygons:** GSHA includes 21568 watershed polygons delineated from the global
164 gauges, which ~~is~~are stored as Esri Shapefile format. The ID and agency of each watershed is the
165 same as the corresponding gauge ID, and the gauge latitude/longitude are in decimal degree. The
166 area denotes the upstream drainage ~~basin~~-area of the gauge. Some of the IDs contain characters
167 (such as ‘.’, ‘-’, etc.) inconsistent with the majority of IDs. For the convenience of the users, we
168 unified these as underscores and stored the new file names as ‘filename’. We also provide
169 independent files summarizing basic information of the watersheds, including matched MERIT
170 river reach COMID, upstream area, order and downstream river reach COMID, as well as
171 verification with officially reported areas of the agencies.

172 **Streamflow indices:** GSHA publishes annual and monthly streamflow indices derived from
173 daily streamflow data, including different percentiles, and mean/median/minimum/maximum. The
174 frequency and durations of extremely high and low streamflow events are also provided, ~~along with~~
175 We also include numbers of zero observations and valid samples to allow ~~extreme streamflow~~
176 analysis and flexible data screening by the users. The indices are stored as comma-separated values
177 (CSV) files ~~by year~~, with each watershed corresponding to one file. A complementary R package
178 can be used to automatically download many of the gauge datasets is available at
179 ~~<https://github.com/Ryan-Riggs/RivRetrieve>~~<https://github.com/Ryan-Riggs/RivRetrieve> (Riggs et
180 al., 2023).

181 **Meteorological variables:** The meteorological variables selected are the most influential

182 drivers for streamflow, which ~~includes~~include precipitation, 2-m temperature, ET, radiation and
 183 wind speed. In main-stream land surface models, ET is a diagnostic variable derived from
 184 meteorological inputs and is not considered as meteorological forcing. However, as many
 185 hydrological models also use potential ET as an input variable, and model calibration sometimes
 186 involves actual ET (Immerzeel & Droogers, 2008), we include the two variables and place ~~it~~them
 187 into the meteorological variable category. For each variable, more than one data sources are used to
 188 allow for uncertainty analysis, which ~~will be~~is provided on a yearly basis in an independent file.

189 **Natural water storage terms and land use/land cover change:** These include soil moisture,
 190 snow water equivalent, and ~~ground-water~~groundwater percentages. We also include yearly land
 191 cover dynamics (i.e., urban, forest, and cropland fraction changes), as well as dynamically changing
 192 reservoir capacity and degree of regulation (DOR) percentage. Leaf area index (LAI) is also
 193 included to reflect the seasonal changes in vegetation canopy that ~~is~~are also key to the streamflow
 194 processes.

195 **Static attributes:** GSHA does not extract updated static attributes because HydroATLAS
 196 already ~~make~~made substantial efforts in this regard. Instead, the listed categories are those mostly
 197 related to streamflow prediction from HydroATLAS selected to be included in GSHA files, and we
 198 direct the readers to the ID match table to access the entire 281 static attributes offered by
 199 HydroATLAS (Lehner et al., 2022; Linke et al., 2019). Our user manual, available at the dataset
 200 download site, also provides more information on it.

203 3 Data sources and methodology

204 3.1 Technical workflow in creating GSHA

205 The creation of GSHA starts from revisiting the data compilation process for the stream
 206 gauging observations from 13 international agencies. The general workflow of GSHA data
 207 production processes is illustrated in **Figure 1**, which consists of watershed delineation, variable
 208 extraction from both grid and non-grid data sources, and uncertainty analysis.

209 First, we delineated the upstream watersheds using gauge locations. Calibration of gauge
 210 longitudes and latitudes were conducted to match the gauges with the MERIT river network exactly.
 211 The delineated watersheds were selected and manually checked using standards of area, topology
 212 correctness, and observation data lengths. The selected watersheds went on to be overlaid with
 213 grid and non-grid variable data sources for to obtain GSHA variables.

214
215
216
217
218

Figure 1 General workflow of GSHA. The yellow parallelograms are the input datasets, the blue ones are the final outputs of GSHA dataset, and the pink ones are the results in the process. The black quadrilaterals represent the extraction and calculation processes, and the red dotted rectangles illustrate different modules of the extraction process.

219 **3.2 Gauge-based streamflow indices**

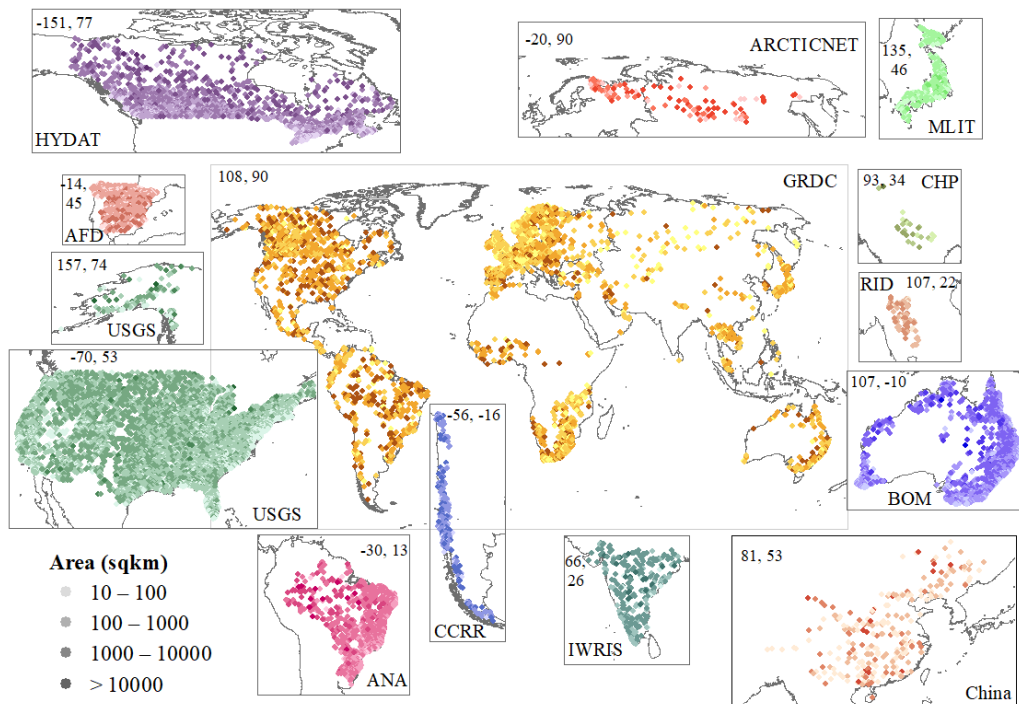

220 As shown in **Table 3**, in total streamflow data from 36497 gauges were initially scraped from
 221 the web and from the Chinese National Real-time Rain and Water Situation Database ~~including the~~
 222 ~~real-time water level and streamflow data of the hydrological stations.~~ For gauges located within
 223 ~100_m of each other, those with ~~shorter record lengths are fewer years of measurements were~~
 224 removed, assuming that they are redundant with one another. The gauge measurements were
 225 converted to a consistent unit (m^3/s) and ~~were~~ then manually compared with GRDC measurements
 226 to ensure accurate unit conversion (Riggs et al., 2023). Gauge databases compiled in this study are
 227 available through a variety of web interfaces, except for the CHP Chinese Hydrology Project (CHP)
 228 data which is provided by the authors of the dataset (Henck et al 2010, Schmidt et al 2011), and
 229 processed into annual scale data that meets the requirements of the synthesis dataset.

Table 3 Gauge data sources used in this analysis. N1 and N2 refers to numbers of gauges with observations after 1979 and used in GSHA. The starting and ending years (Y1 and Y2) of GSHA gauges for each agency are listed.

230 **3.2.3 Watershed delineation**

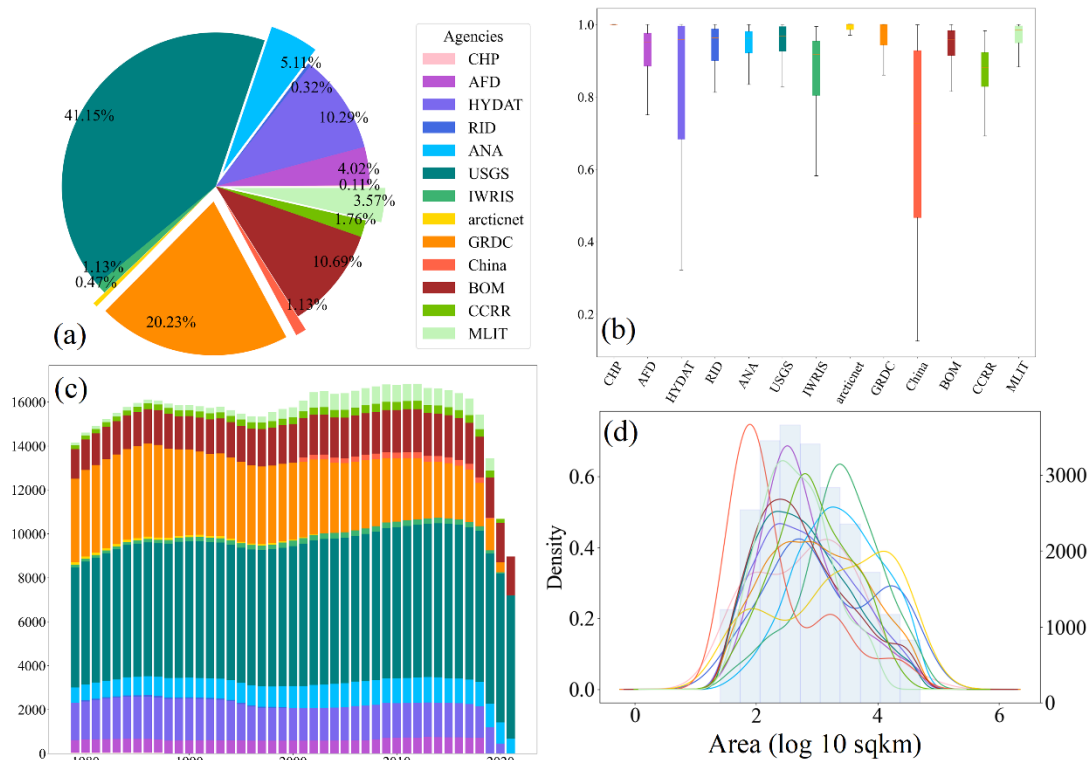

231 The watershed delineation process *iswas* built upon a vector-based global river network dataset
 232 (Lin et al., 2021), which is delineated from the 90-m Multi-Error-Removed Improved Terrain
 233 (MERIT) digital elevation model (DEM) (Yamazaki et al., 2017) and the flow direction and flow
 234 accumulation rasters (Yamazaki et al., 2019). The locations of the gauges may contain locational
 235 errors and direct delineation will result into erroneous watershed boundaries; therefore, gauge
 236 location correction was conducted by relocating the gauges to the nearest MERIT-based river reach
 237 vertices. The adjusted gauge points *arewere* used as the watershed outlets, where the contributing
 238 areas *arewere* extracted by dissolving all upstream catchments based on the topology provided by
 239 MERIT Basins (Lin et al., 2019). Since the area threshold of MERIT Basins is 25 km², we *dedid*
 240 not include watersheds smaller than this threshold. Considering the spatial heterogeneity of very
 241 large basins, we excluded watersheds $\geq 50,000$ km² from the dataset. To ensure GSHA *to*
 242 *support* studies with sufficiently long records, only watersheds with >5 years of
 243 observations since 1979 were selected. For gauges sharing the same watershed, the one with better
 244 data quality (i.e., longer measurement records and more valid observation days) *iswas* used. If the
 245 two gauges share the same quality, we only included the furthest downstream gauge. Eventually, the
 246 selection processes resulted in 21568 valid watersheds out of 35970 gauges initially scraped from
 247 *the* web plus 527 gauges from the Chinese National Real-time Rain and Water Situation Database
 248 (Figure 2).

249
 250 **Figure 2 Spatial distribution of the GSHA gauges (n=21568).** Watershed areas are represented by the
 251 tint of colours. Gauges of different agencies are represented with separate colours and are plotted in
 252 individual frames (except for USGS gauges in two frames to incorporate Alaska). The agency names and
 253 the upper-left coordinates (longitude, latitude) of each frame are also shown in the figure.

254
 255 The GSHA watersheds are unevenly distributed across the globe, more than half of which are

256 located in North America (USGS, HYDAT, and a large proportion of GRDC gauges, **Figure 3a**).
 257 Europe, Australia, and South America also have a relatively good coverage, while Asia and Africa
 258 show the lowest gauge densities. The majority of the gauged watersheds are of medium sizes ranging
 259 from 250 to 2500 km², although for some agencies it does not show the same distribution (**Figure**
 260 **3d**). For instance, ANA (South America), IWRIS (India), and arcticnet (Northern Eurasia)
 261 watersheds are generally larger, while the Chinese National Real-time Rain and Water Situation
 262 Database provides more gauges with smaller drainage areas. Due to the maintenance difficulties,
 263 the ~~numbers~~ number of functioning gauges ~~are~~ is declining for agencies like GRDC, but the lack of
 264 data in recent years (**Figure 3c**) ~~are~~ is mainly due to latency issues. USGS, BOM, and ANA provide
 265 a stable number of observations for the 1980-2021 period (**Figure 3c**) with high proportions of valid
 266 observations each year (**Figure 3b**), while observational periods from arcticnet and China contain
 267 relatively fewer valid samples (**Figure 3b**) and shorter time spans (**Figure 3c**).

268 **Figure 3 Summary statistics of the GSHA gauges.** This includes (a) proportions of gauges from
 269 different agencies, (b) box plots for proportions of valid observations for each agency, (c) proportion of
 270 valid observation for each year by agency and (d) distributions of watershed areas for each agency
 271 (kernel density estimation lines, left y-axis) and all gauges (blue histogram, right y-axis). The colour
 272 legend in subplot (a) applies to all four subplots. In subplot (a) the 0.11% label corresponds to CHP,
 273 and the legend goes counter clockwise in the pie chart. In subfigure (c), CHP bars are at the bottom of
 274 the plot, and the legend goes from bottom to the top of the bars.
 275

276 3.34 Meteorological variables, water storage terms, and land surface characteristics

277 After watershed delineation, publicly available grid or non-grid data were obtained and
 278 overlaid to derive the meteorological, water storage terms, and land surface characteristics. The data

279 sources used for GSHA are listed in **Table 4**. We prioritized the use of multi-source fusion datasets
 280 with relatively high quality surveyed from literature when creating GSHA.

281 3.34.1 Meteorology datasets

282 For precipitation, the Multi-Source Weighted-Ensemble Precipitation (MSWEP) that ~~have~~
 283 merged gauge measurements (CPC Unified), grid data (GPCC), satellite products (CMORPH,
 284 GSMaP-MVK, and TMPA 3B42RT), and reanalysis data (ERA-Interim and JRA-55) with sample
 285 density and comparative performance considered (Beck et al., 2017; Beck et al., 2019) ~~is used~~
 286 are included. Another ~~recent~~ precipitation dataset is the Ensemble Meteorological Dataset for Planet
 287 Earth (EM-Earth) deterministic estimates, which ~~merges~~merged a station-based Serially Complete
 288 Earth (SC-Earth) removing the temporal discontinuities in raw station observations and ERA5
 289 estimates (Tang et al., 2022). ~~The~~

290 For 2-m air temperature, the EUSTACE global land station daily air temperature dataset
 291 (EUSTACE) statistically merged station and satellite observations to obtain global daily near-
 292 surface air temperature (Brugnara et al., 2019), ~~and is used as a source for 2-m temperature in~~
 293 GSHA, is included. Other datasets used for 2-m temperature extraction are the reanalysis datasets
 294 Modern-Era Retrospective analysis for Research and Applications Version 2 (MERRA-2) (Gelaro
 295 et al., 2017) ~~by NASA's Global Modelling and Assimilation Office (GMAO) and the land~~
 296 ~~components of the European Centre for Medium-Range Weather Forecasts (ECMWF) fifth~~
 297 generation of European Reanalysis (ERA5) dataset land component (Muñoz-Sabater et al., 2021).
 298 ~~These reanalysis datasets are also used in extracting long- and shortwave radiation, as well as u- and~~
 299 ~~v-components of wind. MERRA-2 uses, produced by NASA's Global Modelling and Assimilation~~
 300 Office (GMAO), used the Goddard Earth Observing System (GEOS) model and analysis scheme,
 301 and assimilated the latest observations. ~~The land surface model used in ERA5 reanalysis is~~
 302 was developed by the European Centre for Medium-Range Weather Forecasts (ECMWF) using the
 303 Carbon Hydrology-Tiled ECMWF Scheme for Surface Exchanges over Land (CHTESSEL) driven
 304 by the downscaled meteorological forcing from the ERA5 climate reanalysis (Hersbach et al., 2020).
 305 These reanalysis datasets are also used in extracting long- and shortwave radiation, as well as u- and
 306 v-components of wind.

307 For AET, the REA dataset ~~merging, which used the reliability ensemble averaging (REA)~~
 308 method to merge ERA5, Global Land Data Assimilation System Version 2 (GLDAS2), and
 309 MERRA-2 ~~using the reliability ensemble averaging (REA) method~~ is used (Lu et al., 2021), ~~together~~
 310 ~~with). Another AET data source is~~ the product of the Global Land Evaporation Amsterdam Model
 311 (GLEAM) based on satellite observations of surface net radiation and near-surface air temperature
 312 (Martens et al., 2017). For PET, GLEAM is also incorporated. Another PET dataset for GSHA is
 313 ~~the~~an hourly PET at 0.1° resolution for the global land surface ~~from 1981 present (hPET) dataset~~
 314 calculated from ERA5-land wind speed, air and dew point temperature, net radiation components,
 315 and surface air pressure (Singer et al., 2021).

316 3.34.2 Water storage term datasets

317 ERA5-land data ~~was~~is also applied in extracting soil moisture for 4 soil layers, as well as snow

318 water equivalence. For groundwater, an assimilation dataset from ~~the~~ NASA's Gravity Recovery
 319 and Climate Experiment (GRACE) and its follow-on mission (GRACE-FO) is used (Li et al., 2019).
 320 The dataset merged water storage derived from GRACE satellite products into ECMWF Integrated
 321 Forecasting System meteorological data-forced NASA's Catchment land surface model (CLSM).
 322 The data is represented as groundwater drought indicator (GWI), which is the percentage of
 323 groundwater storage estimates from the GRACE data assimilation relative to the climatology
 324 (representing historical conditions), at weekly time scales from 2003-2021.

325 3.34.3 Land surface characteristic datasets

326 Global urban development for 1985-2015 is represented as the urban fraction in each watershed
 327 using the global annual urban dynamics (GAUD) at 30-m resolution. The dataset was derived from
 328 Landsat surface reflectance based on the Normalized Urban Areas Composite Index (NUACI) (Liu
 329 et al., 2020). For forest and cropland fractions, the Terra and Aqua combined Moderate Resolution
 330 Imaging Spectroradiometer (MODIS) Land Cover Type (MCD12Q1) land cover dataset, ~~was~~ used
 331 (Friedl et al., 2010). It covers 2001-2020 with a resolution of 500 m, and the categories used for
 332 GSHA ~~is~~ are the International Geosphere-Biosphere Programme classification (IGBP) forests and
 333 croplands. Another land cover is vegetation, which is represented by LAI obtained from the National
 334 Oceanic and Atmospheric Administration (NOAA) Climate Data Record (CDR) of Advanced Very
 335 High-Resolution Radiometer (AVHRR) product, which ~~relies~~ relied on artificial neural networks and
 336 AVH09C1 surface reflectance product (Claverie et al., 2016).

337 3.34.4 Dams and reservoirs

338 The newly published Georeferenced global Dams And Reservoirs (GeoDAR) dataset that
 339 ~~documents~~ documented the dam and reservoir construction years is used for building the temporally
 340 varying watershed reservoir capacity and DOR. GeoDAR georeferenced the International
 341 Commission on Large Dams (ICOLD) World Register of Dams (WRD), and geo-matched multi-
 342 source regional registers and geocoding descriptive attributes through the Google Maps API (Wang
 343 et al., 2022). The reservoir capacities are used together with the mean annual streamflow to obtain
 344 the DOR based on ~~the~~ equation $dor = SC/Q_{mean}$, where SC refers to reservoir storage capacity
 345 and Q_{mean} is the mean annual streamflow in the corresponding year.

346 3.34.5 Static variables

347 We matched GSHA river IDs and HydroATLAS river reach IDs to link the static attributes.
 348 HydroATLAS includes 56 variables for hydrology, physiography, climate, land cover & use, soils
 349 & geology, and anthropogenic influences for over 8.5 million river reaches globally.

351 **Table 4 Data sources used for the GSHA variables.**

Category	Dataset	Resolution	Interval	Reference
Meteorology	MSWEP	0.25°	Daily	(Beck et al., 2017; Beck et al., 2019)

	EM-Earth	0.1°	Daily	(Tang et al., 2022)
	ERA5-land	0.1°	Hourly	(Muñoz-Sabater, 2019)
	MERRA-2	0.5°* 0.625°	Hourly	(GMAO, 2015)
	EUSTACE	0.25°	Daily	(Brugnara et al., 2019)
	REA	0.25°	Daily	(Lu et al., 2021)
	GLEAM	0.25°	Daily	(Martens et al., 2017; Miralles et al., 2011)
	hPET	0.1°	Daily	(Singer et al., 2021)
Water storage terms	ERA5-land	0.1°	Hourly	(Muñoz-Sabater, 2019)
	GRACE-FO data assimilation	0.25°	Weekly	(Li et al., 2019; Zaitchik et al., 2008)
Land surface	GAUD	30 m	Yearly	(Huang, 2020)
	MCD12Q1	500 m	Yearly	(Friedl et al., 2019)
	CDR Leaf Area Index	0.05°	Daily	(Vermote et al., 2019)
Dam and reservoir	GeoDAR	NaN (polygon)	Yearly	(Wang et al., 2022)
Static Attributes	HydroATLAS	NaN (line)	NaN (static)	(Lehner et al., 2022; Linke et al., 2019)

352 3.4.5 Variable extraction methods

353 For grid data with relatively coarse spatial resolutions ($\geq 0.05^\circ$), we used an area-weighted
354 approach to ~~calculate the weighted average~~ extract the variable (Addor et al., 2017) based on the
355 proportion of the variable grid area contained in the basin boundary, while for high-resolution grid
356 data, we ~~extract~~ extracted the arithmetic mean directly. **Figure 4** shows the area-weighted average
357 approach we used for grid data with spatial resolution $\geq 0.05^\circ$ to reduce the influence of watershed
358 area on data uncertainty (Tang et al., 2022). The grid data (**4a**) and the quality-controlled watersheds
359 (**4b**) ~~are~~ were overlaid and all grids intersecting with the watershed ~~are~~ were obtained (**4c**). For each
360 intersected grid, the proportion of the polygon in the grid ~~is~~ was calculated as the weight (dark blue,
361 **4d**); the product of the weight and the corresponding grid value ~~is~~ was calculated over all intersected
362 grids (**4e**) and ~~are~~ were summed up as the weighted average (**4f**). For wind, the u- and v-wind
363 components ~~are~~ were first used to calculate wind speed, then the basin average ~~is~~ was calculated with
364 the weighted average approach. For grid data with a spatial resolution of $< 0.05^\circ$, the area-weighted
365 approach ~~is~~ was not adopted as it offers limited gains while becoming computationally too expensive.
366 For reservoirs, ~~they are~~ were used the reservoir polygons in GeoDAR, which were spatially joined to
367 GSHA watershed polygons, ~~and all~~ All the intersected reservoirs were considered contributory to
368 the management of the corresponding watershed and were used to calculate the total reservoir
369 storage capacity and degree of regulation.

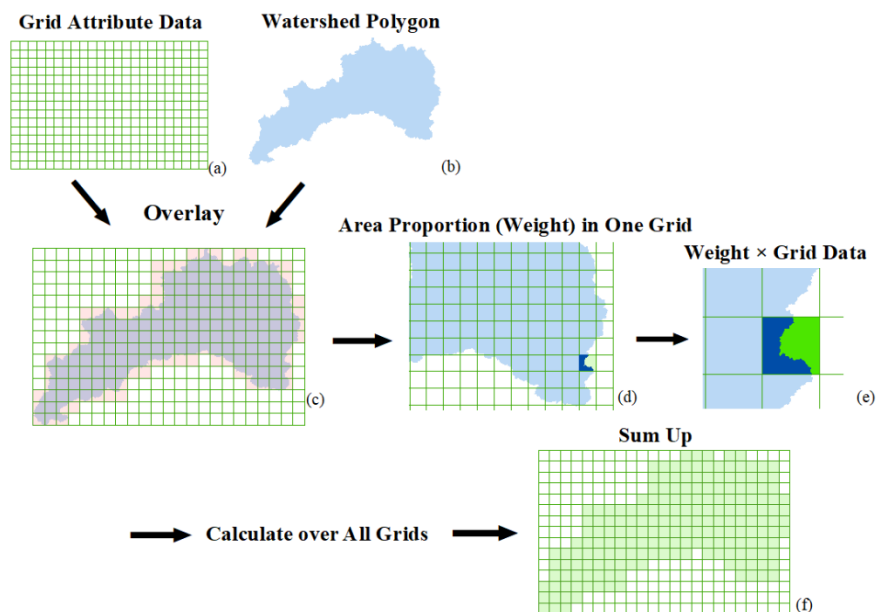

Figure 4 Determination of the area weights in extracting gridded data to GSHA watershed polygons. This weighted approach is applied to data at a resolution of $\geq 0.05^\circ$ but not for data at a finer spatial resolution due to computational costs.

3.5.6 Uncertainty estimates

For meteorological variables, uncertainty estimates are calculated using Eq. (1):

We also provided uncertainty estimates of the meteorological variables by calculating the long-term mean of each dataset in each watershed, where the discrepancy between the maximum and minimum among the data sources (X_{max} and X_{min}) as a percentage of their mean (\bar{X}) was used in the uncertainty estimation (see Eq. 1):

$$uncertainty = \frac{X_{max} - X_{min}}{\bar{X}} * 100\%, \quad (1)$$

where X_{max} and X_{min} are the maximum and minimum among the extracted values from the independent data sources. \bar{X} is the mean of values from all datasets. The uncertainty ranges from 0 to 200%. Note that for some of our data sources such as EC Earth, uncertainty estimates are intrinsically provided, but here we do not include it into GSHA as we consider the uncertainty estimates made from independent data sources more internally consistent among different variables.

3.6 Validation

3.7 Validation

After delineation, we validated our watershed areas with officially reported watershed areas from BOM, HYDAT, and GRDC by matching GSHA watersheds by their agency IDs. We set the

391 criteria of mismatched watersheds as (1) the area difference being over +20% of the officially
 392 reported area, and (2) the area ratio being less than 0.1 or over 10 times the reported areas. Since
 393 not all agency websites reported watershed areas, thus we added a flag field in the attributes as
 394 “unverified”, “verified match”, and “verified mismatch” to allow users to filter the watersheds
 395 flexibly and avoid putting the samples in the dataset under an unfair standard.

396 Postprocessing of the extracted variables ~~include~~includes the unification of units and manual
 397 quality checks. For streamflow characteristics, we validated three of our indices against GSIM for
 398 its global coverage, including the mean annual streamflow, ~~10th~~10th and ~~90th~~90th percentiles. The
 399 spatial joint between GSHA and GSIM gauges in a 10 km buffer zone was performed, and only the
 400 GSIM gauge with a minimum distance and watershed area difference $\leq 5\%$ to a GSHA gauge ~~iswas~~
 401 considered. Pairs with 0 measurements were excluded and 9835 pairs were involved eventually. We
 402 plotted the scatter plot of GSHA-GSIM mean flow, 10th and 90th percentiles, and compared the
 403 fitting line to the 1:1 line, with correlation coefficients calculated (see Section 4.1).

404 We also validated precipitation, potential ET_p and 2 m air temperature with the regional
 405 CAMELS-US dataset. We ~~compare~~compared the Daymet meteorological variables of CAMELS
 406 and the mean of GSHA variables for ~~the~~ validation. Since we ~~include~~included ERA5 data for most
 407 of our variables directly or indirectly as the data source, while Caravan consistently used ERA5, we
 408 did not use Caravan for the global validation as it is not considered as fully independent from GSHA.
 409 The spatial match ~~iswas~~ the same as we did for GSIM which resulted in 906 pairs. This number
 410 ~~iswas~~ larger than the total CAMELS gauge numbers as some gauges might be repeatedly paired due
 411 to location bias of the USGS gauges and MERIT river networks, as well as the adjacency between
 412 gauges of different agencies. Similarly, scatter plots and correlation coefficients are provided for
 413 assessment.

414 3.7.8 Watershed classification and change detection

415 We classified the watersheds as natural and human-~~managed~~ to analyse the influence of human
 416 water management. A watershed is classified as a natural watershed if it satisfies the following: (1)
 417 DOR is smaller than 10%; (2) the urban extent is less than 5%; and (3) the sum of urban and cropland
 418 fractions is smaller than 10% (L. Yang et al., 2021; Zhang et al., 2023). The classification was
 419 performed for 2001-2015, and the changing patterns of the watersheds are divided into six categories:
 420 (1) natural (N) when the watershed remained natural for all 15 years; (2) human managed (H) when
 421 the watershed remained human managed for all 15 years; (3) natural to human managed (NH) when
 422 the watershed was first natural in 2001, but changed to and maintained human managed later; and
 423 (4) human managed to natural (HN) when the watershed was first human managed in 2001, but
 424 changed to and maintained natural later.

425 4 Results

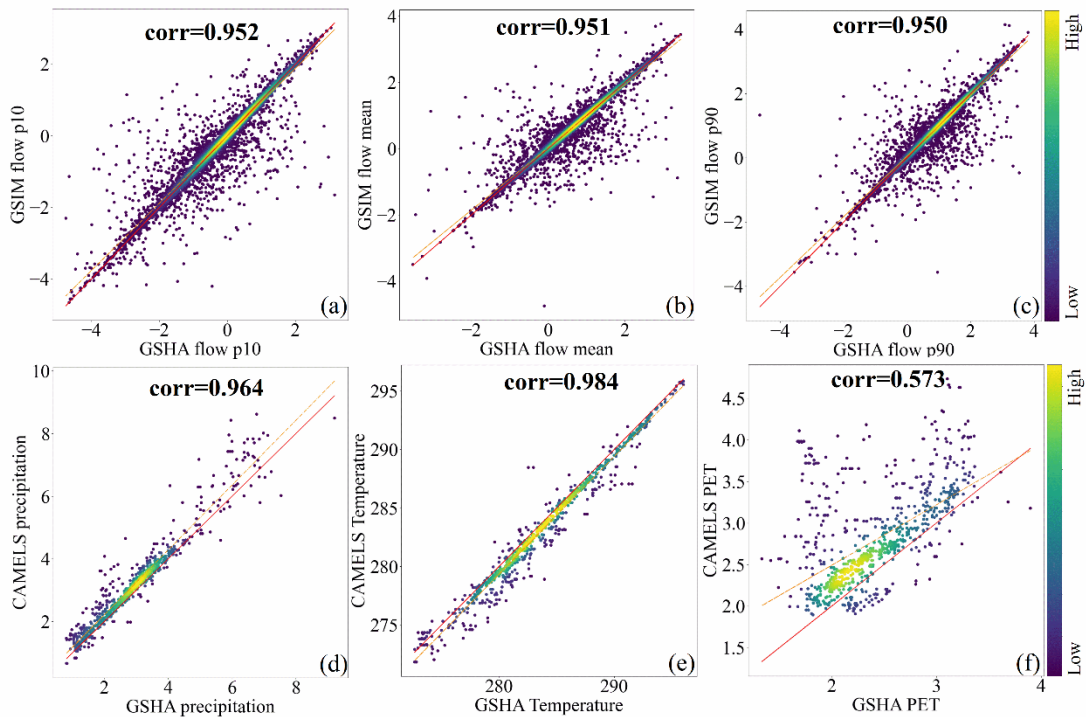

426 As previous studies have already revealed the spatial patterns of the LSH hydrometeorological
 427 variables both locally and globally, ~~therefore~~—here we put the spatial patterns of GSHA

428 meteorological variables and streamflow indices in **Appendix A**, while we focus on using the
 429 Results section to reveal the uniqueness of GSHA, ~~which includes~~. These include a technical
 430 validation of GSHA, uncertainty analysis, and the temporal change of watershed human
 431 management levels.

432 **4.1 Technical validation**

433 The validation result figures of watershed areas are in **Appendix B** since we focused more on
 434 the variables and already added the validity results in the dataset as “unverified”, “verified match”,
 435 and “verified mismatch” fields in the dataset. Under our criterion of filtering “mismatch” watersheds,
 436 1.9% of BOM watersheds, 4.7% of HYDAT watersheds and 8.9% of GRDC watersheds are
 437 mismatched. After removing these watersheds, correlation coefficients between GSHA and the
 438 agencies can reach 0.99, which verified the correctness of our watershed delineation and data
 439 extraction approach.

440 **Figure 5** illustrates the validation results of GSHA. **Figures 5a–5c** show streamflow indices
 441 as validated against GSIM globally, and **Figures 5d–5f** show meteorological ~~variable~~ variables as
 442 validated against Daymet from CONUS CAMELS. For streamflow indices, precipitation, and
 443 temperature, the correlation coefficients exceed 0.95 (significance $p < 0.01$), and the fitting lines are
 444 close to the 1:1 line, indicating high consistencies between GSHA and the reference datasets. For
 445 PET, however, the coefficient is low, at only 0.573 (significance $p < 0.05$), and the CAMELS PET is
 446 generally higher than GSHA ensemble, which is possibly ascribed to the high uncertainty among
 447 PET datasets that is yet to be fully resolved (Singer et al., 2021) (see **Appendix B–C**). Note that
 448 the gauge pairing might bring a small proportion of wrong pairs for some very close gauges, and
 449 differences in temporal ranges of GSHA and GSIM might cause some discrepancies for observed
 450 streamflow.

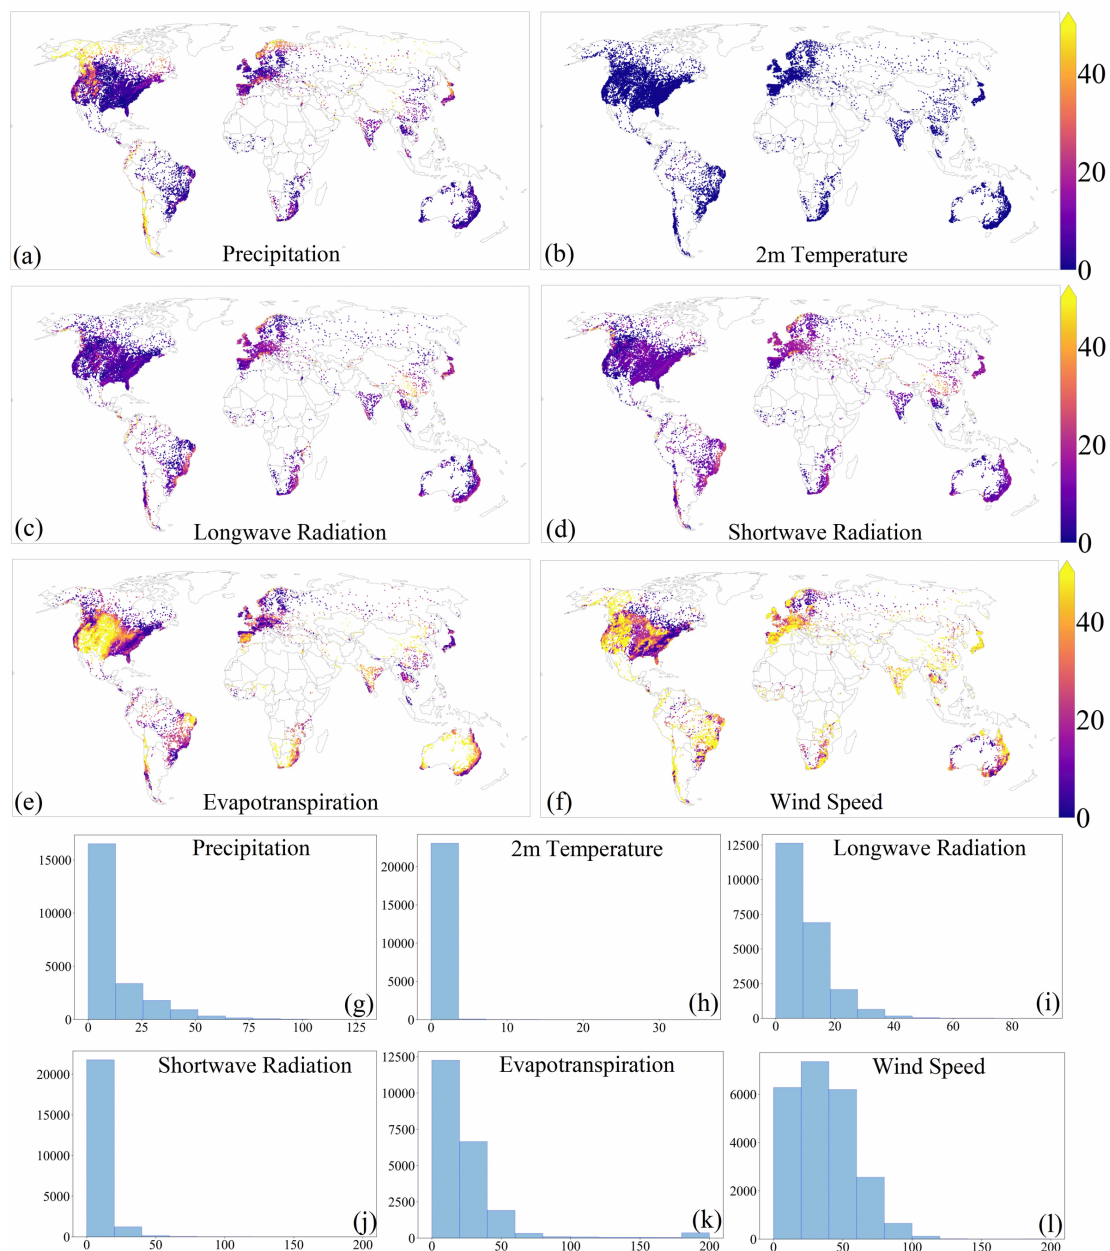

451 **Figure 5 Validation of GSHA with GSIM streamflow characteristics ((a), (b) and (c)), and**
 452

453 **CAMELS meteorological variables ((d), (e) and (f)).** ‘Corr’ in the subfigure is the Pearson correlation
 454 coefficient. The red line is the 1:1 line, while the orange dotted line is the fitting line of the scatter points.
 455 The colour bar represents density of the sample points. The unit of X and Y axes in (a), (b), and (c) is
 456 $\log_{10} \text{m}^3/\text{s}$.

457 4.2 Uncertainty patterns for the GSHA meteorological variables

458 **Figure 6** shows the distributions of the uncertainties for different variables, and the colour bars
 459 are unified to allow for comparisons between different variables.

460

461 **Figure 6 Global patterns of the uncertainty for the GSHA meteorological variables (in percentage).**

462 This includes the uncertainty (a) for precipitation (mm/day), (b) 2-m temperature (K), (c) longwave
 463 radiation (W/m^2), (d) shortwave radiation (W/m^2), (e) evapotranspiration (mm/day), and (f) wind speed
 464 (m/s), and (g) the uncertainty histogram for precipitation, (h) 2-m temperature, (i) longwave radiation,

465 (j) shortwave radiation, (k) evapotranspiration, and (l) wind speed.

466

467 Generally, among all variables, air temperature (**Figures 6b & 6h**) shows the minimum
468 uncertainty (<5%), ~~while the~~ suggesting high consistency of air temperature estimates from different
469 datasets. The uncertainty for wind speed (**Figure 6f**) is the highest among all variables. Uncertainties
470 for other variables show strong spatial variability. For example, uncertainties for precipitation are
471 high in high-latitude or mountainous areas like the Rocky Mountains, northern Europe, the Alps,
472 and the Andes areas (**Figure 6a**). This is reasonable because limited accessibility to in-situ
473 observations and the misestimation of snow (Schreiner-McGraw & Ajami, 2020) can contribute to
474 ~~the~~ precipitation estimation errors, while the data sources show relatively high consistency
475 (*uncertainty* $\leq 25\%$) in other parts of the world (**Figure 6g**). For radiation, as solar/shortwave
476 radiation is largely affected by sky conditions, ~~thus~~ uncertainties are high in regions with less clear
477 sky, including south-west China and its surrounding areas, high latitude regions of the northern
478 hemisphere, and Europe (Brun et al., 2022). These places are also subject to high thermal/longwave
479 radiation uncertainties for similar reasons (**Figure 6c**). Land cover including vegetation and
480 artificial surface, is another factor influencing surface net radiation through the albedo effect (Hu et
481 al., 2017), thus for heavily vegetated and urbanized areas, such as the Amazon region and east
482 coastal Australia, uncertainties for both longwave and shortwave fluxes are also relatively high.
483 Nevertheless, **Figures 6i & 6j** demonstrate that for the majority of watersheds, radiation
484 uncertainties are < 25%, indicating that the radiation data sources are generally consistent ~~to~~ with
485 each other. ET uncertainties are generally larger than the above variables (**Figures 6e & 6k**), and
486 are particularly prominent in dry areas of the globe, e.g., central North America, northern Andes,
487 central Asia, and Australia's grasslands and deserts. It is also prominent in agriculture intensive
488 regions like India and the northern part of China (Sörensson & Ruscica, 2018), where ~~the~~
489 agricultural irrigation may be the contributing factor to the ET uncertainty. The spatial distributions
490 of wind speed do not seem to show clear regional patterns (**Figure 6f**), and uncertainty values of
491 wind speed are generally larger over the majority of watersheds (**Figure 6l**). Nevertheless, the
492 uncertainties are low in ~~the~~ Appalachia and northern Europe, and are high in most parts of Brazil,
493 the Andes, Africa, eastern and southern parts of Asia, as well as Australia (**Figure 6f**). As we already
494 selected relatively high-quality datasets for the variables, these areas might be calling for more
495 attention by the LSH developers, while providing possible explanations for the inconsistencies in
496 interpreting results or understanding the challenges in estimating model parameters by the LSH
497 users.

498

499 **Figure 7 Relationship between variable uncertainties and watershed areas.** The markers indicate
 500 mean values of the variable uncertainties in watersheds smaller than the corresponding x-axis value. The
 501 error bars represent the range between 25 and 75 percentiles of the uncertainty values.

502

503 Apart from the spatial ~~characteristics~~patterns above, we also ~~investigate~~investigated the
 504 emergent patterns of the uncertainties. Existing studies indicate small basins can show larger
 505 uncertainties due to coarse resolution data inputs (Kauffeldt et al., 2013), while sub-grid variabilities
 506 might be offset by averaging over large watersheds. ~~Therefore,~~As we plotted the uncertainty against
 507 watershed areas in **Figure 7**, ~~which~~it verifies that for most variables, the uncertainty declines as the
 508 watershed area increases. ~~In addition to the general understanding,~~Figure 7 also reveals some
 509 interesting patterns. ~~The~~ which were rarely discussed in existing studies. For example, the most
 510 obvious decline ~~comes of data uncertainty with area came~~ from ET (green) and longwave radiation
 511 (red), both of which are). ET is highly dependent on ~~the land surface conditions and are~~and
 512 significantly affected by land surface spatial heterogeneity, thus ~~benefiting it~~benefits the most from
 513 spatial averaging for large river basins. Longwave radiation uncertainty (red) experiences a
 514 moderate decline, likely due to its linkage with land surface complexity and cloud conditions.
 515 Shortwave radiation and precipitation uncertainty show a similar decline pattern (blue and purple),
 516 which is possibly related to their strong ties to cloud covers. Temperature has a low uncertainty, and
 517 its relationship to watershed area is also not obvious. Wind speed uncertainty only declines slightly
 518 as the area increases, and ~~we believe this is~~may be because wind speed uncertainty can be traced
 519 back more to the atmospheric circulation patterns instead of ~~the~~ land surface conditions, thus
 520 showing a non-prominent relationship with watershed area. Overall, GSHA provides uncertainty
 521 estimates that capture these prominent patterns, which can be helpful to hydrologic modellers and
 522 users.

523 4.3 Natural and human managed watersheds and changing patterns

524 We also demonstrate the other key features of GSHA by categorizing global watersheds into
 525 natural and human-managed, and more prominently their temporal shifts in **Figure 8**. Overall, the
 526 majority of human-managed watersheds ~~loea~~are located in the US, Europe, and other regions
 527 with intensive industrial or agricultural activities such as East and South Asia (**Figures 8a and 8b**).
 528 During 2001-2015, 46.89% of the watersheds remained natural, while another 47.62% under human
 529 management in 2001 remained in the category throughout the study period (**Figure 8d**). Generally,
 530 the northern hemisphere has a larger proportion of human-managed watersheds, while watersheds
 531 in the less populated and urbanized southern hemisphere largely remain natural.

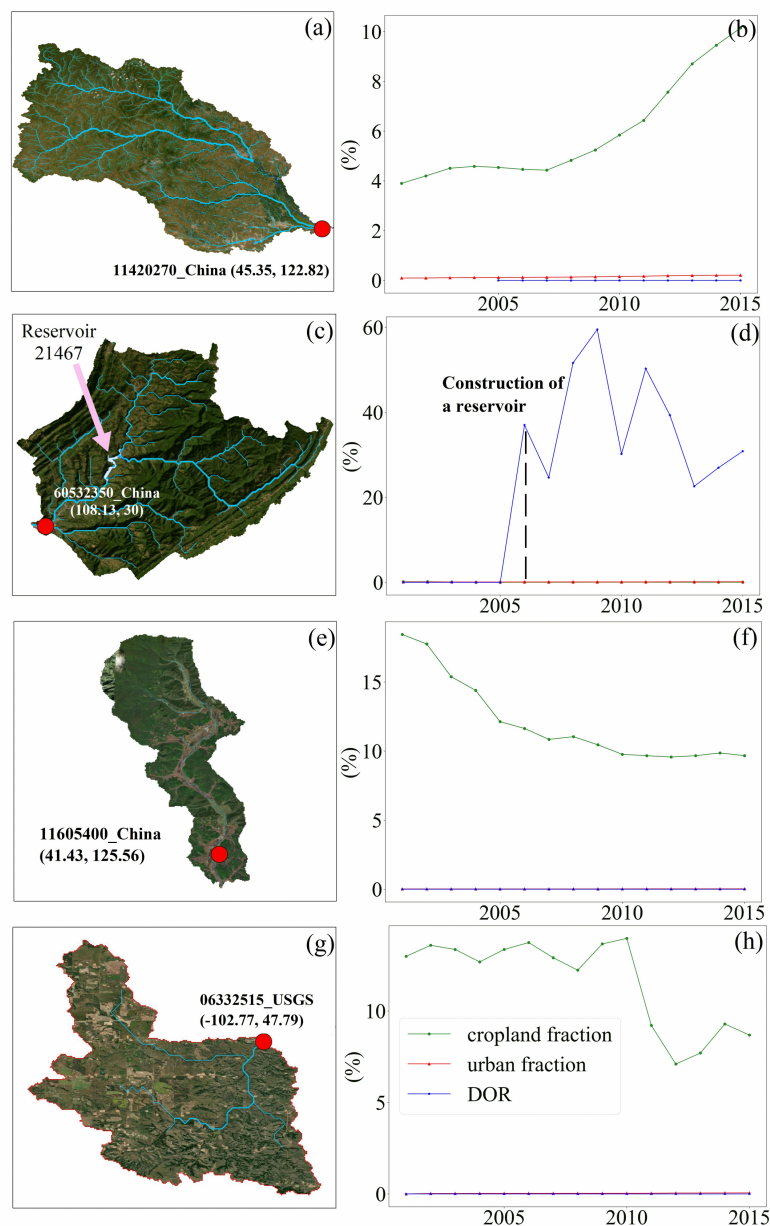

532 Noticeably, 4.36% of GSHA watersheds switched from natural to human-managed (1011
 533 watersheds), and the remaining 1.13% changed ~~backed~~back to natural states from human managed-
 534 during 2001-2015. For instance, watersheds in the middle and lower Yangtze River area ~~in~~and the
 535 north-eastern China show a shift from human-managed to natural state, where environmental
 536 projects for ecological restoration projects were in place (Qu et al., 2018; Zhang et al., 2015).
 537 Although the time span of GSHA LULC dynamics restricted the change detection for developed
 538 regionscountries as their urbanizations and infrastructure developments have long been completed,
 539 and for fast emerging economies after 2015, the time series arewere also missing; nevertheless, the
 540 changing human activities captured by GSHA may be helpful to understand the streamflow changes
 541 including flood characteristics (Long-Yang et al., 2021; Zhang et al., 2022).

542
 543 **Figure 8 Classification of natural and human managed watersheds in 2001 (a) and 2015 (b).**
 544 **Changes in watershed categories are illustrated by (c) and (d).** H and N in (c) and (d) represent
 545 watersheds that maintained human managed or natural from 2001-2015; NH and HN represent those
 546 changing from natural to human managed and from human managed to natural, respectively.

547
 548 We further useused several examples to illustrate the changing status of GSHA watersheds
 549 (**Figure 9**). **Figures 9a and 9b** show a watershed located in ~~Northeastern~~Northeast China, where

550 the rapid increase in cropland shifted the watershed from natural states to human-managed in recent
 551 years. **Figures 9c and 9d** correspond to a mountainous area in Sichuan Province, China, which
 552 became human-managed due to the construction of a reservoir in 2006. For another case in
 553 ~~Northeastern~~Northeast China (**Figures 9e and 9f**) and a USGS case (**Figures 9g and 9h**), the
 554 watersheds shifted from human-managed to natural, which is mainly manifested by the reduction
 555 in cropland fraction due to the environmental policy. For instance, afforestation during 2000-2010
 556 in Changbai Mountains where the watershed in **Figures 9e and 9f** is located, significantly increased
 557 the forest cover and might bring a decline in human disturbance in the form of land use (Zhang &
 558 Liang, 2014). These results highlight the shifting watershed status that would require further
 559 attention from LSH users, which is encapsulated in GSHA v1.0 and will be continuously improved
 560 in the future.

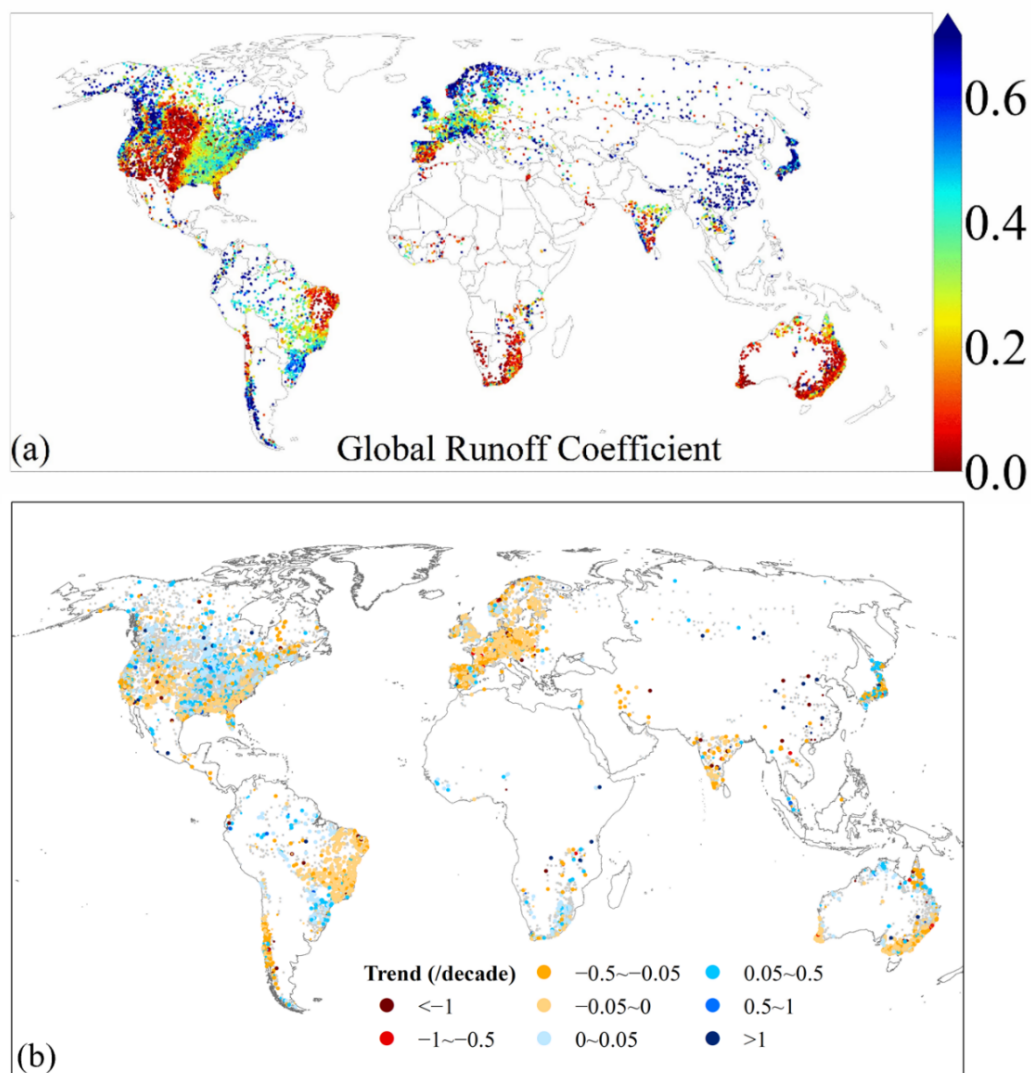

561
 562 **Figure 9 Cases for shifting status of the watershed classification.** (a) and (b) correspond to
 563 11420270_China, and (c) and (d) correspond to 60532350_China, both of which changed from natural

564 to human managed category. (e) and (f) represent 11605400_China, and (g) and (h) correspond to
 565 06332515_USGS watershed changing from human managed to natural watershed.

566 4.4 Changing runoff coefficient patterns derived from GSHA

567 Finally, we also analysed the ~~spatial global~~ pattern ~~and in the~~ trend of ~~global~~ runoff coefficient
 568 (RC), as a brief demonstration ~~of on~~ what GSHA can offer out of its many potential usages. RC is
 569 defined as R/P , where R denotes runoff (mm) and P denotes precipitation (mm) ~~in the~~
 570 ~~corresponding period~~. **Figure 10a** shows that, regions ~~where with high RC (i.e.,~~ a large proportion
 571 of rainfall goes into rivers instead of being evaporated or consumed ~~(i.e., high RC)~~ are in east Asia
 572 and North America, most parts of Europe, ~~the~~ west coast of North America and the Amazon, in
 573 general agreement with the aridity patterns across the globe. For arid/semiarid areas and places with
 574 intense water use (e.g., western US, eastern Brazil, Australia, Africa), RC is low, meaning most of
 575 the precipitation does not reach the gauged river.

576 ~~Interestingly, we show the RC trend for the past decades.~~ We found that RC generally remained
 577 stable ~~in most parts of for the world past decades~~ (i.e., grey dots, ~~in Figure 10b~~), ~~where~~; >80% of the
 578 gauges ~~did not show~~ observe a statistically significant trend), while 4252 watersheds observed a
 579 statistically significant trend ($p > 0.05$). ~~In total, 4252 watersheds demonstrate a 95% significant~~
 580 ~~trend in RC at 95% level~~ (5690 watersheds at a 90% ~~significance~~ level), ~~and among~~. Among them,
 581 decreasing RC is more widespread ~~compared to than~~ increasing RC. The most pronounced RC
 582 decreasing trends are observed in Europe, India, eastern Brazil, Chile, eastern Australia, and the
 583 Euphrates and Tigris, which largely correspond to regions with known ~~increasing intense~~ agricultural,
 584 industrial, and residential water use that may have reduced the river water. We ~~also found~~ note that
 585 the global RC trend patterns ~~are were~~ different from a recent study ~~showing that showed~~ mostly
 586 increasing RC in ~~the high-latitude watersheds latitudes~~, central North America, eastern Australia,
 587 and Europe, ~~which can largely be explained by the ET changes~~ (Xiong et al., 2022). ~~Here GSHA~~
 588 ~~reveals that RC trend~~ Given Xiong et al. (2022) used estimated runoff while we used runoff directly
 589 ~~from gauge observations, it is decreasing more widely than the increasing trend, which may be likely~~
 590 ~~that the concerning for the~~ water availability issues in ~~the context of increasing human water use~~
 591 ~~may not be fully captured by existing studies. Regional studies also tend to show inconsistent results.~~
 592 ~~For example, a changing study based on models incorporating climate, change and land use change~~
 593 ~~but ignoring human water consumptions suggested that deforestation and will warrant more future~~
 594 ~~research along this line.~~ urbanization generally increase RC (Lucas-Borja et al., 2020), while another
 595 study identified a significant decreasing trend for RC by focusing on cases with intense irrigational
 596 water use (Banasik and Hejduk, 2012). These collectively preclude a clear identification of
 597 consistent RC trends (Velpuri and Senay, 2013) and a clear causal factor attribution given the
 598 complexity of the anthropogenic factors. As such, GSHA may offer a new path to fill in the gap of
 599 disentangling the influences of large-scale water use on decreasing RC.

600
601
602
603
604
605
606
607

Figure 10 Patterns of runoff coefficient (a) and its trend (b). Only watersheds with statistically significant trend ($p<0.05$) are shown with colours in (b); the small and large sized points represent 95% ($p<0.05$) and 90% significance level ($p<0.1$), respectively. Note that the temporal coverage is different for different gauges; readers can refer to the GSHA temporal coverage for interpreting the patterns. The figure illustrates 18987 GSHA watersheds. Watersheds with less than 10 years of indices calculated from over 250 valid observations per year, as well as with runoff coefficient trend over 20 per decade, are not demonstrated in subfigure b.

608 5 Conclusions

609 Large sample hydrology (LSH) datasets play a critical role in data-driven analyses and model
610 parameter estimation for hydrological studies. From MOPEX (Duan et al., 2006) to Caravan
611 (Kratzert et al., 2023), significant efforts have been made to improve the comprehensiveness of LSH,
612 yet issues related to data spatial coverage, uncertainty estimates, and ~~the~~ human activity dynamics
613 ~~and the data spatial coverage~~ remain to be solved. This study ~~focuses on~~

614 ~~complementing~~complements existing LSH with a new synthesis dataset named the Global
 615 Streamflow characteristics, Hydrometeorology, and catchment Attributes for large sample river-
 616 centric studies (GSHA v1.01).

617 To summarize, GSHA contributes the following aspects to the LSH development:

- 618 1. It includes streamflow indices, hydrometeorological data, and surface characteristics data for
 619 21568 gauges compiled from 13 agencies worldwide, which represents one of the most
 620 comprehensive LSH by far.
- 621 2. We ~~incorporate~~incorporated multiple data sources to provide uncertainty estimates for each
 622 meteorological variable (including precipitation, 2 m air temperature, radiation, wind, and ET).
 623 The spatial patterns and the relationship between the uncertainty and the watershed
 624 characteristics ~~that~~ GSHA ~~revealed~~reveals may be helpful to identify inconsistencies among
 625 data-driven studies or biases for model parameter estimation studies using existing LSH.
- 626 3. Dynamic data are provided for previously static data descriptors for land cover changes
 627 including urban, cropland and forest fractions, as well as reservoir storage change including
 628 storage capacity and degree of regulation.

629 Although GSHA does not cover watersheds of <25km² or the dynamics of cryosphere variables
 630 (e.g., glacier and permafrost) that ~~have~~become increasingly important in terrestrial hydrological
 631 changes, and the time spans for the dynamic descriptors of LULC are unable to cover the critical
 632 periods for the advanced and less-advanced economies due to the constraints with existing LULC
 633 data, GSHA is ~~expected to be~~utilized to unravel the following insights:

- 634 1. The uncertainty patterns vary between variables and geographical regions, indicating that the
 635 interpretation of model and analysis results need to consider inconsistencies of raw data, apart
 636 from looking into the methodologies and patterns themselves.
- 637 2. Although most watersheds have remained natural or human managed throughout the GSHA
 638 time span, a considerable number of watersheds shifted between the two categories, which can
 639 be ascribed to urbanization, cropland increase, reservoir construction and ecological restoration
 640 such as returning farmland to natural states, and these can be clearly manifested using GSHA.
- 641 3. Analysis with runoff coefficient reveals that ~~while 80% of among~~ gauges ~~do not observe with~~
 642 a statistically significant trend, a greater portion ~~of gauges have~~experienced a declining RC
 643 trend than an increase trend. This pattern revealed by GSHA can be used to further study water
 644 availability issues in a changing climate.

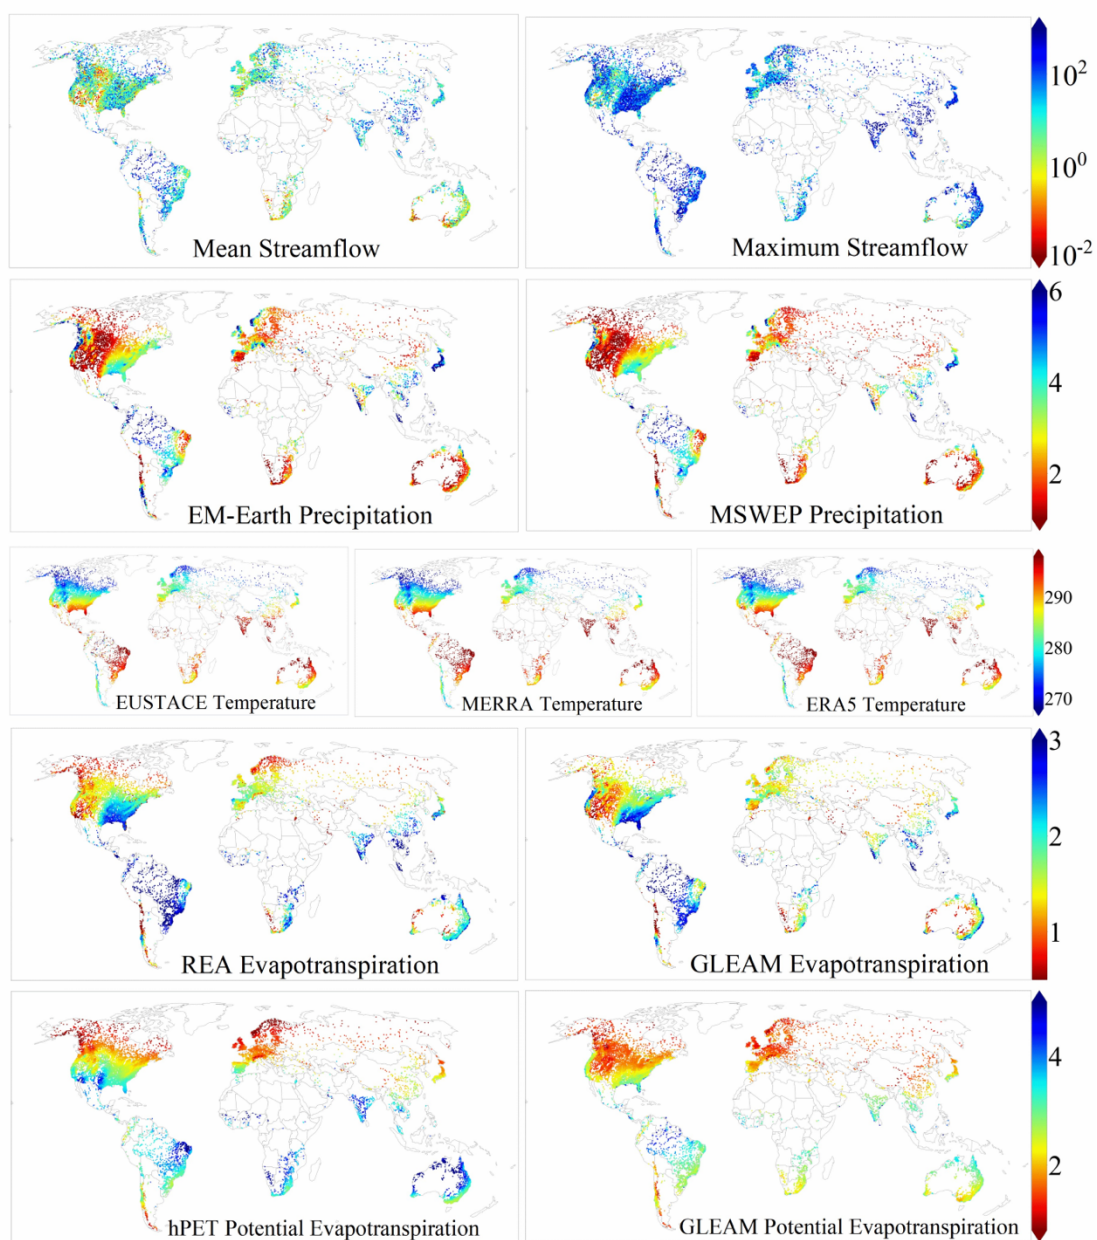

645 As our knowledge on the above processes continues to improve, we expect that future versions
 646 of GSHA will be continuously updated. Finally, better hydrological data sharing is crucial to
 647 advance global change hydrology studies.

648 Appendix

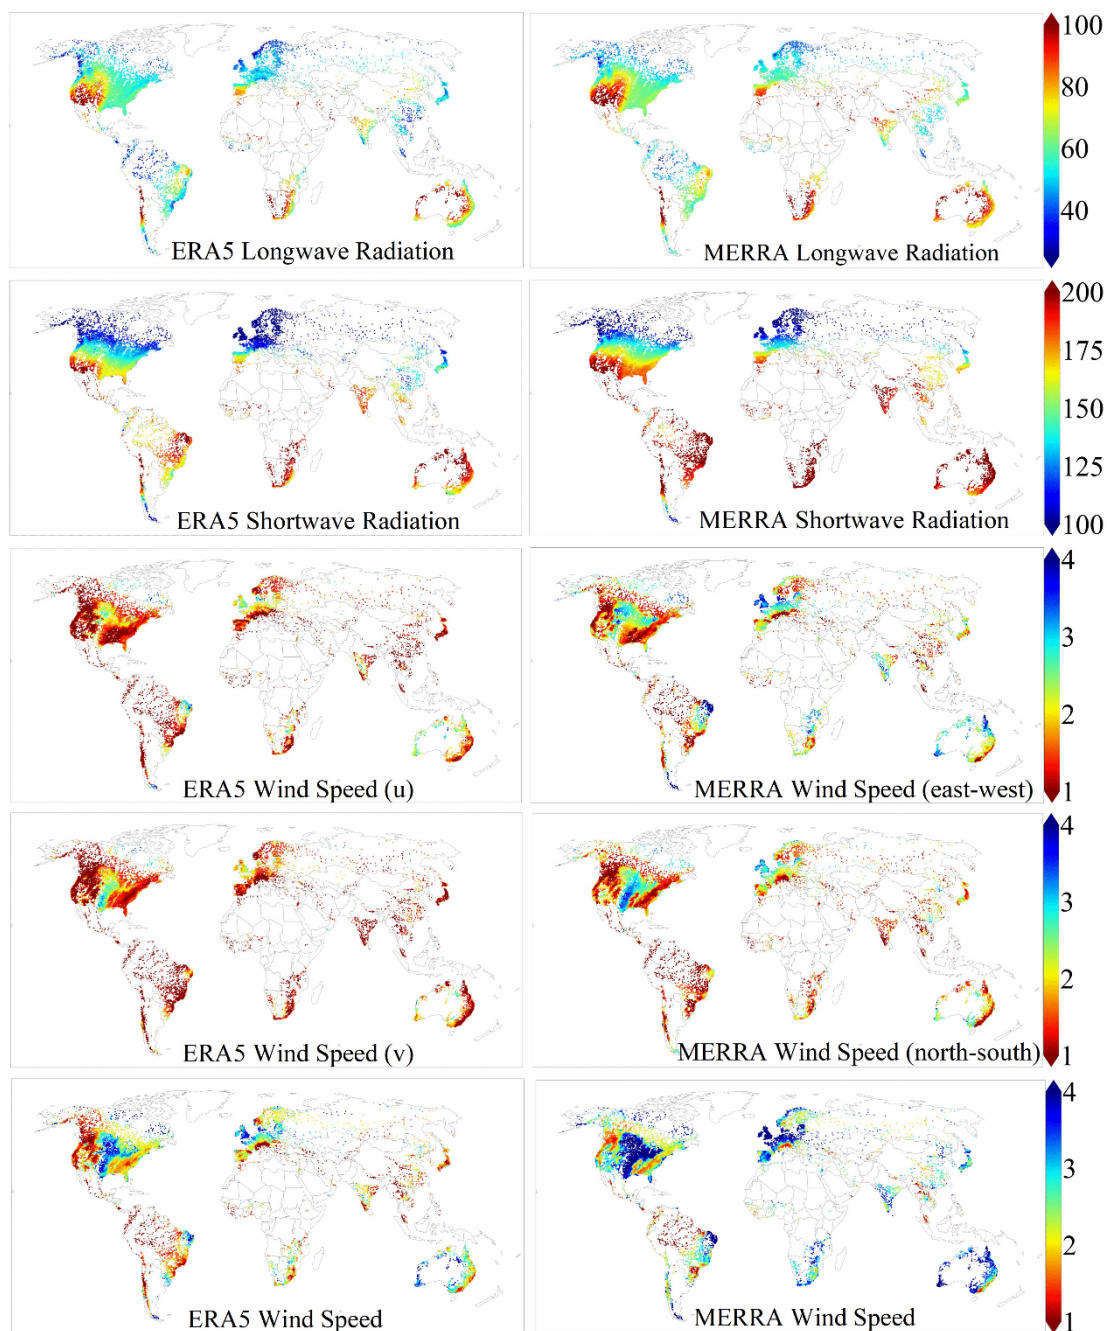

649 A. Spatial patterns of GSHA meteorological variables

650 **Figures A1 & A2** show the spatial distributions of GSHA meteorological variables and selected

651 streamflow indices. The spatial pattern derived from each individual data source is plotted separately.

652
 653 **Figure A1** Spatial distribution of streamflow indices (row 1, m^3/s), precipitation (row 2, mm/day), 2 m
 654 air temperature (row 3, K), actual ET (row 4, mm/day), potential ET (row 5, mm/day).

655

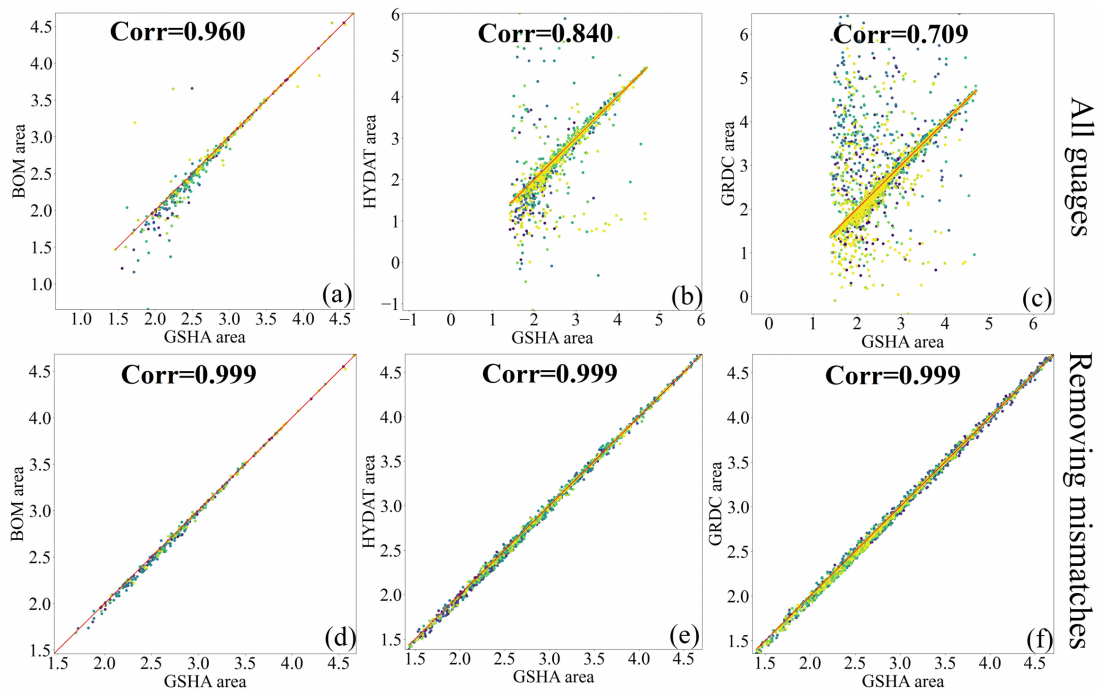

656 **Figure A 2** Spatial distribution of longwave radiation (row 1, W/m^2), shortwave radiation (row 2, W/m^2),
 657 wind u- (row 3, m/s) and v- components (row 4, m/s) and the wind speed (row 5, m/s).

658

659 **B. Validation results of watershed areas**

660 The validation results with BOM, HYDAT, and GRDC on watershed areas are plotted in
 661 Figure B1 and B2, where the mismatches between GSHA areas and the officially reported areas are
 662 shown. Before removing the mismatched watersheds, their correlation coefficients are 0.960, 0.840,
 663 0.709, respectively, as shown in Figure B1 (a), (b), (c). After removing the mismatched watersheds,
 664 correlation coefficients for all three agencies reach 0.999, as shown in Figure B1 (d), (e), (f). As we

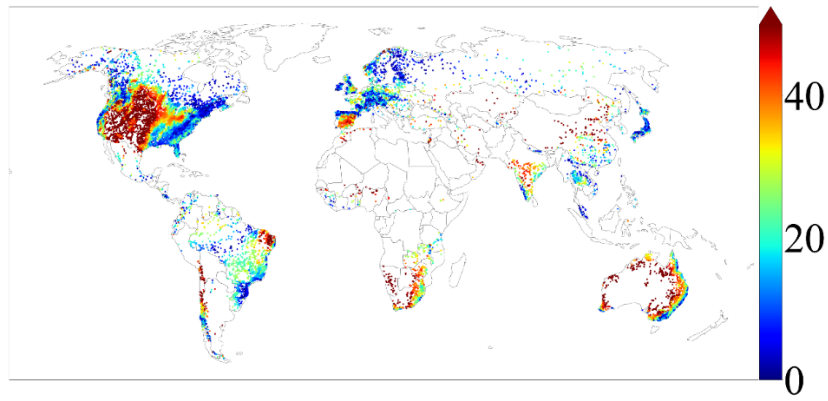

665 traced the MERIT Basins (Lin et al., 2019) for our watershed delineation, the mismatches are
 666 believed to occur when the gauge locates in the vicinity of the intersection point of a river reach and
 667 its main stream, which makes it difficult to decide which reach the gauge belongs to while matching
 668 the gauge to the MERIT river network. This explains why in **Figure B1** most of the mismatches
 669 appear at relatively small areas. As we do not have access to all official watershed areas, and **Figure**
 670 **B1 (a), (b), (c)** suggest that matching qualities differ among the agencies, to simply remove the
 671 mismatched watersheds or to modify them might put the samples in the dataset under an unfair
 672 standard. Additionally, some agencies such as GRDC experienced some updates of their gauge
 673 locations and upstream areas, thus watershed boundaries in all datasets mentioned might come with
 674 uncertainties. Therefore, we gave the watersheds as “unverified”, “verified match”, and “verified
 675 mismatch” identifiers to allow users to flexibly filter the watersheds.

676
 677 **Figure B1** Validation of GSHA with officially reported areas of BOM (a, d), HYDAT (b, e), and GRDC
 678 (c, f). Subfigures (a) to (c) are the results before removing the mismatched watersheds, and subfigures
 679 (d) to (f) represent results after removing the mismatched watersheds. The Pearson correlation coefficient
 680 are represented by “Corr” in the figure. The areas are represented by the unit of (log10 km²).

681 **B.C. Potential evapotranspiration uncertainty**

682 The spatial and numerical distributions of potential evapotranspiration (PET) uncertainties are
 683 illustrated in **Figure B4C1** and **Figure B2C2**. PET uncertainty is high compared with other
 684 variables (see 5.2 section). The majority of high PET uncertainty watersheds are in dry areas, but
 685 since it is calculated from meteorological variables, exceptions exist for places including eastern
 686 Pacific coast, where the climate is dry but PET uncertainty is low, and India, which is located in a
 687 wet climate zone but has high PET uncertainty. As demonstrated by **Figure B3C3**, PET uncertainty
 688 do not decrease with the increase of watershed area, probably because PET is calculated from
 689 various variables, and the calculation over large watersheds involves more uncertainties for
 690 individual grids.
