Abstract

Agricultural, fisheries, forestry and agro-processing activities produce large quantities of residues, by-products and waste materials every year. Inappropriate disposal and inefficient use of these resources contributes to greenhouse gas emissions and non-point pollution, imposing significant environmental and economic burdens to society. Since many nations do not keep statistics of these materials, it has not been possible to accurately quantify the amounts produced, their competing uses and the ~~amount~~ quantities potentially available for recycling at local level. Therefore, the objectives of the present work were to provide: (1) definitions, typologies and methods to aid consistent classification, estimation and reporting of the various residues and by-products; (2) a global organic matter database (OMD) of residues and by-products from agriculture, fisheries, forestry and related industries; and (3) regional and global estimates of residues and by-products potentially available for use in a circular bio-economy. To the best of our knowledge, the OMD is the first of its kind consolidating quantities and nutrient concentrations of residues and by-products from agriculture, fisheries, forestry and allied industries globally (available at: https://doi.org/10.5281/zenodo.10450921). The OMD will be continuously updated as new production data are published in FAOSTAT and country-specific ~~improved methods~~conversion coefficients become available. This information is expected to contribute to evidence-based policies and actions in support of sustainable utilization and the transition towards a circular economy. The database could be used for a variety of purposes including estimation of residue availability for soil amendment, livestock feed, bioenergy and other industrial applications, and assessment of environmental impacts of residue management practices such as soil application and burning. The estimates in OMD are available only at the national level. Due to the lack of uniform methodology, conversion coefficients and data on competing uses across countries, it was difficult to accurately estimate the quantities of all agricultural, fisheries and forestry residue and by-products. Therefore, we strongly recommend investment in the inventory of agricultural, fisheries and forestry residues, by-products and wastes at the national and sub-national levels for use in a circular bio-economy.

Keywords: Agro-processing; anaerobic digestate; biochar; bioeconomy; compost; manure

1. Introduction

Agricultural, fisheries, forestry and agro-processing activities produce large quantities of residues, by-products and waste materials every year (Gontard et al., 2018; Lopes and Ligabue-Braun, 2021; Millati et al., 2019). Some of these residues are already being used in a variety of effective ways, such as animal feed and bioenergy feedstock. However, a large proportion of the residues and by-products is either burnt or inappropriately disposed off, without further use (Domingues et al., 2017; FAO, 2022a; Venkatramanan et al., 2021). This has been widely documented to cause environmental pollution and spread of diseases. For example, manure produced in large-scale dairy, poultry and pig farms continue to cause non-point pollution where disposal is not well-regulated (Marin et al., 2023; Wang et al., 2017). Similarly, slaughterhouse residues and agro-processing wastes are often disposed of in open dumps and landfills, where they become a significant source of greenhouse gas (GHG) emissions (Mozhiarasi and Natarajan, 2022). Some of the wastes from slaughterhouses and agro-processing plants is discharged as effluents into water bodies (Al-Gheethi et al., 2021). The burning of crop residues is a major contributor to dangerously high levels of air pollution and emission of greenhouse gases (FAO, 2022a; Oanh et al., 2018; Venkatramanan et al., 2021). In 2019 alone, around 458 million tonnes of crop residues were burnt globally resulting in 1238 kilo tonnes of methane (CH_4) and 32 kilo tonnes of nitrous oxide (N_2O) emissions (FAO, 2022a). Burning agricultural residue also results in substantial losses of nutrients in the residue. For example, burning crop residues results in nearly complete loss of the organic carbon and nitrogen, and loss of 25% of the phosphorus, 20% of the potassium and 5–60% of the sulphur (Dobermann and Fairhurst, 2002). In addition to causing air pollution and respiratory ailments in human, burning also removes opportunities for adding value to crop residues (Lin and Begho, 2022; Oanh et al., 2018; Venkatramanan et al., 2021). Indeed, the inefficient use of agricultural residues and wastes imposes significant environmental and economic burdens to society (Gontard et al., 2018).

Conversely, a significant portion of these residues could enter a circular bio-economy, and their efficient use can ensure achievement of sustainability goals, through reduction of GHG emissions and non-point pollution.

Agricultural residues are used in many different ways including soil amendment, for animal feed and bedding, bioenergy generation, as fuel in industrial and domestic set-ups, mushroom production, industrial applications such as textiles, natural fibres, polymers, biosorbents and reinforcement material in composites (Siqueira et al., 2022; Smerald et al., 2023; Zhao et al., 2024; see also discussion under sections 4.1–4.4). A growing body of evidence suggests that currently unused residues could in principle be more effectively managed to increase soil fertility and productivity, and to mitigate greenhouse gas emissions (Lu et al., 2014; Liu et al., 2015).

Over the years, agriculture has increasingly depended on synthetic fertilizers to meet crop nutrient demands. The increased fertilizer use and inefficient fertilizer management practices have led to large nutrient losses to the environment in some regions (FAO, 2022b; Singh and Craswell, 2021). On the other hand, farmers in low-income countries have limited access to fertilizer inputs, and this has led to depletion of native soil nutrient stocks from croplands. Access to fertilizers has been further limited by the recent war by Russia on Ukraine, which disrupted a large portion of the global fertilizers supply. The resultant increases in prices are likely to constrain fertilizer use by farmers into the foreseeable future (FAO, 2022c; Behnassi and El Haiba, 2022). In 2020, the production and use of synthetic fertilizers resulted in GHG emissions of 1.0 Gt CO_2 equivalent, of which 62% (or 0.63 Gt CO_2) is emitted when nitrogen fertilizers are used on croplands (FAO, 2022d; Tubiello et al., 2022).

A growing body of evidence from meta-analyses suggests that the combined use of organic inputs and inorganic fertilizers can increase fertilizer use efficiency (Ba et al., 2022; Chivenge et al., 2011; Sileshi et al., 2019; Wang et al., 2020; Zhang et al., 2020; Melo et al., 2022). There is also a growing consensus that judicious use of agricultural residues can partially substitute for inorganic fertilizers (Fan et al., 2021; Huang et al. 2013; Zhang et al., 2020) and thereby contribute to enhancing the sustainability of food production by reducing costs and carbon footprints while reducing pollution caused by nitrate leaching (Zhang et al., 2020). The savings resulting from recycling agricultural residues and wastes can also be an important contribution to national and local economies. Recycling of organic residues, by-products and wastes can also address waste management problems and reduce GHG emissions from residues and wastes (Andrews et al., 2021; FAO, 2022a).

Yet, the potential contributions of agricultural, fisheries and forestry residues and by-products to soil health improvement and carbon management has not been estimated fully. This is largely due to a lack of country statistics on the production of residues and by-products from agriculture, fisheries and forestry, which makes it difficult to accurately quantify the amounts produced and available for recycling. The designation of residues as a resource, by-product or waste may also not always align with how the material is subsequently managed or its potential utility as a soil amendment. For example, livestock manure may be classified as a waste in some jurisdictions but not in others, whether or not it is subsequently used as an organic fertilizer. Importantly, a clear typology of residues and by-products also does not exist in many regions. This hinders the systematic documentation and reporting of the different categories of organic resources. Information is also scant on the quality of most of the residues produced. The quality of organic resource varies with the plant species, plant parts and their maturity level (Palm et al., 2001; Cobo et al., 2002), and determination of the quality attributes using traditional laboratory methods is both timely and costly (Shepherd et al., 2003). Despite these challenges, Palm et al. (2001) published an organic resource database containing data on plant species and plant part, resource quality, decomposition rates, N release rates, digestibility indices and site characteristics. Rapid plant nutrient analysis based on spectroscopic methods have been developed (Shepherd et al., 2003), and complemented with methods assessing functional differences (e.g., carbon and nitrogen release rates, digestibility) (Vanlauwe et al., 2005). Additional efforts to make this organic resource data useful included a decision support system for different categories of organic resources (Palm et al., 2001; Vanlauwe et al., 2005). A related effort is the Phyllis database developed by the Energy Research Centre of the Netherlands (ECN, 2018) primarily focussing on biomass properties that are relevant to bioenergy and biochar production. Data on primary crop and animal products are available through FAOSTAT, but equivalent data for quantities of residues are not available (Ludemann et al., 2023; Woolf, 2020).

In 2020 the Food and Agriculture Organization (FAO) of the United Nations commissioned a scoping study to assess the state of organic resource databases in the agriculture sector and related industries (Woolf, 2020). The study arrived at the following conclusions: (1) large uncertainties exists in the annual production of crop residues; (2) the fate and use of residues and wastes is poorly quantified in many regions of the world; (3) existing decision tools and classification schemes for residue biomass are not well suited for allocating resources amongst a comprehensive portfolio; (4) data on residue biomass composition and properties are diffuse, have large gaps, and rarely relate composition to production conditions; and (5) paucity of data on residue biomass production, composition and fate is a critical constraint on improving resource-use efficiency (Woolf, 2020). Further, the study recommended the development of a global biomass resource database to support sustainable development goals. Therefore, a global database providing estimates of the different residues and by-products is urgently needed for practitioners and policy-makers to quickly refer to when making decisions. Accordingly, the objectives of the present work were to provide: (1) definitions, typologies and methods to aid consistent classification, estimation and reporting of the various residues and by-products; (2) a global organic matter database of residues and by-products from agriculture, fisheries, forestry and related industries; and (3) regional and global estimates of residues and by-products potentially available for use in a circular bio-economy. Wherever possible, this work also tried to highlight the competing uses of the various residues and the challenges and opportunities for their use as soil amendments. The database could be used for a variety of purposes including estimation of availability of residues for livestock feed, soil amendment, bioenergy production, industrial applications, and assessment of environmental impacts (e.g., pollution, greenhouse gas emissions, nutrient flows) of residue management practices (e.g., residue retention, burning, and disposal).

2. Methods

To guide development of the OMD, a review of the literature was performed. This was aimed at identifying the various categories and a typology (systematic classification) of organic residues and by-products, their competing uses and the challenges and opportunities for their use as soil amendments. The review also aimed at identifying industry's best-practices and conversion factors for estimating agricultural, fisheries and forestry residues and agro-processing by-products.

2.1. Data used for creating the OMD

The OMD was designed to provide data on both quantity and quality of residues and by-products (Sileshi et al., 2024 available at: https://doi.org/10.5281/zenodo.10450921). Residue datasets were estimated from the FAOSTAT and FishStatJ databases. FAOSTAT provides free access to historical data on food, agriculture, forestry, trade, and land use for over 200 countries and territories. Data on production of primary crop and animal products were extracted from FAOSTAT's Crop and Livestock Products database (https://www.fao.org/faostat/en/#data/QCL), while data on forestry residues came from FAOSTAT's Forestry Production and Trade database (https://www.fao.org/faostat/en/#data/FO) (FAO, 2023). In the case of capture fisheries and aquaculture, production (in tonnes live weight) came from FAO's FishStatJ statistical software (https://www.fao.org/fishery/static/FishStatJ) for the periods 2015–2019 for selected species in each country/territory. In all cases, production refers to the total quantity produced per country in a given year.

Not only the quantity, but also the quality of residues, is important for their use in soil amendment. Therefore, a supplementary database was created consolidating data on the nutrient concentrations of various residues to complement the OMD. The concentrations of carbon, macronutrients (nitrogen, phosphorus, potassium), micronutrients (sulphur, calcium, magnesium), lignin, polyphenols and ratios for crop residues and manure were compiled from existing databases (e.g., Cornell Substrate Composition Table, FAOSTAT, Phyllis database), International Panel on Climate Change guidelines (IPCC) default values (IPCC, 2019) and the scientific literature (e.g., Ludemann et al., 2023 on crop residues, and Shen et al., 2015; Sileshi et al., 2017 on manure). Wherever available, the range of values (minimum and maximum) available in OMD and IPCC default values are summarized in Table 1. All values were reported on dry matter basis. The moisture contents of most residues have not been reported in the original publications and therefore values should be used with caution.

Table 1. Range of values (minimum and maximum) reported for the carbon, nitrogen (N), phosphorus (P), potassium (K), calcium (Ca) and magnesium (Mg) concentrations of crop residues and manure (on dry matter basis). Values were summarized from the OMD supplementary database described above.

Residue	Carbon (%)	Nitrogen (%)	C:N ratio	P (%)	K (%)	Ca (%)	Mg (%)
Barley straw	47	0.9* (0.5-0.7))		0.09-1.03	1.11-1.18		
Coconut shell	53	1.43	37	0.18	0.50	0.36	0.20
Cocoa beans		2.8		0.18	0.62		
Cocoa pod husks		0.75		0.23	1.02		
Groundnut straw	42	1.30	30	0.15-0.20	1.31-2.19	1.97	1.15
Groundnut hull	49	1.2-2.16	28	0.37	1.27	1.96	0.77
Maize stalks	55	0.81-1.26	69	0.15-0.37	1.20-1.61	0.35	0.48
Rice straw	45-61	0.64-1.69	78-88	0.05-0.11	1.16-2.10	0.42-1.2	0.3-0.52
Rice husk (hull)	39-52	0.48-0.70	70-106	0.11-0.46	0.28-1.3	0.21-0.34	0.09-0.40
Rice bran	50-55	2.0-2.4	18-22	3.60-4.47	1.43-2.45	0.13-0.35	1.11-1.78
Sorghum stalks	53	0.7* (0.7-1.4)	73	0.18-0.25	1.50-1.94	0.60	0.62
Soybean straw	51	0.8* (1.73-2.0)	40	0.14-0.19	0.97-1.63	0.18	0.15
Sugarcane bagasse	33-45	0.3-0.5	65.9	0.03	0.1	0.2	
Wheat straw	47-55	0.7* (0.3-1.4)		0.07	0.86-0.92		
Manure – dairy cows	4.3-61	2.9* (0.3-4.0)	16* (1-98.8)	0.01-3.2	0.03-6.1	0.02-3.5	0.01-1.9
Manure – swine	16-47	4.1* (0.9-4.4)	11* (8-26.1)	0.6-1.8	0.9-1.6	0.4-1.4	0.4-0.8
Manure – poultry	11-50	5.1* (0.5-6.8)	10* (6-37)	0.05-3.9	0.0-4.7	0.02-9.4	0.02-4.8
Manure – sheep and goats	15-49	3.3* (0.8-5.1)	11*	0.12-0.80	0.5-1.8	1.1-3.4	0.4-1.6

* Represents IPCC default values

2.2. Definitions and typology

The literature reviewed identified many sources of organic input that can be used for soil amendment. These include crop residues, agro-processing by-products, forestry and logging industry residues, manure, poultry and meat processing and fisheries and aquaculture by-products. Authors have used the terms ‘residue’, ‘by-product’, ‘co-product’, ‘waste’, when referring to the various organic resources. Therefore, it was necessary to provide clear definitions and typologies (systematic classification) to facilitate their consistent estimation and compilation in the OMD. A clear definition could only be found in relation to an existing EU directive (European Parliament and Council, 2008; 2008/98/EC), which was adopted herein. Accordingly, a “by-product” is defined as a substance or object whose primary aim is not the production of that item, whereas “waste” is defined as any substance or object which the holder discards, intends to discard, or is required to discard. According to the Directive, an object or substance should be regarded as a by-product only when certain conditions are met as specified under Article 5. In this paper, this norm was followed and the term “by-product” was consistently used to refer to side products originating from the food manufacturing stage. By-products may be products of either primary or secondary processing of crops and animals, which are available at breweries, wineries, milling and refining facilities or slaughterhouses and fish processing facilities (Lopes and Ligabue-Braun, 2021). Wastes were not included in the OMD as they consist of a wide variety of materials that may be required to be disposed of in accordance with local legislation. Crop residues, agro-processing by-products, manure and forestry residues were included in the OMD.

2.2.1. Crop residues

Crop residues were defined as plant parts left on the field after harvest including straw of cereals, pods and stems of legumes, tops, stalks, leaves, and shoots of tuber crops, oil crops, sugar crops, and vegetable crops, and pruning and litter of fruit and nut trees.

2.2.2. Agro-processing by-products

Agro-processing by-products were defined as products from the food and agriculture industry (Lopes and Ligabue-Braun, 2021). According to literature reviewed, the main sources of agro-processing by-products are cereal processing, sugar processing, breweries, the beverage industry, oil presses and bioenergy production, slaughterhouse by-products and fish processing by-products, which are further defined below.

2*.2.2.1. Cereal processing by-products*

Cereal processing by-products are defined here as the by-product of rice milling and the multi-stage process of flour production from cereals such as wheat, rice and maize. In the milling process of rice, the husk (hull), which is the outer cover of the grain, is removed. Further milling removes the bran resulting in white rice. Rice husk constitutes about 20% of the dry weight of rice grains (Singh, 2018). The bran is part of cereal grain that could be used in a further milling process or as a biorefinery feedstock (Caldeira et al., 2020).

2*.2.2.2. Sugar industry by-products*

The by-products from the sugar industry include bagasse, sugar beet pulp, molasses, and filter press mud, which are available at the milling and refining facilities. Bagasse is the fibrous residue remaining after the milling of cane stalks for juice extraction, and it is roughly 27–28% dry weight of the plant biomass (Bezerra and Ragauskas, 2016). The residue to product ratios (RPR) of bagasse was reported to vary from 0.14 to 1.16 (Koopmans and Koppejan (1998).

2*.2.2.3. Brewery and winery by-products*

Spent grain and grape pomace are the main by-product from the brewery and winery industry, respectively. Barley grain is the main raw material for beer, and ∼20 kg of wet brewer’s spent grains is produced per 100 litres of beer produced (Gonzalez-Garcia et al., 2018). Approximately 75% of grapes produced is intended for wine production, out of which 20–30% represents by- grape pomace consisting of the skin, pulp, seeds, and stalks (Antonić et al., 2020).

2*.2.2.4. Beverage industry by-products*

The beverage industry manufactures ready-to-drink products such as fruit juice, cocoa, coffee and tea-based products, soft drinks, energy drinks, milk products, nutritional beverages. The by-products of fruit processing include the peels, skin, rind and seeds. The main by-products of cocoa processing are cocoa pod husk, cocoa bean shells and cocoa mucilage. In the initial stage of cocoa processing, 70–80% of the fruit is discarded and, approximately ten tonnes of shells are generated for each tonne of cocoa (Dutra et al., 2023).

In making the coffee beverage, approximately 90% w/w dry matter of the coffee cherry is discarded in the form of husks, parchments, mucilage, silver skin and spent coffee grounds (Iriondo-DeHond et al., 2020). On wet weight basis, in 100 kg of mature coffee cherries, 39 kg corresponds to the skin and pulp and 22 kg of mucilage and about 39 kg of parchment is generated (Iriondo-DeHond et al., 2020).

2.*2.2.5. Oil processing by-products*

The main oil crops include oil palm, coconut, groundnut, soybeans and olives. By-products from palm oil mills include empty fruit bunches (EFB), palm oil mill effluent, decanter cake, seed shells and the fibre from the mesocarp. A hectare of oil palm produces 10–35 tonnes of fresh fruit bunch (FFB) per year on wet weight basis. EFB, fibber, shells and decanter cake account for 30, 6, 3 and 29% of the fresh fruit bunch (FFB), respectively (Embrandiri et al., 2012). EFB is the residue left after the processing of fresh fruit bunch at the mill. Palm press fibre (PPF) or mesocarp fibre is produced after pressing fruit or mesocarp to obtain oil. On average, for every tonne of FFB processed, 120 kg of fibre is produced on wet-weight basis (Embrandiri et al., 2012). Palm kernel shell (PKS) is difficult to decompose and it has been used as mulch. Decanter cake is another waste product used as either fertilizer or animal food. Palm oil mill effluent is the outcome of oil extraction, washing and cleaning processes in the mills. On wet weight basis, about 3 tonnes of oil mill effluent is produced for every tonne of oil extracted in an oil mill.

Coconuts consists of husks (33–35%), shell (12–15%) and copra (28–30%) on wet weight basis. According to Onwudike (1996) bout 2,220 kg of dry husks and 1,040 kg of dry shells become available per hectare per year. Lim (1986) gives figures of 5,280 kg of dry husks and 2,510 kg of dry shells per ha per year in large-scale estates. Copra production ranges from 0.5–1 tonnes per ha per year with traditional harvesting on small holdings to 3–9 tonnes per ha for improved clonal varieties and intensive management (Lim, 1986).

The processing of groundnut oil produces a large portion of peanut meal as a by-product, and skins and hulls. On wet-weight basis, a 1000 kg of peanuts can generate about 500–700 kg of peanut meal depending on the procedure of oil extraction (Zhao et al, 2012). An estimated 35–45 g of skin and 230–300 g of hulls are generated per kg of shelled groundnut kernel (Zhao et al, 2012). Soybean curd residue is the main by-product of soybean products, and about 1.1 kg of fresh curd residue is produced from every kilogram of soybeans processed into soymilk or tofu (Khare et al., 1995). The manufacturing process of the olive oil yields a semi-solid waste called olive cake (30%) and aqueous liquor (50%). About 10 g of olive cake is produced per kilogram of virgin olive oil processed (Masella et al., 2014).

2*.2.2.6. Bioenergy by-products*

The main routes in the production of bioenergy are pyrolysis and gasification and anaerobic digestion (Hamelin et al., 2019; Masoumi et al., 2021). The main bioenergy by-products with potential use in soil amendment include (1) biochar from thermochemical conversion with pyrolysis producing bio-oil and gasification producing syngas as the main product; (2) hydrochar from hydrothermal liquefaction with bio-oil as the main product; (3) digestate from anaerobic digestion with biogas as the main product; and (4) molasses from lignocellulosic ethanol production with bioethanol as the main product (Hamelin et al., 2019; Karan and Hamelin, 2021; Masoumi et al., 2021). Conversion of agricultural residues and by-products into biochar provides an option for better waste management and reducing the residue volume to be applied (Alkharabsheh et al., 2021). Biological methods such as digestion and composting do not reliably get rid of contaminants such as antibiotics, heavy metals and pathogens from agricultural and fisheries residues. Processing these materials into biochar, however, can destroy pathogens and pollutants such as hormones and antibiotics given the high temperatures during pyrolysis. In addition, biochar has been reported to control plant diseases (de Medeiros et al., 2021; Poveda et al., 2021).

Due to the need for drying the feedstock for pyrolysis that can be energy-intensive and costly for very wet feedstock, hydrothermal carbonization is considered as an alternative to pyrolysis. Hydrothermal carbonization is carried out at relatively lower temperatures of 80-240 °C, under subcritical water pressure (Padhye et al., 2022). The solid output of this process is called hydrochar (Masoumi et al., 2021; Padhye et al., 2022).

Biogas production involves anaerobic digestion of organic wastes to produce methane (Akbar et al., 2021; Ma et al., 2022). This process produces large quantities of digestate that can be used as soil amendment. Since anaerobic digestion deactivates pathogens (Ma et al., 2022), it is also safer than direct application biowaste. Due to increasing numbers of livestock feeding operations and the consequent increase in the number of large-scale biogas plants, huge quantities of digestate are produced in some regions. Digestate probably has more than 80% moisture, whereas hydrochar can have 20-50% moisture content.

2.2.2.7. Slaughterhouse by-products

Slaughterhouse by-products consist of poultry and meat processing by-products. The inedible parts of slaughtered animals vary with the species, ranging from 22% for turkey, 37% for broilers, 38-40% for pigs, 47% for sheep and goats, and 49% for cattle (Mozhiarasi and Natarajan, 2022).

2.2.2.8. Fish processing by-products

Fish processing by-products include the trimmings of fish either in aquaculture or capture fisheries, for example heads, frames, skin and tails. These materials may constitute up to 70% of fish and shellfish after processing. Depending on the market, some species are not processed at all, while others, especially larger fish, are often extensively transformed to fillets or parts of fillets. Fish fillet yield is species-dependent and is often in the range of 30–50% of the fish on wet weight basis.

2.2.3. Livestock manure

Livestock manure is defined here as the excreta of domestic animals (e.g., poultry, cows, sheep, horses, rabbits, etc.) including the plant material used as bedding for animals. Two major categories of manure source are recognized by the IPCC: manure management systems and manure left on pasture. Manure left on pasture is difficult to collect and therefore largely unavailable for use as soil amendment. In management systems, manure may be found in liquid (liquid or slurry) or solid form in cattle, pig and poultry farms. In such systems, cattle produce large quantities of manure, with dairy cows producing 62 kg per day or about 10% of the weight of an average cow on wet weight basis (EnviroStats, 2008). Feedlot cattle can generate manure about 5–6% of their body weight each day or a dry mass of roughly 5.5 kg per animal per day (Font-Palma, 2019). Full-grown milking cows can produce 7–8% of their body weight as manure per day or roughly 7.3 kg dry mass per animal per day (Font-Palma, 2019). Bulls, beef cows, steers, heifers and calves produce 42, 37, 26, 24 and 12 kg manure per animal per day, respectively (EnviroStats, 2008). Different categories of pigs produce 1–4 kg of manure per day, while poultry species produce less than 1 kg of manure per day.

2.2.4. Forestry residues

Forestry residues can be divided into primary and secondary residues (Karan and Hamelin, 2020). Primary residues are defined as residues that are left after logging operations (e.g., branches, stumps, treetops, bark, etc.), whereas secondary residues are by-products and co-products of industrial wood-processing operations (Karan and Hamelin, 2020). Primary residues were excluded from the OMD because they are often unavailable for agricultural use. Here, only wood residues were included. The FAOSTAT definition of wood residues covers wood that has passed through some form of processing but which also constitutes the raw material of a further process such as for particle board, fibreboard or energy purposes (FAO, 2022e). This excludes wood chips, made either directly in the forest from roundwood or made in the wood processing industry (i.e., already counted as pulpwood or wood chips and particles), and agglomerated products such as logs, briquettes, pellets or similar forms as well as post-consumer wood.

2.3. Estimating the quantities produced

Crop residue production is typically estimated from grain yield using the harvest index (Smerald et al., 2023). The challenge with this approach is that the harvest index varies widely in response to genetic, environmental and agronomic factors, and hence universally applicable harvest indices are lacking at the country level. As a result~~Due to the lack of databases on agricultural residues and by-products~~, practitioners often use residue to product ratios (RPR) to estimate residue biomass from data on production of primary products obtained from local statistics or global databases such as FAOSTAT and EUROSTAT (e.g., Bentsen et al., 2014; Bedoić et al., 2019; Karan and Hamelin, 2021; Ronzon and Piotrowski, 2017). The estimation is sometimes done assuming a mathematical relationship (e.g., linear, logarithmic, hyperbolic or exponential) between the primary crop yield and the residue yield (Bentsen et al., 2014; Ronzon and Piotrowski, 2017; Smerald et al., 2023). The disadvantage of the RPR is that it is constant over time and space for a given crop, whereas methods based on mathematical functions can be more flexible. In this work, the estimation of residues and by-products generally followed IPCC guidelines (IPCC, 2019) and the FAO guidelines in the Bioenergy and Food Security Rapid Appraisal user manual for crop and livestock residues (FAO, 2014).

In the case of crop residues, country-specific harvest indices or RPRs are not available for almost all countries. Therefore, the IPCC approach was used for estimating crop residues from harvested produce.~~In the case of crop residues, the~~ The IPCC provides two alternative methods for estimation of the aboveground crop residue yield ($AG_{DM(T)}$) in kg ha^{-1} on dry mass basis. The first method involves multiplying the harvested crop yield with the ratio of aboveground dry matter ($R_{AG(T)}$) provided in Table 11.A of IPCC (2019). The second method involves estimation of residue yields from crop yield using linear equations in Table 11.2 (IPCC, 2019). For any given ~~given ~~crop (T), the following two methods we~~a~~re ~~expressed as follows following~~available based on the exact IPCC notations:

First method: $AG_{\mathrm{DM(T)}} = Crop_{(T)} \times \mathrm{R}_{\mathrm{AG(T)}}$

Second method: $AG_{\mathrm{DM(T)}} = Crop_{(T)} \times Slope_{(T)} + Intercept_{(T)}$

The first method always yields a constant harvest index, and most of the times it yields larger than the typical values reported in the literature (e.g., Ludemann et al., 2023). For example, the IPCC default values of $\mathrm{R}_{\mathrm{AG(T)}} = 1$ and 1.2 for maize and barley yield harvest indices of 0.50 and 0.47, while the typical values are less than 0.47 and 0.41, respectively. As a result, the first method systematically underestimates residue production relative to the second method. The advantage of the second method is that it yields a more realistic harvest index commensurate with the grain yield achieved in a particular country and year. Therefore, the second method was chosen for estimating $AG_{\mathrm{DM(T)}}$ from $Crop_{(T)}$ in FAOSTAT for the period 2015-2020. Then, the total annual above-ground residue production ($AGR_{\mathrm{(T)}}$) was calculated for each crop (T) by multiplying $AG_{\mathrm{DM(T)}}$ by the harvested area available in FAOSTAT per country and year for maize, wheat, rice, barley, soybean and groundnut. The average values of six years (2015–2020) per country were summed across countries to provide annual aboveground residue production estimates ($\mathrm{AGR}_{\mathrm{(T)}}$) in tonnes on dry matter basis) for each region. Then these values were added to produce a global estimate of total residue production. The uncertainty around each estimate was expressed with 95% confidence limits (CLs). It is not possible to generate estimates such as the standard errors or 95% confidence limits of the sum of quantities using conventional statistical methods. Therefore, the 95% CLs were estimated using bias-corrected bootstrapping, a non-parametric method which involves random resampling of the sample totals (sum) with replacement.

Table 2. The IPCC equations used for estimation of above-ground crop residue yield ($AG_{DM(T)}$) in tonnes per ha) from grain yield ($Crop_{(T)}$ in tonnes per ha) from FAOSTAT, and IPCC default values for dry matter fraction of harvested product and dry matter fraction of aboveground crop residue.

Crop	IPCC equation for $AG_{DM(T)}$ †	IPCC default values	
		Dry matter fraction of harvested product ($R_{AGR(T)}$)†	Dry matter fraction of aboveground crop residue‡
Wheat	$0.52+1.51*Crop_{(T)}$	0.89	0.86
Maize	$0.61+1.03*Crop_{(T)}$	0.87	0.82
Oat	$0.89+0.91*Crop_{(T)}$	0.89	0.77
Barley	$0.59+0.98*Crop_{(T)}$	0.89	0.84
Rice	$2.46+0.95*Crop_{(T)}$	0.89	0.87
Millet	$0.14+1.43*Crop_{(T)}$	0.90	0.85
Sorghum	$1.33+0.88*Crop_{(T)}$	0.89	0.85
Rye	$0.88+1.09*Crop_{(T)}$	0.88	0.85
Groundnuts	$1.54+1.07*Crop_{(T)}$	0.94	0.90
Dry beans	$0.68+0.36*Crop_{(T)}$	0.91	--
Soybean	$1.35+0.93*Crop_{(T)}$	0.91	0.85

†These are all dry matter values at grain moisture contents of 9–13% or dry matter fraction of 0.87–0.91.

‡ Values are from Ludemann et al. (2023).

Production of agro-processing by-products is often estimated using country-specific ~~the RPR and related~~ coefficients following the FAO guidelines (FAO, 2014). Wherever available, these values defined as extraction rates, were obtained from FAO’s Technical Conversion Factors for Agricultural Commodities (FAO, 2009). When not available, average values from the literature were used for estimating the various by-products from the production data in FAOSTAT. For example, the median value of 0.29 from Koopmans and Koppejan (1998) was used to estimate bagasse from sugarcane.

Poultry processing by-products were estimated using country-specific ~~from the~~ take-off rates, dressed carcass weight (% of live weight) and stocks (heads) ~~using the~~as follow~~ing equation~~s:

$$\textit{Residue = (take-off rate/100)*average live weight*(100-\% carcass weight)*stocks}$$

For each poultry species (chickens, ducks, geese and turkeys) in each country/territory, the take-off rate (in %), average live weight (kg/animal), and dressed carcass wet weight (in %) were obtained from FAO’s Technical Conversion Factors for Agricultural Commodities (FAO, 2009), while stocks (number of animals) were obtained from FAOSTAT Crops and livestock products (https://www.fao.org/faostat/en/#data/QCL).

Similarly, meat processing by-products were estimated using country-specific ~~from the~~ take-off rates, dressed carcass weight (% of live weight) and stocks (heads) ~~using the~~as follow~~ing~~ ~~equation~~s:

*Residue = (take-off rate/100)*average live weight*(100-% carcass weight-% hides/skins-%edible offal)*stocks*

The dressed carcass weight is the weight of the carcass after removal of hide/skin, head, feet, offal, raw fats, and blood which is often not collected in the course of slaughter. For each species (buffaloes, cattle, sheep, goats, horses, camels and pigs) in each country/territory, the take-off rate (in %), average live weight (kg/animal), and dressed carcass wet weight (in %) were available in FAO’s Technical Conversion Factors for Agricultural Commodities. As in the poultry species, stocks were available in FAOSTAT Crops and livestock products for each country/territory. Carcass weight, edible and non-edible offal was used as defined in FAO’s Livestock statistics: Concepts, definitions and classifications (FAO, 2011). According to the definition in FAO (2011), edible offal in most countries include head or head meat, throat bread, thick skirt, tongue, sweet bread, genital organs, brains, lungs, udder, feet, liver, stomach or tripes, tail meat, spleen, blood, heart and diaphragm. In this calculation, the non-edible portions are assumed to be disposed off in slaughter houses and these were considered as residues. However, in certain circumstances parts such as head, feet, fat and blood can be used in a variety of ways. Since data are not available from slaughter houses on specific uses of non-edible offal, we were unable to establish the alternative uses.

Residues from capture fisheries and aquaculture species were estimated using ~~the~~ country-specific conversion factors available in the Handbook of Fishery Statistical Standards (CWP, 2004) for selected species. In the fisheries industry, the term "conversion factor" is used principally when converting the volume or mass (more commonly referred to as the "weight") of a product at one stage to its volume or mass at another stage in the chain (FAO, 2004). Conversion factors for a particular state of processing vary according to species and state of processing. The state of processing is hierarchical, and may consist of the following categories: (a) gutted, (b) headed and gutted, (c) dressed, (d) fillet (skin on or off), etc. The FAO global inland and marine capture database includes catches for over 2000 species/items (including the "not elsewhere included" categories). Since conversion factors are not available for all species, first species were ranked based on the number of countries producing and the total production in 2019. Then the top 6 species were selected for the present analysis because of availability of conversion factors and the large number of countries involved in their production. Among the aquaculture species, rainbow trout (*Oncorhynchus mykiss*) was chosen as it was the topmost grown in aquaculture in 91 countries. In capture fisheries, yellow fin tuna (*Thunnus albacares*), skipjack tuna (*Katsuwonus pelamis*), swordfish (*Xiphias gladius*), Bigeye tuna (*Thunnus obesus*) and albacore (*Thunnus alalunga*) were chosen for the analysis. Each of these species were harvested in 96, 90, 83, 79 and 71 countries, respectively. The production quantity was then converted to residues as follows: Value-(Value/CF) where CF is the indicative factors for converting product weight to live weight. The FAO database of capture fisheries production covers only retained catches; data on by-catch (discarded catches) are not included (Garibaldi, 2012). This means that the by-products can be severely underestimated.

Manure production (in tonnes/year on dry matter basis) was estimated from manure excretion rate (kg/head/day on dry-weight basis) and stocks (from FAOSTAT) following the FAO guideline for the different animal categories (FAO, 2014). The general formula for manure production is as follows:

*Manure production (tonnes/year) = (365*stocks*manure excretion rate)/1000*

Since there is no global database which provides country-specific data on manure production, the FAO tool uses the IPCC default values (FAO, 2014). For each species, average manure excretion rates were obtained from values compiled from the literature. For the USA, excretion rates were obtained from ASAE Standards D384.1 of the American Society of Agriculture Engineers (ASAE) Manure production and characteristics (2005). Manure production was estimated for different management systems of cattle (non-dairy and dairy) and chicken (broilers and layers) separately because these are always managed as separate enterprises.

When compiling forestry residues, primary residues were excluded because of the concerns related to the environmental and economic sustainability of removing them from the forest for soil application on farm-land. Therefore, the analysis focused on wood residues following the FAO definition. Country-specific d~~D~~ata on production quantity of wood residues (item code 1620) in FAOSTAT (https://www.fao.org/faostat/en/#data/FO) were used for compiling the OMD. These are reported in cubic meters solid volume excluding bark on FAOSTAT.

A database of all the coefficients and RPR used in the estimation of the various residues and by-products is now available in the OMD.

3. Results

3.1. Crop residues

Maize had the largest global total annual above-ground residue production (~1.28; CL: 0.43–2.33 billion tonnes) followed by wheat (~1.25; CL: 0.66–1.91 billion tonnes) and rice (~1.11; CL: 0.09–1.93 billion tonnes) (Table 3). The estimated quantities of crop residue varied widely by continent and region. For example, the largest total annual production of maize residue was recorded in Northern America including Canada and USA (~0.41 billion tonnes) followed by Eastern Asia (~0.30 billion tonnes) including China, Democratic People’s Republic of Korea, South Korea and Japan; China accounted for over 99% of the residues produced in Eastern Asia. The largest wheat residue production was recorded in Southern Asia (~0.24 billion tonnes) including

Afghanistan, Bhutan, India, Iran, Nepal and Pakistan and Sri Lanka, of which over 67% was produced in India. Rice residue production was highest in Southern Asia (~0.38 billion tonnes), of which over 70% was produced in India. The global total annual residue production from soybean was ~0.49 million tonnes, while for groundnuts the corresponding value was ~0.10 billion tonnes (Table 3). The largest soybean residue production was recorded in South America (~0.25 billion tonnes) of which Brazil accounted for 61% of soybean residue production in that region. This was followed by Northern America (~0.16 billion tonnes) of which USA accounted for 94% of soybean residue production in Northern America.

Table 3. Estimated total[†] annual crop residue potentially produced (in 1000 tonnes on dry matter basis) by selected crops across different regions estimated from FAOSTAT data (see methods).

3.2. Agro-processing by-products

3.2.1. By-products from processing crops

Globally, maize processing yielded the largest quantity of by-products (0.12; CL: 0.04–0.23 billion tonnes) followed by wheat (0.10; CL: 0.05–0.15 billion tonnes), rice (0.09; CL: 0.03–0.16 billion tonnes) and barley (0.04; CL: 0.03–0.06 billion tonnes) (Table 4). The largest quantity of maize processing by-products was recorded in Northern America, followed by Eastern Asia and South America. The largest quantity of wheat processing by-products was recorded in Southern Asia followed by Eastern Europe and Eastern Asia (Table 4). The global sugarcane bagasse production is estimated at 548.7 million tons per annum (Table 5), of which of 44.8 and 23.8% is produced in South America and Southern Asia, respectively. Brazil accounts for 89.1% of the annual bagasse production in South America. Similarly, India accounts for 80.3% of the annual bagasse production in Southern Asia.

The global annual production of by-products of coffee, cocoa and oil palm processing were estimated at 20.5, 5.3 and 170.1 million tonnes (Table 4). The largest quantity of coffee-processing by-products was recorded in South America, with Brazil producing about 6.5 million tonnes accounting for over 71% of the annual production in South America. This was followed by South-Eastern Asia, where Viet Nam produced 3.3 million tonnes annually. The largest quantity of by-products from cocoa was produced in West Africa, where Cote d'Ivoire accounted for over 60% of the production in that region. Out of the 170.1 million tonnes of global annual oil palm by-products, Indonesia accounted for over 59% of the total annual global production.

Table 4. Estimated total annual agro-processing by-products of selected cereal and legume crops produced (in 1000 tonnes on dry matter basis) across different regions. All values were estimated using FAOSTAT data (see methods).

3.2.2. By-products from slaughterhouses

Globally, the largest quantity of residues produced annually was from cattle (16.5 million tonnes) followed by chicken (10.7 million tonnes) and pigs (6.2 million tonnes), but with wide variation among regions (Table 6). The largest quantity of by-products from cattle was recorded in South America (5.31 million tonnes) of which Brazil accounted for 77% of by-products produced in that region. This was followed by Northern America (4.59 million tonnes of which 94% was in USA) and Eastern Asia (0.99 million tonnes of which 84% was produced in China). The total annual production of by-products from poultry processing was largest in North America (6.0 million tonnes) of which over 99% was produced in the USA. This was followed by East Asia (0.91 million tonnes) of which China accounted for over 72% of the production in East Asia.

Table 6. Estimated total annual quantity of slaughterhouse by-products potentially produced (in 1000 tonnes on dry matter basis) across different regions. All values were estimated using FAOSTAT data (see methods).

3.3.3. By-products from fisheries and aquaculture

The estimated annual quantity of by-products potentially produced from processing of selected fish species in aquaculture and capture fisheries are summarized in Table 6. Among the species grown in aquaculture, the largest quantity of by-products was produced by rainbow trout (over 0.08 million tonnes) across 91 countries (Table 7). The largest proportion was recorded in Southern Asia (predominantly in Iran and Tukey), followed by South America (mainly in Peru and Chile) and Northern Europe (mostly in Norway) (Table 7). Among the capture fisheries species, the largest quantity of by-products was produced from skipjack tuna harvest (0.14 million tonnes) followed by yellowfin tuna (0.08 million tonnes).

Table 7. Estimated total annual quantity of by-products potentially produced (in tonnes on dry matter basis) by selected fish species in aquaculture and capture fisheries across different regions. All values were estimated using FishStatJ data (see methods).

3.3. Livestock manure

Globally, cattle, buffaloes and chicken produced the largest proportion of the potential annual manure produced every year (Table 8). On dry matter basis, non-dairy cattle produce an estimated 2.23 billion tonnes (CL: 1.32–3.23), while dairy cattle produce about 0.82 billion tonnes (CL: 0.50–1.21) annually. The largest quantity of non-dairy cattle manure was produced in South America (where Brazil accounts for 60%) followed by South Asia (where India accounts for 68%). Annual production of dairy cattle manure was largest in South Asia (where India accounts for 68%). The largest annual manure production by buffaloes occurs in East Asia (China accounts for 99%) and South Asia (India accounts for 70%). The largest quantity of broiler chicken manure was recorded in South-Eastern Asia, where Indonesia accounts for 76% of broiler chicken manure in that region. The next largest production was recorded in South Asia where Pakistan and Iran account for 42% and 37% of the regional production (Table 8).

Table 8. Estimated total amount of manure potentially produced annually (in 1000 tonnes on dry matter basis) across different regions. All values were estimated using FAOSTAT data (see methods).

3.4. Wood residues

Globally, an estimated 0.23 billion tonnes (CL: 0.08–0.43) of wood residues are produced every year (Table 9), but the largest production occurs in East Asia (China producing the highest) followed by South America and North America where Brazil and USA have the highest production, respectively. Annual wood residue production was highest in China (95.1 million tonnes) followed by Brazil (18.8 million tonnes). The values presented in Table 8 are based on countries for which data were available in FAOSTAT. Since data are not available for all countries in many regions, it was not possible to calculate the residue production per country as a proportion of the total production in the respective region. Countries in the Caribbean, Central Asia, Middle Africa, Western Africa, Northern Africa and Southern Asia are poorly represented (Table 9).

Table 9. Estimated total annual wood residue potentially produced (in 1000 tonnes on dry matter basis) across different regions. All values were estimated using FAOSTAT data (see methods).

4. Discussion

The preceding sections have presented indicative estimates of the quantities of agricultural residues and by-products for selected crops and animals available in the OMD. Due to the lack of uniform methodology and data across countries, it was not possible to accurately estimate the quantities of residues produced by all crops and agro-processing activities. We are also keenly aware that the values presented could either overestimate or underestimate the global residue production. However, OMD is a living database that will be updated and enriched as new data and methods become available to build a solid reference resource for industry, researchers and decision-makers in soil health management, pollution risk reduction, bioenergy production and other sectors. The

OMD is envisaged to complement existing databases such as FAOSTAT, FishStat and organic resource quality databases such as Phyllis. The OMD may be used for various purposes including estimation of availability for soil amendments, animal feed, bioenergy and other agricultural activities such as mushroom production. The use of agricultural and forestry residues and by-products for soil amendment may be constrained by these competing uses (Duncan et al., 2016; Ji et al., 2018). The following sections will discuss the production and competing uses of agricultural, fisheries and forestry residues, and the opportunities and challenges for their use as soil amendment.

4.1. Crop residues

The estimates provided for the selected crops (Table 3) reveal that large quantities of crop residue biomass are produced annually. However, there are large differences in the share of residues of the different crops among countries and regions. For example, the largest total annual production of maize residue was recorded in Northern America, whereas the largest wheat and rice residue production was recorded in Southern Asia. Our estimates are based on uniform application of a single equation for each crop across countries due to lack of country-specific conversion coefficients. We are keenly aware that this can affect the accuracy of estimates in the database. The use of country-specific harvest indices or equations could have provided more accurate data.

The~~re are also large differences in the~~ competing uses of residues may vary among~~across~~ regions, ~~and~~ countries and even farming systems within countries. We were unable to disaggregate the total residue into the different categories due to the lack of country-specific data on the proportion fed to animals, burnt or left on the ground. According to estimates by Smerald et al. (2023), about 44% of cereal residues is left on field, 33% is used for animal feed and bedding, 16% is used for other purposes and 6% is burnt globally. In China, which is one of the largest producers of crop residues, 82.3% is currently collected and used either as fertilizer (62.3 %), feed (16.0 %), energy (9.6 %), cultural substrate (0.8 %), or as a raw materials (1.1 %) (Zhao et al., 2024). In many parts of the world crop residues are widely used as soil amendments or as a mulch to protect the soil from erosion. Farmers also remove residues to feed animals or use them as beddings. For example, about 16% of the collectible crop residues is used as animal bedding in Europe (Monforti et al., 2013). In the EU member states alone, around 28 million tonnes of crop residues are used for animal bedding annually (Scarlat et al., 2010). Crop residues are also used as fuel in industrial and domestic set-ups. For example, in rural areas in Africa and Asia, crop residues are used for cooking. There is also a growing interest in the use of crop residues for the generation of biofuels as alternatives to fossil fuels and industrial applications including textiles, natural fibres, polymers, biosorbents and reinforcement material in composites (Siqueira et al., 2022). However, country-specific data are virtually lacking to produce a database of the competing uses.

The estimated total annual crop residue produced by the top cereal and legume crops across the different regions indicate the high potential for their use in soil amendment and contribution to bioeconomy processes. Depending on the availability of technology for recovery, some of the crop residues produced may be used for recycling in bioenergy production and use as soil amendments. Raw crop residues such as straw can be incorporated into the soil or applied on the soil surface as a mulch, and this can reduce erosion, maintain soil moisture and add carbon and nutrients to the soil. A growing body of meta-analyses have provided compelling evidence that residue retention significantly increases crop yields, soil nutrient stocks, water use efficiency, carbon sequestration, microbial diversity and functionality (Shu et al., 2022; Wang et al., 2020).

While crop residues can contribute to enhancing soil organic carbon stocks and nutrient availability to crops, and reduce soil erosion, not all crop residues produced are readily available as a soil amendment. Some of the crop residue is burnt in the field or used as fuel for domestic purposes, for animal feed and/or bedding, mushroom production, construction, industrial applications (FAO, 2022a; Ji et al., 2018). In some cropping systems and regions, residues are burned in the field during land preparation because it is the easiest option for farmers. For example, the intensification of rice cropping with high-yielding and short-duration varieties in Asia has resulted in larger volumes of rice straw, which must be managed over a very short time between two or three cropping rounds per year (Van Hung et al., 2020). In such systems, soil application of residue poses challenges due to the insufficient time for decomposition of the straw, which hinders crop establishment. This has led to an increase in open field burning of rice straw in some Asian countries (Lin and Begho, 2022; Van Hung et al., 2020).

Of the residues produced annually, only a small fraction may be recovered because the collection, storage and transportation of raw residues poses challenges for their use outside their production area. One way to reduce the cost of transport and increase their use is to convert bulky residues and by-products into briquettes, pellets, biochar or anaerobic digestate that can be more easily handled and transported than the raw residues (Bora et al., 2020). In some regions, the short time frame between two cropping seasons may not allow collection of the available residues (FAO, 2014; 2021). Even when collection is feasible, the cost of transportation may limit soil application far from the farm where the residues were produced. This may be overcome by mechanized collection, high-density compaction, briquetting, pelletizing or on-site processing (e.g., composting or anaerobic digestion). High-density compaction can reduce the volume of crop residues thus making it easier to store and transport over a long distance. For example, the volumetric weight of mechanically compacted rice straw bales is 50–100% higher than that of loose straw. Briquetting and pelletizing can further increase the volumetric weight of baled straw by up to 700% and reduce transportation costs by more than 60% (Balingbing et al., 2020).

The quality of residues may play a critical role in the build-up of carbon and nutrients in the soil (Cotrufo et al., 2013) against the backdrop of the importance of the soil ecosystem (Schmidt et al., 2011). The carbon content of residues is about 30-50% (Table 1). The nitrogen content of various cereal straws ranges between 0.3 and 2.8%, and only pulse straws are relatively nitrogen-rich (Table 1). With low C:N ratios (Table 1), residues from legumes are likely to decompose more rapidly than cereals. The phosphorus and potassium content of most residues is 0.05-0.3% and 0.2-2%, respectively (Table 1). As such, crop residues represent a substantial store of carbon and nutrients that can be used as inputs for soil amendment. A role of crop residue incorporation that has remained less appreciated is their contribution to soil micronutrient stocks especially sulphur, calcium, magnesium, zinc and silicon that are often not part of the recommended fertilizers. Where straw is incorporated, reserves of soil nitrogen, phosphorus, potassium and silicon have also known to be maintained at acceptable levels (Dobermann and Fairhurst, 2002).

4.2. Agro-processing by-products

Our estimates indicate that substantial quantities of by-products are produced every year, but with a great deal of variability across regions. Unlike crop residues, most of the by-products are produced in localized processing plants, which makes their collection more convenient. However, some of the by-products may not be available for soil amendment as they have various other uses. For example, husks of rice are mostly used as fuel in the rice mills (Petersen et al., 2015). Rice husk is also used as an insulating material. In crops such as oil palm, cocoa and coffee, the processing also occurs in a few countries where the commodities are grown on commercial scale.

Although oil palm is widely cultivated in plantations across the humid tropics of Asia, Africa and the Americas, over 90% of the global palm oil production occurs in just five countries, namely, Indonesia (58.8%), Malaysia (25.6%), Thailand (3.9%), Colombia (2.9%) and Nigeria (1.4%) (Murph et al., 2021). Although the oil palm industry is one of the best sources of organic inputs for agricultural use (Adu et al., 2022; Embrandiri et al., 2012), the residues may not be available for direct soil application in areas far from processing plants. However, this can be circumvented through conversion into compost or digestates, which are easier to handle and transport.

Our global estimate of sugarcane bagasse production (548.7 million tonnes is very closes to the 540 million tonnes reported in Bezerra and Ragauskas (2016). Unlike other crop residues, bagasse is not readily available for soil amendment. This is because much of the bagasse produced is used for steam generation in sugar mills and the remainder is burnt as dry bagasse is known to be a fire hazard. Bagasse consists roughly of 20–30% lignin, and 40–45% cellulose and 30–35% hemicellulose, making it a promising feedstock for second-generation biofuel production (Bezerra and Ragauskas, 2016; Petersen et al., 2015). In some countries bagasse is also used as a raw material for the paper and board industry.

While slaughterhouse operations produce large quantities of by-products, some of are processed by the rendering industry for conversion into animal feed, pet food, poultry meal and animal fats (Mozhiarasi and Natarajan, 2022). There are challenges to the availability of by-products from slaughterhouse and fish processing facilities for soil application. Different parts of animal such as head, feet, fat, and blood can be used in a variety of ways, and therefore may not be readily available for soil amendment. Some fish parts, especially viscera, deteriorate very rapidly and therefore they require preserving as soon as possible after being produced. This is not always possible due to inadequate processing facilities or limited volumes making recovery of the by-products unprofitable. When fish are processed to fillets at sea, viscera, the head and frames are often discarded since refrigeration facilities are used for the most valuable product (Olsen et al., 2014).

4.3. Livestock manure

Our estimates in Table 7 show that large quantities of manure are produced annually albeit large variability across regions. These estimates include both manure management systems and manure left on pasture. Only a fifth of livestock manure produced is applied on cropland due to various constraints. For example, much of the manure produced may not be available for application as soil amendment on cropland because over 70% is directly deposited on pasture (FAO, 2018). Manure applied to soil can be a significant source of macronutrients and micronutrients (FAO, 2018; Sileshi et al., 2019). In addition, manure is a significant source of organic matter, which is a key determinant of soil health (FAO, 2018). For example, globally manure applied to soil was estimated to contribute 24 and 31 million tonnes of nitrogen per annum based on IPCC Tier 1 and Tier 2 approaches, respectively (FAO, 2018). According to van Dijk et al. (2016), manure application on soil constitutes approximately 53% of the P and 33% of the N applied annually to agricultural land in the EU27.

Even if manure is available in abundance, its application may be constrained by environmental quality and economic considerations in some jurisdictions. For example, in the USA, the Environmental Protection Agency regulation requires large animal feeding operations to meet nutrient planning requirements for land application of manure. Similarly, according to the EU Council Directive 91/676/EEC, the amount of livestock manure applied to land each year shall not exceed 170 kg N per hectare. Legislation may also forbid manure application during certain periods (e.g., in non-cropping seasons) or land that would otherwise lead to environmental impact through run off or nutrient leaching (Loyon, 2018).

The bulky nature of manure limits the areas over which it can be economically applied. According to Paudel et al. (2009), the economically optimal distances for dairy manure application is 30 km for nitrogen and 15 km each for phosphorus and potassium to meet the recommended N, P_2O_5 and K_2O needs on cropland. Conversion of manure into anaerobic digestate or compost can circumvent the handling, storage and transportation costs of raw manure from intensive animal production units. When efficiently managed and recycled within agricultural systems, livestock manure represents a large source of plant nutrients that can reduce the need for synthetic fertilizer inputs and reduce GHG emissions (FAO, 2018). Manure may be applied by injection, band application, surface spreading or incorporation (Emmerling et al., 2020). Injection has been cited as the best application method to reduce NH_3 emissions, while surface application using splash plates has been banned in most European countries because of its strong impact on NH_3 emission (Emmerling et al., 2020).

4.4. Wood residues

Wood residues are obviously underestimated for many regions because data were unavailable for some countries. Among the countries for which data exist, annual wood residue production was highest in China and Brazil, representing 42% and 8.3% of the annual global wood residue production. Wood log production in Brazil generates about 50.8 million m^3 of lignocellulosic residue yearly (Domingues et al., 2017). Assuming a wood density of ~450 kg m^3 this value is approximately 22.9 million tonnes, which is slightly higher than 18.8 million tonnes in our database. The competing uses of wood residues include use as woodfuel for domestic purposes (Flammini et al., 2022), bioenergy generation (Karan and Hamelin, 2020) and as raw materials for the manufacture of agglomerated products such as pulp, particle board and fibreboard (FAO, 2022f). Although wood residues could be potentially used for soil amendment after processing (e.g., wood-ash, biochar, compost, etc.), the proportion actually available may be small due to their various competing uses. Agroforestry trees and plantation crops such as coconut, oil palms, and rubber generate considerable amounts of woody and leafy biomass from pruning and lopping. A large proportion of such residues can be used for soil amendment directly or after processing into compost or biochar (Bluhm and Lehmann, 2023). However, data were not readily available for these residues, and therefore it was not possible to collate their quantities in the OMD.

5. Limitations of the OMD and challenges ahead

One of the key limitations of this work is the lack of country-specific data on the quantities of the some categories of residues such as crop residues and manure. Country-specific conversion factors or equations are also lacking to convert production statistics to residue data. As a result we were forced to use a single conversion factor or a single equation in some cases. A second limitation of this work is our inability to provide global estimate of all residues from agriculture, fisheries and forestry. The effort to compile estimates of all residues and by-products was hampered by the lack of methods for conversion of primary products to residues and industry standards for collection and aggregation of such data. For example, we did not included the quantities of residues produced by minor crops, fruit trees and other trees in agroforestry and forestry. A third limitation of this work is that were unable to account for situations where products are processed in a different country than their origin as this would entail additional data on export and import. This could be considered an important future endeavour in the development new versions of the OMD.

The OMD also does not contain the quantities of by-products such as biochar, compost and digestate produced in each country due to lack of data on their production. By-products of secondary processing that occurs in the breweries and beverage industry could also not be compiled due to lack of mechanisms to capture them at the country levels~~data~~. By-products from capture fisheries were estimated only for a few species because conversion factors were unavailable for the majority of species. Even for those species where conversion factors were available, residues from capture fisheries were probably underestimated by a large margin because recovery of inedible parts is challenging. This is because fish are processed at sea, and non-edible parts may be discarded in the sea (Olsen et al., 2014). Commercial fish products are often directly processed on-board vessels and, by the time they are landed, the fish have been frozen, gutted, headed, and/or processed, leading to a considerable change from their original weight. This leaves a great deal of uncertainty about estimation of fisheries by-products. We were also unable to provide uncertainties associated with estimates of the quantities presented at national or sub-national level due to the lack of data. Therefore, we strongly recommend investment in the inventory of agricultural, fisheries and forestry residues, by-products and wastes at the national and sub-national levels for use in a circular bio-economy.

This work only provides an inventory of the various residues at the country level, which is valuable in its own right. However, further work needs to be done to produce a global map of carbon and nutrients from residues at much greater spatial distribution and finer resolution than individual countries to inform policy and good practice for more efficient allocation of biomass resources. There is also an urgent need for documenting the alternative and competing uses of the various categories of residues estimation of the share of different uses of each residue and unused or wasted residues at the national and local levels. This requires further work and deemed outside the scope of this publication.

Due to lack of basic data, this work was unable to determine the proportion of the residues in each category that is actually available for use as soil amendment. Even where data were available, legislative and regulatory issues may limit their use as soil amendments. For example, environmental concerns of pollution by antibiotics, heavy metals and pathogens have led to regulations on direct spread of manure on land (Font-Palma, 2019). Strict regulations such as those under the EU Nitrates Directive 91/676/EEC (EEC, 1991) mean that only a small proportion of the total volume of manure produced can be used for soil amendment. It is also forbidden to apply manure or anaerobic digestate at particular times in the year or on certain types of land (Loyon, 2018). In some jurisdictions, organic matter that has been designated as waste may be subject to regulatory restrictions on how it can subsequently be used or managed (Loyon, 2018). In this analysis, it was not possible to evaluate the extent to which national policies and regulatory frameworks governing the classification of organic matter streams as wastes or by-products, and waste management can provide incentives or not to the use of organic inputs for soil amendment. Legislation banning residue burning and incentives for farmers to adopt good agricultural practices can also incentivise appropriate use of agricultural residues. For example, EU Regulation No 1307/2013 has established rules for direct payments to farmers under support schemes within the framework of the common agricultural policy. To receive full payments, farmers in the member states have to comply with statutory management requirements and standards for good agricultural and environmental conditions, and the requirements of ‘greening’ (Heyl et al., 2021). Quantitative targets are used to incentivize the implementation of agricultural practices that increase SOC stocks (Bruni et al., 2022). For example, the EU Mission Board for Soil Health and Food proposed a series of quantitative targets for soils to become healthier. Among them, the current SOC losses of about 0.5% per year in the 20 cm soil depth of croplands should be reversed to an increase of 0.1–0.4% per year by 2030 (Bruni et al., 2022). Such targets and related regulations will have implications for how and where agricultural residues can be used for soil amendment.

Transport costs may also hinder the use of the excess volume produced in one region in other regions. In some regions, anaerobic digestate is produced in excess of its agricultural assimilation potential (Torrijos, 2016). For example, in the EU digestate production reached 56 million tonnes per annum by 2010, of which 80% could be recycled back into agriculture (Kizito et al., 2019). Similarly, in China the annual digestate production is approximately 2.3 billion tonnes of which less than 70% is recycled back to agriculture due to land limitations (Kizito et al., 2019). These observations highlight the need to explore opportunities for use of residues and by-products outside the country where they are produced.

Data availability: The OMD data is available at: https://doi.org/10.5281/zenodo.10450921 (Sileshi et al., 2024).

6. Conclusions

This work has provided typologies, definitions and quantities of the various agricultural residues and by-products, which can be useful for the inventory and estimation of the various residue streams potentially available for recycling in agriculture, bioenergy and other sectors. The OMD is the first of its kind to consolidate biomass estimates of residues and by-products from agriculture, fisheries, forestry and allied industries globally. The OMD will be continuously updated as new production data are published in FAOSTAT and will be publicly available for use by different decision-makers. It is hoped to contribute to the Better Production and Better Environment dimensions of FAO’s Strategic Framework 2022-2031 supporting the 2030 Agenda. The OMD is also expected to contribute to evidence-based policies and actions in support of the transition towards a circular economy, and more sustainable agriculture and food systems. Currently, the estimates of crop residues and manure in OMD are available only at the national level based on a single equation applied uniformly due to the lack of country-specific conversion factors. Therefore, finer scale data and country-specific conversion factors and/or equations are urgently needed for spatial targeting of residues and by-products for various applications. Detailed site-specific inventory of various categories of residues and their local uses are highly recommended. An inventory of the competing uses and fate of the various residues and wastes is also urgently needed in each country.

Authors' contributions

EB, GWS, FNT conceptualized and designed the study. GWS, JL developed the methodology and GWS conducted data curation and formal analysis. GWS, EB wrote and edited the manuscript, while JL, FNT reviewed and edited the manuscript. EB funding acquisition. All authors have read and approved the final version of the manuscript.
