## 16 **Abstract**

17 The quantification and mapping of surficial seabed sediment organic carbon has wide-scale  
18 relevance across marine ecology, geology and environmental resource management, with carbon  
19 densities and accumulation rates being a major indicator of geological history, ecological function,  
20 and ecosystem service provisioning, including the potential to contribute to nature-based climate  
21 change mitigation. While global analyses can appear to provide a definitive understanding of the  
22 spatial distribution of sediment carbon, regional maps may be constructed at finer resolutions and  
23 can utilise targeted data syntheses and refined spatial data products and therefore have the  
24 potential to improve these estimates. Here, we report a national systematic review of data on  
25 organic carbon content in seabed sediments across Canada and combine this with a synthesis  
26 and unification of best available data on sediment composition, seafloor morphology, hydrology,  
27 chemistry and geographic settings within a machine learning mapping framework. Predictive  
28 quantitative maps of mud content, dry bulk density, organic carbon content and organic carbon  
29 density, were produced along with cell specific estimates of their uncertainty at 200 m resolution  
30 across 4,489,235 km<sup>2</sup> of the Canadian continental margin (92.6% of the seafloor area above  
31 2,500 m). Fine-scale variation in carbon stocks was identified across the Canadian continental  
32 margin, particularly in the Pacific and Atlantic Ocean regions. Overall, we estimate the standing  
33 stock of organic carbon in the top 30 cm of surficial seabed sediments across the Canadian shelf  
34 and slope to be 10.9 Gt (7.0 – 16.0 Gt). Increased empirical sediment data collection and higher  
35 precision in spatial environmental data-layers could significantly reduce uncertainty and increase  
36 accuracy in these products over time.

37

## 38 **1. Introduction**

39 The organic carbon contained in seafloor sediments has a major influence on global carbon cycles  
40 and earth's climate (Hülse et al., 2017; Bauer et al., 2013). Seabed sediments have been  
41 estimated to accumulate approximately 126–350 Mt of organic carbon per year (Keil, 2017;  
42 Berner, 1982) and contain 87 Gt of organic carbon in their top 5 cm (Lee et al., 2019), 168 Gt in  
43 the top 10 cm (LaRowe et al., 2020a) and up to ~2,300 Gt in the top 1 m (Atwood et al., 2020),  
44 with the latter being equivalent to nearly twice that of soils on land. Continental shelves have the  
45 highest densities of sediment carbon across the global ocean, covering only 5-8% of the marine  
46 area but an estimated 15-19% of surficial organic carbon stocks (LaRowe et al., 2020a; Atwood  
47 et al., 2020) and 80% of annual carbon burial (Bauer et al., 2013; Burdige, 2007). Continental

48 margin zones (continental shelves and slopes) also contain the largest spatial variation in organic  
49 carbon due to highly heterogenous geological, geographic, biological and oceanographic settings  
50 (Smeaton et al., 2021; Diesing et al., 2017, 2021; Atwood et al., 2020). They are also subjected  
51 to high levels of human activity, being impacted by many coastal and marine industries including  
52 fishing, shipping, energy generation, telecommunication, mineral extraction, and pollution from  
53 land based activities (Halpern et al., 2019; Amoroso et al., 2018; Keil, 2017). The quantification  
54 and mapping of organic carbon on continental margins is therefore imperative for best practise  
55 seabed management; with the densities and accumulation rates being a major indicator of  
56 ecological function, geological history and ecosystem service provision (Legge et al., 2020;  
57 Snelgrove et al., 2018; Middelburg, 2018).

58 In the marine environment, organic carbon can originate from the fixation of carbon dioxide (CO<sub>2</sub>)  
59 by primary producers in the photic zone or via lateral transport from terrestrial sources (LaRowe  
60 et al., 2020b). Organic carbon then passes through a variety of biotic and abiotic pathways being  
61 consumed, transformed, respired or remineralised, with a large proportion converted back into  
62 inorganic compounds, leaving only ~5% of marine production and less than 1% of earth's gross  
63 production eventually reaching the seafloor (Middelburg, 2019; Hülse et al., 2017; Turner, 2015;  
64 Bauer et al., 2013; Burdige, 2007). Once at the seafloor, a similarly complex process occurs on  
65 and within the sediment, with a wide range of biotic, biochemical and physical processes all  
66 influencing the rates of accumulation, remineralisation and resultant long term burial, with ~90%  
67 of all carbon reaching the seafloor being remineralised (LaRowe et al., 2020b; Middelburg, 2018,  
68 2019; Arndt et al., 2013). Even when considering this complex carbon cycle, the mass and  
69 accumulation of organic carbon in surficial seabed sediments will still have a direct influence on  
70 the scale of long-term carbon storage at the seafloor (LaRowe et al., 2020a; Middelburg, 2018).

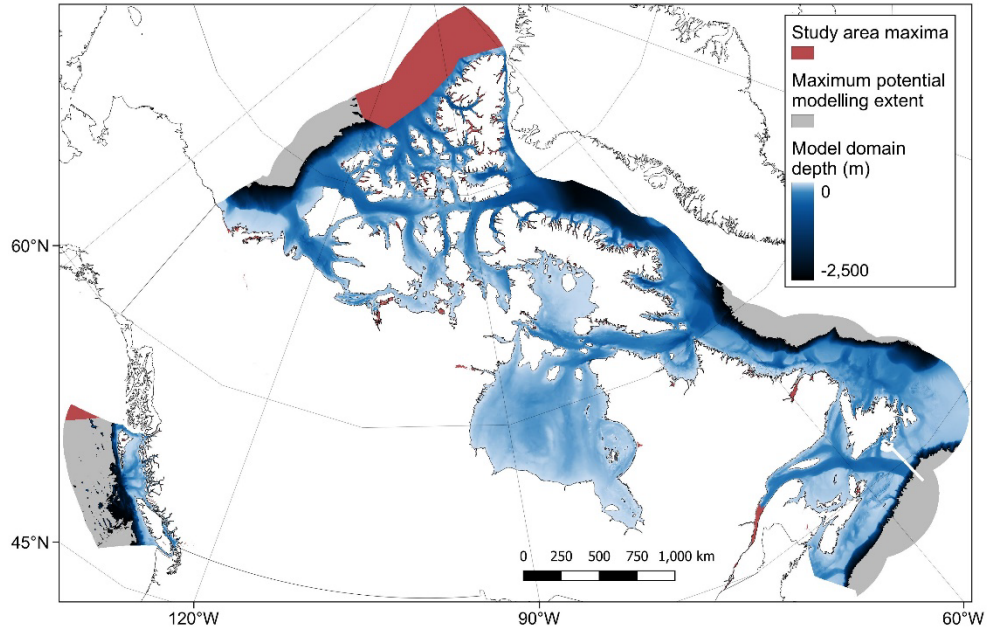

71 Marine habitats are being increasingly recognised as contributors to nature-based climate change  
72 mitigation (also known as nature-based climate solutions and natural climate solutions) due to  
73 their ability to both fix CO<sub>2</sub> and store organic carbon for centennial to millennial timescales  
74 (Macreadie et al., 2021; Hoegh-Guldberg et al., 2019). This “blue carbon” potential was initially  
75 recognised in coastal vegetated habitats (i.e. mangrove, seagrass and saltmarsh) (Nellemann et  
76 al., 2009; Duarte et al., 2005), but has more recently been applied to other habitats such as kelp  
77 forests and unvegetated sediments (Luisetti et al., 2020; Raven, 2018; Avelar et al., 2017). There  
78 is increasing evidence that human activities are influencing seabed sediment carbon stores from  
79 both perturbations of upstream processes and physical impacts directly on the seafloor (Cavan  
80 and Hill, 2022; Epstein et al., 2022; Keil, 2017; Bauer et al., 2013). For example, a recent study

81 estimated that the direct physical impacts from global fishing activities could cause considerable  
82 remineralisation of seabed sediment organic carbon stocks back to CO<sub>2</sub> (Sala et al., 2021),  
83 however the validity of the scale of these estimates has been called into question (Hiddink et al.,  
84 2023; Hilborn and Kaiser, 2022; Epstein et al., 2022). By improving sediment carbon mapping  
85 products, there may be opportunities to better research and design appropriate management  
86 strategies to limit potential remineralisation from disturbance (Epstein and Roberts, 2022; Sala et  
87 al., 2021; Luisetti et al., 2019).

88 Historically, studies measuring seabed sediment carbon stocks and accumulation rates had small  
89 geographic scope, largely considering the ecological function, geological characteristics or  
90 biochemical functioning at local to regional scales (see citations within LaRowe et al., 2020b;  
91 Snelgrove et al., 2018; Middelburg, 2018; Burdige, 2007). In recent years, made possible by  
92 modern machine learning and statistical spatial prediction techniques, there has been increasing  
93 interest in estimating the size and distribution of carbon standing stocks and accumulation rates  
94 at national to global scales to better understand natural carbon cycles and biological productivity,  
95 and to identify the potential for improved management as a natural climate mitigation strategy  
96 (Restrepo et al., 2021; Smeaton et al., 2021; Diesing et al., 2021; Atwood et al., 2020; LaRowe  
97 et al., 2020b; Lee et al., 2019; Wilson et al., 2018; Avelar et al., 2017). Although global mapping  
98 products can appear to give a complete understanding of seabed sediment organic carbon stocks  
99 (Ludwig et al., 2023; Atwood et al., 2020; Lee et al., 2019), regional mapping studies which utilised  
100 targeted data syntheses, refined spatial data products and finer resolution outputs, have shown  
101 distinct spatial patterns in organic carbon distribution and disparate estimates of total standing  
102 stocks when compared with these global studies. (Smeaton et al., 2021; Diesing et al., 2017,  
103 2021; Luisetti et al., 2020; Wilson et al., 2018).

104 Canada has the world's longest coastline and approximately the seventh largest Exclusive  
105 Economic Zone (EEZ) (Fig. 1), it could therefore be expected to contain a significant proportion  
106 of the global stock of seabed sediment organic carbon. Data from recent global studies estimated  
107 that the Canadian EEZ contains approximately 2.2 Gt of organic carbon in the top 5 cm and 48  
108 Gt in the top meter of seabed sediments, equivalent to ~2.3% of total global marine sediment  
109 carbon stocks covering around 1.3% of the area (Atwood et al., 2020; Lee et al., 2019). However,  
110 these modelled estimates from global studies are at coarse spatial resolutions, have incomplete  
111 coverage of the Canadian EEZ and contain very limited empirical data from within the Canadian  
112 EEZ itself. Here, we conduct a systematic review of data on seabed sediment organic carbon  
113 content across Canada and combine this with a synthesis and unification of best available data

114 on sediment composition, seafloor morphology, hydrology and chemistry in a machine learning  
115 predictive mapping process, to construct the first high-resolution national assessment of  
116 Canadian seabed sediment organic carbon stocks. To aid clarity, a workflow diagram of the  
117 proceeding methods and results sections is shown in Figure 2.

118  
119 **Figure 1. Map of the Canadian Exclusive Economic Zone (EEZ).** The study area spatial maxima (red) was defined  
120 using best available bathymetry data and covers the entire sub-tidal portion of the Canadian EEZ (see high resolution  
121 figure for further detail around the coastline and Section 2.1.1 for more details). This is overlaid by the maximum  
122 potential modelling extent (grey) which indicates only those areas where data were present for all predictor variables  
123 (see Section 2.1.7). Due to the distribution of available response data, the final modelling domain was limited to a depth  
124 of 2,500 meters (see Section 2.4) and is indicated with the colour relative to the estimated depth, from 0 (light blue) to  
125 -2,500 (black). Country outlines from World Bank Official Boundaries, available at  
126 <https://datacatalog.worldbank.org/search/dataset/0038272>.

130 **Figure 2. Study workflow diagram.** Outline of the structure and linkages within the proceeding methods and results  
 131 sections. Light blue shapes indicate input data; white ovals indicate data processes; dark shapes indicate output data;  
 132 rectangles indicate raster data; circles indicate point data. OC = organic carbon; DBD = dry bulk density.

133

## 134 2. Methods

### 135 2.1 Predictor variables

#### 136 2.1.1 Bathymetry

137 Best available contiguous Digital Elevation Model (DEM) data were combined and unified to a  
 138 200 m x 200 m equal area grid covering the Canadian EEZ (co-ordinate reference system (CRS)  
 139 EPSG:3573 - WGS 84 - North Pole Lambert Azimuthal Equal Area Canada) (Table 1; see  
 140 Appendix A2 for further details). Data were filtered to contain only sub-tidal areas (those cells with  
 141 elevations of less than or equal to 0 m), with the resultant extent defined as the study area spatial  
 142 maxima (Fig. 1).

143

144 **Table 1. Summary of predictor variables constructed for the Canadian EEZ.** For more information on methods  
 145 used to derive these layers see Section 2.1

150

151

152 2.1.2 Benthic terrain features

153 A set of 10 benthic terrain features were constructed from the unified bathymetric layer (Table 1).  
154 As benthic terrain measures use data on the depth of a location relative to the depth of  
155 surrounding cells up to a given distance, bathymetric data within a given buffer outside the study  
156 area maxima were included as needed to avoid edge effects in each terrain feature. Slope and  
157 total curvature were calculated using the *terra.terrain* (Hijmans, 2022) and *spatialEco.curvature*  
158 (Evans and Murphy, 2021) functions respectively. As these measures can be particularly sensitive  
159 to artifacts from the DEM models and projections, they were constructed at two resolutions – the  
160 native 200 m resolution, and after aggregating the bathymetry by 5-fold to 1 km x 1 km (termed  
161 “smoothed”). Smoothed layers were disaggregated back to a 200 m resolution to maintain  
162 uniformity across predictor layers.

163 Benthic position index (BPI) and vector ruggedness measures (VRM) were each calculated using  
164 the *MultiscaleDTM* package at 3 different levels to capture both small local features and larger  
165 spatial variation in terrain (Maxwell and Shobe, 2022; Ilich et al., 2021). Benthic position index  
166 was calculated as the difference between the depth of a focal cell and the mean of cells contained  
167 in annulus shaped window of 0.2 km to 5 km (BPI fine), 2 km to 25 km (BPI medium) and 4 km to  
168 100 km (BPI broad). Vector ruggedness was measured by considering variation in the depth  
169 surrounding each cell within square windows of width 1 km (VRM fine), 5.8 km (VRM medium)  
170 and 11.6 km (VRM broad). Due to extremely inhibitive computational times when calculating VRM  
171 broad, BPI medium and BPI broad at 200 m resolution, for these features the bathymetric layer  
172 was first aggregated to a 400 m resolution before feature calculation, and then disaggregated  
173 back to 200 m to maintain uniformity.

174

175 2.1.3 Predictors describing the geographic setting

176 The geographic setting of each cell was described by its distance to shore and rivers, its broad  
177 bioregional classification, and a proxy measure for exposure describing the degree of exposition  
178 vs. shelteredness (Table 1). The geographic setting features are also influenced by the values of  
179 surrounding pixels, therefore appropriate buffers were also applied to the processing of these  
180 layers to avoid edge effects. Distance to shore was measured by the Euclidian distance to the  
181 nearest land cell (indicated by an ‘NA’ value in the bathymetry layer), while bioregion was defined  
182 by the Fisheries and Oceans Canada Federal Marine Bioregions classification (DFO, 2022). The

183 bioregion polygons were edited to include all bathymetry cells and re-classified with an integer  
184 scale of 1 to 12 from east to west.

185 CanVec is a digital cartographic reference product produced by Natural Resources Canada  
186 (NRCan) which includes the location of rivers across Canada at three mapped scales (NRCan,  
187 2019). Firstly, the coarsest scale data (1:15,000,000) was projected onto the CRS of the  
188 bathymetry layer and converted from polylines to a 2 km resolution raster. A 2 km buffer was  
189 added around each river to ensure overlap of river mouths with the bathymetry data. The resultant  
190 raster layer was resampled onto the bathymetry raster and the grid distance of each bathymetry  
191 cell to the nearest river-mouth cell was calculated using the *terra.gridDist* function (Hijmans,  
192 2022). This was then repeated for the medium scale (1:5,000,000) and fine scale (1:1,000,000)  
193 layers with each river raster overlayed with the previous coarser scale layer to ensure all rivers  
194 were included as the scales decreased.

195 To approximate the exposure setting of each cell, data on the mean distance from shore of  
196 surrounding cells was used to construct a proxy value of fetch. Using the *terra.focal* function  
197 (Hijmans, 2022), the mean distance to shore of surrounding pixels was calculated in square  
198 windows of width 10 km, 20 km, 50 km, 100 km, 175 km and 250 km. Due to extremely inhibitive  
199 computational times when calculating these values at the two largest distances, the distance to  
200 shore layer was first aggregated to a 400 m resolution before focal calculations of these  
201 components, and then disaggregated back to 200 m to maintain uniformity. The maximum value  
202 in each layer was then set to the relative window size, and all data in each layer normalised  
203 between 0 and 1. The mean of all layers was then calculated which resulted in continuous  
204 measure of relative exposure/shelteredness ranging from 0 (highly sheltered) to 1 (highly  
205 exposed).

206

#### 207 2.1.4 Satellite derived predictors

208 Using data from the Copernicus Marine Data Store, two layers were created approximating the  
209 mass of suspended particulate matter in surface waters and the orbital velocity of waves at the  
210 seafloor. Data on suspended particulate matter (SPM) in surface waters across Canada from  
211 2007 to 2019 was extracted in netCDF format from ACRI-ST (Sophia Antipolis, France)  
212 company's global Bio-Geo-Chemical products at 4 km spatial resolution and a monthly temporal  
213 resolution (Copernicus, 2022b). The climatological mean across this entire period was then  
214 calculated for each cell and the netCDF converted to a raster for further processing. Due to the

215 complex nature of the Canadian coastline and the large disparity in spatial resolution of the  
216 satellite data product (4 km) and the layers created above (200 m), the satellite raster layer was  
217 allowed to extrapolate by 1 cell in its native resolution by taking the mean value of neighbouring  
218 pixels. This allowed better overlap of satellite layers with the study area maxima at the coastline  
219 but limited over-extrapolation. The raster layer was then reprojected to the equal area CRS and  
220 resampled onto the bathymetry layer using cubic-spline interpolation. Due to a lack of consistent  
221 SPM data recorded in the northern Arctic Basin, this portion of the data layer was manually  
222 removed within QGIS.

223 To calculate the estimated orbital velocity of waves at the seafloor, two satellite wave data  
224 products were combined with the unified bathymetry layer as constructed above. Hourly data from  
225 2007 to 2019 on the significant wave height ( $H_s$ ; VHM0) in meters, and primary wave swell mean  
226 period ( $T_z$ ; VTM01\_SW1) in seconds, were extracted from the 0.2° resolution Global Ocean Wave  
227 Reanalysis (WAVERYYS) produced by Mercator Océan International (Copernicus, 2022c) and the  
228 3 km resolution Arctic Ocean Wave Hindcast produced by MET Norway (Copernicus, 2022a). All  
229 data were processed as the SPM data layer (except for lack of removal of the Arctic basin data),  
230 and converted to an estimate of orbital wave velocity at the seafloor ( $U_{rms}$ ; measured in  $m\ s^{-1}$ )  
231 using the following equation from Soulsby (2006);

$$232 \quad U_{rms} = \left(\frac{H_s}{4}\right) \left(\frac{g}{d}\right)^{0.5} \exp\left\{-\left[\left(\frac{3.65}{T_z}\right) \left(\frac{d}{g}\right)^{0.5}\right]^{2.1}\right\} \quad (1)$$

233 where  $g$  is the acceleration due to gravity ( $9.806\ m/s^2$ ) and  $d$  is the water depth (m), taken as the  
234 unified bathymetry layer multiplied by -1, and all values less than 1 meter depth rounded up to  
235 the nearest meter (as needed for the above calculation). The resultant Arctic orbital velocity data  
236 layer was then bias corrected to the global orbital velocity data layer utilising the *qmap* package  
237 with quantile mapping using a smoothing spline (Gudmundsson et al., 2012). Finally, the two data  
238 layers were overlaid with the regional Arctic data taking priority over the global data where  
239 available.

240

### 241 2.1.5 Ocean circulation model predictors

242 To incorporate best available regional evidence, data on the mean surface ice cover, seafloor  
243 salinity, temperature and current velocity was collated from three different ocean circulation model  
244 products covering different regions of Canada (Table 1; see Appendix A3 for further details).  
245 Three-dimensional data for salinity, temperature, u-velocity (eastward) and v-velocity (northward)

246 were extracted from each model and the climatological mean across all time points between 2007-  
247 2019 was calculated. For each horizontal cell, data were only retained from the lowest vertical  
248 cell within a given position (i.e. the cell which contacts the seafloor). Individual model outputs  
249 were then converted to spatial point data using the cell centroid positions and transformed to the  
250 unified CRS. Point data was then converted to rasters with the respective resolution of each  
251 model, and the mean value taken if two points from the same model lay within a single raster cell  
252 as an artifact of reprojection. As the Arctic-Atlantic model (ANHA12) has a varying horizontal  
253 resolution, point data were rasterized using the smallest resolution of the original model (1.6 km)  
254 and then interpolated using the *gstat* package (Gräler et al., 2016) and a nearest neighbour  
255 interpolation method (including cells for land within the original model grid to suppress  
256 extrapolation). For all three models, mean current velocity was then calculated as the root mean  
257 square of the u-velocity and v-velocity values in each cell. Finally, as carried out for the satellite  
258 data layers, each raster was allowed to extrapolate by one cell in its native resolution (or for the  
259 case of the ANHA12 model – its median resolution) and resampled onto the 200 m bathymetry  
260 grid using cubic-spline interpolation. The three rasters were then combined with data only being  
261 assigned to the spatial extent of the respective bioregions as defined in Section 2.1.3. Although  
262 this means that different model products were used to measure the same predictor variable in  
263 different regions, which can create biases, the bioregion predictor variable was included as a co-  
264 variate in all models which included the ocean circulation variables, thus allowing for interactive  
265 effects and accounting for differences in circulation model structures. Combining different models  
266 can also create edge-effects, however the Arctic-Atlantic model is entirely spatially distinct so  
267 contains no common edges with other models. The only significant edge between the remaining  
268 two models lies at the mouth of the Juan de Fuca Strait and minimal disparity was seen (with the  
269 other common edge occurring in the narrows of Johnson Strait).

270 Predictor layers describing the mean concentration and thickness of sea ice for the same temporal  
271 period across the Arctic and Atlantic were also derived from the ANHA12 model. Processing of  
272 model data and spatial rasters was conducted as above, except a value of zero ice concentration  
273 and thickness was applied to all cells across the British Columbia Pacific bioregions.

274

#### 275 2.1.6 Global model predictors

276 Four additional predictor variables were derived from Bio-ORACLE version 2.2 – a global unified  
277 marine environmental data-layers collation which gives climatological mean values at 1/12<sup>th</sup>

278 degree resolution, for 2000-2014 and a wide-range of environmental variables (Assis et al., 2018).  
279 Although these datasets are of lower resolution when compared to the regional data used above,  
280 based on previous research there were some additional variables not available from the regional  
281 circulation models which were considered potentially important for carbon modelling (Diesing et  
282 al., 2021; Atwood et al., 2020). Three described the oceanographic chemistry/biology – namely  
283 primary production and chlorophyll content of the surface water column, and dissolved oxygen  
284 concentration at the seafloor. The fourth predictor was an additional measure of current velocity  
285 (maximum current velocity), which was selected on top of the previously derived mean values  
286 because current velocity has been identified as a particularly strong predictor within previous  
287 seafloor sediment composition and carbon content predictive mapping studies (Gregr et al., 2021;  
288 Diesing et al., 2021; Mitchell et al., 2019). Raster data were downloaded from the Bio-ORACLE  
289 website and processed as the satellite data layers (i.e. allowed to extrapolate by 1 cell in its native  
290 resolution by taking the mean value of neighbouring pixels, reprojected to the unified equal area  
291 CRS and resampled to the unified 200 m grid using cubic-spline interpolation).

292

#### 293 2.1.7 Final collation of predictor variables

294 The resulting 28 predictor variable raster layers were combined into a single raster stack and any  
295 cells containing NA values removed, leaving only those cells which contained values across all  
296 predictor layers. The remaining cells covered 92.3% of the subtidal zone of the Canadian EEZ  
297 and delineated the maximum potential modelling area (Fig. 1). The final predictor variable layers  
298 are shown in the Supplement.

299

### 300 **2.2 Sediment mud content data**

301 Empirical point data on seabed sediment mud content across the Canadian EEZ were extracted  
302 from two sources (Enkin, 2023; NRCan, 2022) (see Appendix A4 for further information). Data  
303 were only retained if they originated from within the top 30 cm of the sediment and had associated  
304 geographic position information (latitude-longitude co-ordinates; lat-lon). Data were further filtered  
305 by excluding those where the sum of mud, sand and gravel content was greater than 102% and  
306 lower than 98% - to allow for rounding errors but to exclude invalid data. Data were also excluded  
307 if samples/sub-samples were not present from at least the top 1 cm to 5 cm below the sediment  
308 surface within a given sampling event. After data filtering, the mean percentage of mud was taken

309 across replicates/sub-samples, leaving a single value for each sampling event. We chose to  
310 concentrate on sediment mud content as this has previously been identified as the key sediment  
311 composition component from a number of related carbon mapping studies (Smeaton et al., 2021;  
312 Diesing et al., 2017, 2021; Pace et al., 2021; Wilson et al., 2018). Finally, mud content data were  
313 projected onto the CRS of the predictor layers and only retained where overlap occurred. This led  
314 to a final dataset of 19,730 samples (Fig. B1).

315

## 316 **2.3 Organic carbon content data**

### 317 2.3.1 Organic carbon data collation and extraction

318 Data on the percent organic carbon content within dried surface sediments (%OC) was collected  
319 from three different structured searches. Firstly, a systematic literature review was conducted  
320 through Web of Science and Scopus. Both searches were conducted on the 21<sup>st</sup> September 2022.  
321 Within Web of Science, its “Core collection” was searched via the field “Topic”, which examines  
322 a paper’s title, abstract, author, keywords and “keywords plus”. Within Scopus, the search was  
323 run via the field “Title-Abs-Key”, which scans a paper’s title, abstract and keywords. Within both  
324 databases the same search string was used:

325 (“organic carbon” OR “organic matter” OR “organic content” OR TOC OR TOM) AND (coast\* OR  
326 sea\* OR ocean\* OR estuar\* OR marine OR gulf) AND (sediment\* OR mud\* OR sand\* OR clay\*  
327 OR silt\* OR gravel\* OR seabed) AND Canad\*

328 All articles identified from the searches were exported into a single Zotero library and duplicates  
329 removed, leaving 1,581 results. Screening was conducted via a hierarchical process that first  
330 assessed the title, then abstract and finally full text. At each stage an article was assessed against  
331 the inclusion criteria described below, with those considered relevant or of unclear relevance  
332 passing to the next level of assessment.

333 The inclusion criteria were defined as: 1) Study conducted on subtidal seabed sediments (those  
334 concerning rock, shale or fauna were not included); 2) Physical samples collected using a seabed  
335 sediment sampling device (e.g. cores or grabs – sediment-trap samples were not included); 3)  
336 Samples from within the Canadian EEZ; 4) Studies concerning the chemical composition of the  
337 sediment; 5) Organic carbon content (%) directly measured after separation of organic and  
338 inorganic components (e.g. by acidification). After the title screening stage 242 articles remained,  
339 followed by 123 remaining after abstract screening, and a final set of 49 articles left for data

340 extraction after review of the full text. Four additional primary literature papers were added based  
341 on expert advice. This included two large data collation studies, one concentrating on the Arctic  
342 (CASCADE; Martens et al., 2021) and one having global scope (MOSAIC v2; Paradis et al., 2023)

343 The second structured search was conducted on the Canadian Federal Science Libraries Network  
344 – a repository which contains departmental publications, reports and data sets from seven  
345 science-based Canadian government departments. The search was carried out on the 7<sup>th</sup>  
346 November 2022 using the same search string as for the primary literature and querying all fields.  
347 The search led to only 178 results and therefore each result was assessed individually against  
348 the selection criteria first by their abstract and then by a full text assessment, leading to data  
349 extraction from 15 reports. The third search was carried out on the 15<sup>th</sup> November 2022 using  
350 GEOSCAN – the NRCan bibliographic database for scientific publications. As GEOSCAN does  
351 not allow search strings containing “AND”, the search was conducted on all fields using only the  
352 terms: “organic carbon” OR “TOC” OR “OC”; leading to 655 search results. The metadata of all  
353 entries was exported as a text file and further refined using a secondary manual search for the  
354 remainder of the search terms listed above within Microsoft Excel. This led to a final set of 233  
355 results, 178 which were excluded by screening of the title, and a further 51 excluded by abstract  
356 or full text screening, leaving 4 reports for data extraction.

357 In total, these three structured searches of primary literature and government reports led to 72  
358 publications for data extraction. As well as data on the %OC, metadata extracted included the  
359 maximum depth of sample into the sediment (cm), geographic position (lat-lon), sample ID, year  
360 of sampling (approximated as publication year where not clearly stated), sampling method (e.g.  
361 multicorer, Van Veen grab) and water depth of sample site (where recorded). Data were extracted  
362 from data tables or supplementary databases when available, otherwise the PlotDigitizer online  
363 application was used to extract data from graphical products. Where possible data were extracted  
364 on the %OC in different depth-layer sub-samples through a single core-sample up to 50 cm,  
365 otherwise a single mean value was taken.

366 Additional to data collated through the structured searches, %OC data were also extracted from  
367 PANGAEA – a global data repository for geographic earth-system data (PANGAEA®, 2022). A  
368 data search across all topics was conducted on the 25<sup>th</sup> October 2022 using the same search  
369 terms as for the structured search, except for removal of the term “*Canada*”. The geographic  
370 extent of the results was instead delineated using the spatial tool within PANGAEA which allows  
371 results to be filtered by the geographic co-ordinates of a square/rectangular extent. Overall, this  
372 led to a total of 1,489 potential datasets. All relevant data within these datasets were exported

373 using the Data Warehouse Download tool within Pangaea. Based on expert knowledge, two  
374 additional PANGAEA datasets were added to the output from published global %OC data-  
375 syntheses (Atwood et al., 2020; Seiter et al., 2004). Lastly, where the date of the sample was not  
376 recorded, the sampling year was manually added by further exploring the metadata or cited  
377 studies. To align the PANGAEA data with the systematic review data, PANGAEA data points  
378 were excluded if: 1) they lacked data on %OC; 2) they lacked metadata on the depth of a sample  
379 within the sediment; 3) if the sample originated from greater than 50 cm below the sediment  
380 surface; or 4) metadata on the elevation/water depth indicated sampling above the subtidal.  
381 Additionally, metadata within PANGAEA were coalesced where necessary (due to different  
382 names being given to the same data type), and mean values of %OC taken if replicates were  
383 measured within a single sub-sample.

384 All organic carbon data were converted into spatial point data, transformed to the unified equal  
385 area CRS and masked by the predictor variable's maximum model area to leave only overlapping  
386 data. Additionally, values were only retained from the sampling year 1959 and onwards. The extra  
387 year was included when compared to the mud content data because there were some widescale  
388 surveys undertaken across the Labrador Sea in 1959 which was lacking from any additional %OC  
389 datasets. While this large temporal extent may add uncertainty in relation to the quality and  
390 uniformity of the response data, similar extents have been used by previous global mapping  
391 studies (Atwood et al., 2020; Lee et al., 2019; Seiter et al., 2004) and, 72% of the %OC data  
392 within this study were sampled after 1980 and 55% after 2000. The larger temporal extent also  
393 allows for the inclusion of a larger frequency and wider spatial extent of data, therefore potentially  
394 improving robustness of our spatial predictive models. In total our %OC dataset contained 2,518  
395 point-samples (Fig. B2) and 3,308 sub-samples across different depth layers within cores.

396

### 397 2.3.2 Organic carbon data processing

398 Due to commonly adopted uneven sampling distributions within single core samples (i.e. more  
399 sub-samples towards the top of the core), where sub-sample data were present on the %OC in  
400 different depth-layers these were converted into weighted cumulative means assuming linear  
401 distribution between sub-samples. Additionally, there was large variation in the maximum  
402 sediment depth of point-samples, ranging from %OC measures from only the top 1 cm of  
403 sediment, to values up to the chosen data extraction limit of 50 cm deep. We chose to standardise  
404 all samples to 30 cm depth as only 6% of the point-samples covered sediment depths below this

405 layer and because 30 cm is a commonly suggested carbon stock accounting depth for terrestrial  
406 soil and marine sediment habitats in both carbon accrediting methodologies and greenhouse gas  
407 inventories (VERRA, 2020; IPPC, 2019).

408 To estimate the cumulative mean of %OC at 30 cm for all individual point-samples, we created a  
409 transfer function using a generalised additive mixed model (GAMM) smoothing spline. It is  
410 generally expected that the %OC in marine sediments decreases with depth within the seafloor  
411 (Middelburg, 2018); we used the collated data above to approximate a mean trend for this study.  
412 Firstly, only those data that contained at least five sub-sampled depth layers were retained for  
413 modelling as fitting distributions to those with fewer points would likely be invalid. This left 183  
414 unique samples with 2,640 weighted cumulative mean sub-samples for model construction.  
415 Cumulative mean %OC data were arcsin transformed ( $\arcsin\{\sqrt{[\%OC/100]}\}$ ; a commonly adopted  
416 transformation for percentage data), and a simple GAMM model applied with sub-sample  
417 sediment depth as the fixed factor modelled with a cubic regression spline and sample ID as the  
418 random factor. The GAMM model was fitted using the *mgcv* package; a scaled-t distribution family  
419 was used for heavy tailed Gaussian-like data, the number of basis dimensions was set to 20 and  
420 smoothing parameter estimation was conducted by Restricted Maximum Likelihood (REML)  
421 (Wood et al., 2016). Model validation was carried out using visual assessment of diagnostic plots  
422 of residuals, as well as observed vs fitted values. Significance of the sampling depth smoothing  
423 spline was assessed by an analysis of variance (ANOVA) with a chi-squared test comparing the  
424 full GAMM model to a null GAMM model containing only the random factor and the intercept (see  
425 Appendix C for results). The difference between estimated deviance explained in the full and null  
426 models was also used to approximate the variance explained by the fixed and random factors. To  
427 create a transfer function, the cumulative %OC was predicted from the mean fixed effects of the  
428 GAMM model at sediment depths from 0 – 30 cm at 0.1 cm intervals. The predictions were then  
429 back-transformed to percentage data and the cumulative mean %OC at each depth was  
430 converted to an inverse proportion of the mean across 30 cm. Overall, this gave an estimated  
431 proportional conversion factor from the cumulative mean at any given depth to an expected mean  
432 across 30 cm (Appendix C).

433 All point-sample data from PANGAEA and the systematic review were combined, corrected to  
434 weighted cumulative means where sub-samples were present, checked for duplication, and  
435 unified to a mean %OC value of the top 30 cm of sediment using the above transfer function. One  
436 outlier was removed from the dataset as it was reported to have a carbon content twice that of  
437 any other sample within the dataset. Finally, for further analyses %OC data were arcsin

438 transformed due to a highly right skewed distribution and its application within similar modelling  
439 exercises (Smeaton et al., 2021; Diesing et al., 2017).

440

#### 441 **2.4 Final model domain selection**

442 After visual assessment of the coverage of both the mud content and %OC data, the final model  
443 domain was limited to a water depth of 2,500 meters. This depth limit (as delineated by the  
444 bathymetry predictor layer) encompassed 99.95% of mud content point data (Fig. B1) and 99.3%  
445 of %OC data (Fig. B2). The predictor layer raster stack was filtered with all cells deeper than  
446 2,500 meters excluded from the model domain. This final model domain covers 4,489,235 km<sup>2</sup>  
447 which is 78.4% of the EEZ or 92.6% of the seafloor area above 2,500 m (Fig. 1).

448

#### 449 **2.5 Random forest modelling**

450 For predictive mapping we adopted random forest machine learning techniques due to their  
451 flexibility regarding violations of traditional statistical assumptions, ability to handle a range of data  
452 types and predictor variables and elucidate both drivers of model response and predictions of  
453 uncertainty, as well as their successful application in previous similar modelling tasks (Diesing et  
454 al., 2017, 2021; Pace et al., 2021; Atwood et al., 2020; Wilson et al., 2018). Mud content and  
455 organic carbon content (%OC) were both modelled using the following framework. Firstly, each  
456 response variable was overlain onto the predictor variable grid and the mean values were taken  
457 if more than one data-point fell within a single raster cell. All predictor variable data were then  
458 extracted for each response dataset; however, the three biological/biochemical predictor  
459 variables (primary production, chlorophyll concentration and dissolved oxygen) were only used  
460 within the %OC model as they are not expected to drive variation in physical sediment properties  
461 (Restrepo et al., 2021; Gregr et al., 2021; Graw et al., 2021; Mitchell et al., 2019).

462 Contemporary research in spatial machine learning techniques have highlighted that robust  
463 spatial cross-validation (CV) strategies and predictor variable selection processes are essential  
464 to calculate valid performance metrics, limit overfitting and construct reliable spatial predictions  
465 (Zhang et al., 2023; Ludwig et al., 2023; Meyer and Pebesma, 2022; Meyer et al., 2019). Details  
466 of the methods used to ensure appropriate cross-validation design and feature selection are  
467 discussed in Appendix A5. For both response variables, following identification of an appropriate  
468 35-fold spatial CV structure, a single fold was held-back as testing data, with all other data

469 retained for model training. To ensure an absence of duplication between the training and testing  
470 data, 34 spatial CV folds were reconstructed on the training data (i.e. all training data assigned to  
471 one of 34 validation sets). Using these CV folds, the *CAST.ffs* function (Meyer et al., 2023) was  
472 then used to run a forward predictor variable selection processes with appropriate spatial  
473 considerations (see Appendix A5 for further information).

474 Following variable selection, hyperparameter tuning was conducted on the hyperparameters *mtry*  
475 (the number of variables to randomly sample as candidates at each split) and *min\_n* (the number  
476 of observations needed to keep splitting nodes); with the *trees* hyperparameter (the number of  
477 random forest trees to construct and take mean predictions across) set to 1,000 (Probst et al.,  
478 2019). 11 potential combinations of hyperparameters were selected using a semi-random Latin  
479 hypercube grid (Kuhn and Silge, 2023; Kuhn and Wickham, 2020). The tuning process fitted  
480 separate models across all CV folds and hyperparameter combinations (i.e. 34 CV folds x 11  
481 hyperparameter options = a total of 374 models) (Kuhn and Silge, 2023; Kuhn and Wickham,  
482 2020). The performance of each of the 11 hyperparameter combinations was assessed by  
483 calculating the root mean squared error (RMSE) on predictions of the validation data across all  
484 CV folds, with the optimal hyperparameter combination selected as that with the lowest RMSE  
485 (Meyer et al., 2019, 2023). After selection of the best performing hyperparameter combination, a  
486 single last-fit model was constructed on the entire training set and evaluated on the held-back test  
487 set (Kuhn and Silge, 2023; Kuhn and Wickham, 2020), with the absence of overfitting determined  
488 by the RMSE and  $R^2$  of the last-fit model falling within the range of those found across CV folds  
489 with optimal hyperparameters. Final model performance metrics (RMSE and  $R^2$ ) were then  
490 calculated using all predictions of validation data from CV folds (with optimal hyperparameters)  
491 and from predictions of the testing data from the last-fit model (Meyer et al., 2019, 2023).  
492 Predicted values were then calculated across the entire model domain using the last-fit model  
493 and the predictor variable raster stack (Kuhn and Silge, 2023; Kuhn and Wickham, 2020), and  
494 cell-specific estimation of uncertainty was calculated using standard error on out-of-bag  
495 predictions using infinitesimal jack-knife for bagging (Roy and Larocque, 2020; Wager et al.,  
496 2014). Due to computational restraints when calculating predictions across the entire model  
497 domain (which contains 112,230,871 cells), the predictor variable raster stack was split into 150  
498 non-overlapping partitions by random sampling and both prediction and standard error estimates  
499 made serially on each partition. All predictions were then merged to create a raster layer covering  
500 the entire model domain (although edge effects were not expected between partitions, random  
501 sampling without replacement across the entire domain was chosen to ensure its absence).

502 A cell-specific approximation of the upper and lower bounds of the 95% confidence interval (CI)  
503 was calculated by adding/subtracting the cell-specific standard error estimates, each multiplied  
504 by 1.96, from the mean predictions and then back transformed where needed (Kuhn and  
505 Wickham, 2020; Wager et al., 2014). After calculation, CI values were corrected where necessary  
506 – being bounded by 0 and 100. The resulting three raster layers from the mud content model were  
507 also used as available additional predictor variables when constructing the random forest models  
508 for %OC (Fig. 2). Although this gives the potential for data leakage if mud content and %OC data  
509 were from the same samples, we found only 31 occurrences (1.3% of OC samples) where direct  
510 spatial overlap occurred, and therefore do not consider that significant data leakage is present  
511 and no impact on variable importance or model performance calculations will be seen. Finally, a  
512 measure of relative predictor variable importance was calculated by fitting an additional single  
513 random forest model on all training data using optimal hyperparameters, and the predictor  
514 importance calculated on out-of-bag data through permutation of predictor variable values (for  
515 further details see Kuhn and Silge, 2023; Wright et al., 2016). Accumulated local effects (ALE)  
516 plots for the last-fit model were produced for the six predictor variables with highest importance  
517 in each model using the *iml* package (Molnar et al., 2018) to give a visual representation of the  
518 average effect of predictors on model prediction outcomes.

519

## 520 **2.6 Estimating sediment dry bulk density**

521 An estimate for the dry bulk density of the sediment ( $\rho_D$  – the mass of dried sediment per unit  
522 volume within the seafloor;  $\text{g cm}^{-3}$ ) was constructed across the model domain based on the  
523 predictions of mud content from the random forest model (Fig. 2). We identified three published  
524 functions which describe the relationship between mud content and porosity ( $\Phi$ ; the proportion of  
525 sediment volume which is water) in seabed sediments. The following equations are respectively  
526 from Jenkins (2005), Diesing et al. (2017) and Pace et al. (2021):

$$527 \quad \Phi = 0.3805 \cdot \text{mud} + 0.42071 \quad (2)$$

$$528 \quad \Phi = 0.4013 \cdot \text{mud} + 0.4265 \quad (3)$$

$$529 \quad \Phi = 10^{\{0.138 \cdot \log_{10}(\text{mud}) - 0.486\}} \quad (4)$$

530 Due to each of these equations being approximations of the relationship between mud content  
531 and  $\Phi$ , we chose to take the mean response. In all equations *mud* represents the predicted mean  
532 mud content values as calculated above, each expressed as a decimal proportion. For Equation

533 4, mud content was rounded up to the nearest 0.01 as lower values give unrealistic porosity  
534 estimates. Sediment porosity can then be converted to an estimate of dry bulk density using the  
535 following equation:

$$536 \rho_D = \rho_S(1 - \phi) \quad (5)$$

537 where  $\rho_S$  is the grain density of seabed sediments in  $\text{g cm}^{-3}$ , which was set at the frequently used  
538 constant approximation of 2.65 (Diesing et al., 2017, 2021; e.g. Pace et al., 2021; Lee et al., 2019;  
539 Wilson et al., 2018; Kuzyk et al., 2017). Although this standard approximation of grain density is  
540 not ideal, the variation under different environmental settings is generally found to be small when  
541 compared to differences in %OC and porosity, therefore the values of grain density are not  
542 expected to strongly drive variation in organic carbon density (Atwood et al., 2020; Lee et al.,  
543 2019; Middelburg, 2019; Martin et al., 2015; Berner, 1982).

544 To incorporate uncertainty from our mud content predictions, estimates of dry bulk density were  
545 also calculated from the cell-specific predictions of the lower and upper bounds of the 95% CI of  
546 mud content. We used these derived lower and upper bounds of dry bulk density estimates as  
547 best available approximations of uncertainty around the dry bulk density mean estimate values.  
548 Equivalent approaches to estimating uncertainty have been used in other seabed sediment  
549 carbon mapping studies (e.g. Diesing et al., 2017, 2023; Lee et al., 2019).

550

## 551 **2.7 Estimating organic carbon standing stock**

552 The organic carbon density ( $\text{g cm}^{-3}$ ) is calculated by multiplying the %OC (expressed as a decimal  
553 proportion) by the sediment dry bulk density (Fig. 2). For the final calculations, the respective  
554 means, upper and lower uncertainty bounds were multiplied together to incorporate uncertainty  
555 from both components. These compound uncertainties were used as best available  
556 approximations of the lower and upper bounds of uncertainty around the estimates of mean  
557 organic carbon density (akin to Diesing et al., 2017, 2023; Lee et al., 2019). To create a more  
558 meaningful response value, organic carbon density was converted to  $\text{kg m}^{-3}$  (multiplied by 1000).  
559 Finally, the organic carbon stock in each mapped cell can be calculated by multiplying the organic  
560 carbon density by the reference sediment depth of this study (0.3 m) and the cell area (40,000  
561  $\text{m}^2$ ) and converted to metric tonnes (divided by 1000). Overall, this allows estimates to be  
562 calculated for the total values of organic carbon stock across different parts of model domain.

563

564

## 565 **2.8 Rock substrate distribution case studies**

566 The method followed in this study is similar to that used for many similar seabed sediment  
567 predictive mapping exercises in that it uses data only from sediment grab and core samples to  
568 build predictive maps across the model domain (Restreppo et al., 2021; Graw et al., 2021; Diesing  
569 et al., 2017, 2021; LaRowe et al., 2020a; Atwood et al., 2020; Lee et al., 2019; Mitchell et al.,  
570 2019; Wilson et al., 2018; Stephens and Diesing, 2015). One major limitation with this modelling  
571 approach is that areas of bedrock, which would have zero values for all sediment response  
572 variables, will not be recorded in these datasets. Therefore, the under representation of zero  
573 values in the response data could lead to an overestimate of organic carbon standing stocks as  
574 zero values are unlikely to be predicted from model outputs.

575 In the context of this study, information regarding the distribution of bedrock is lacking for many  
576 regions. We therefore use two regional case studies from the Pacific British Columbian EEZ and  
577 the Atlantic Scotian shelf and slope where recent publications have made estimated maps on the  
578 distribution of rock substrates (Philibert et al., 2022; Gregr et al., 2021). Each of these products  
579 was overlaid onto the final spatial predictions of sediment carbon densities and all cells set to  
580 zero where rock substrates were predicted. The proportional effect on the mean, upper and lower  
581 estimates of carbon stock was then calculated in each bioregion.

582

## 583 **3. Results**

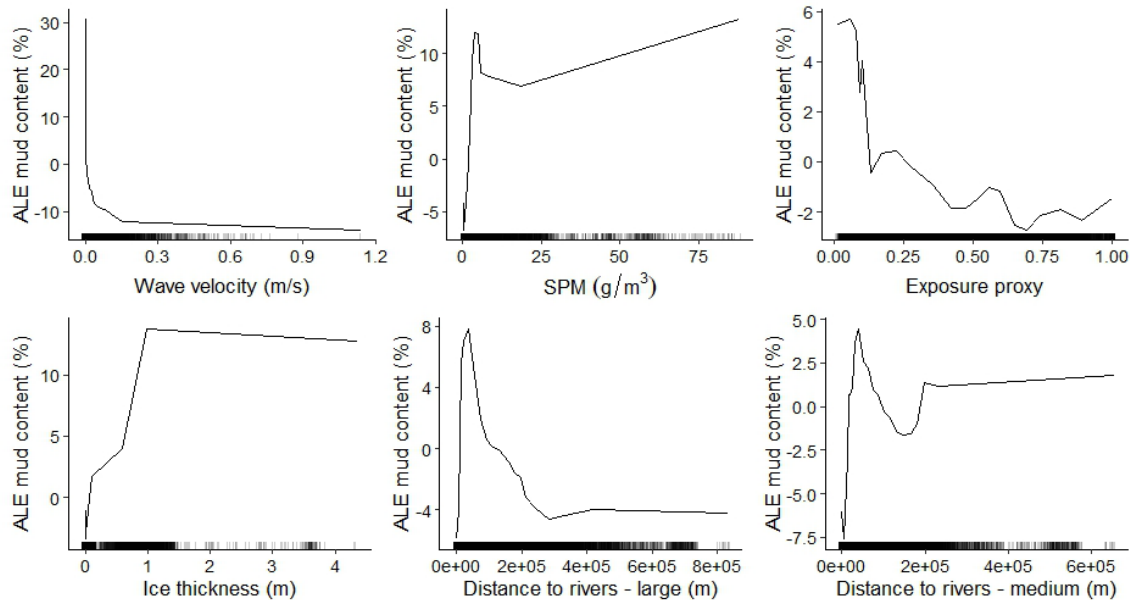

### 584 **3.1 Mud content predictive mapping**

585 Of the 25 predictor variables available for mud content random forest modelling, 13 were selected  
586 in the optimal model (Fig. 3). Mean orbital velocity of waves at the seafloor and the mass of  
587 suspended particulate matter at the surface were the variables with highest importance (Fig. 3).  
588 Other variables with relatively high importance for predicting mud content included the exposure  
589 setting, ice thickness, distance to rivers, bathymetry, and benthic position indices (Fig. 3). Higher  
590 mud content was generally predicted in areas of low wave velocity, low exposure and close to but  
591 not directly adjacent to river mouths; with the effect of SPM and ice thickness less distinct, likely  
592 due to more complex interactive effects (Fig. 4).

593

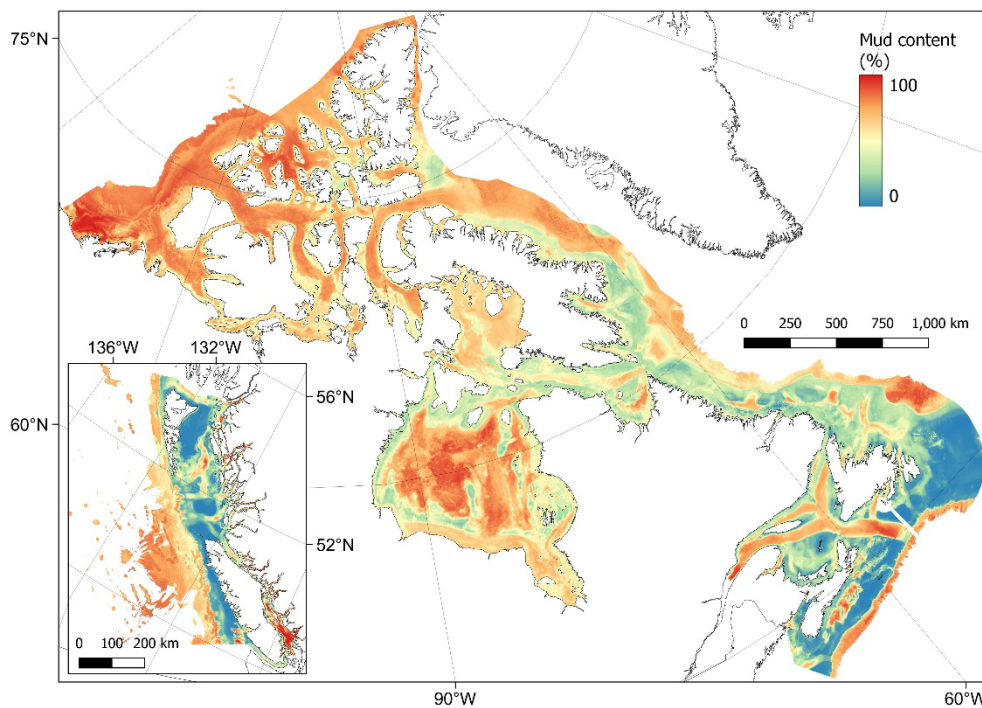

594  
 595 **Figure 3. Predictor variable importance from random forest models of mud content in marine subtidal**  
 596 **sediments.** The y-axis is a unitless relative variable importance score for each model. Asterisks indicate the two initial  
 597 predictors which were selected based on variable importance, with all other predictor variables selected using a forward  
 598 selection process (see Appendix A5 for further details). WaveVel = Orbital wave velocity at the seafloor, SPM =  
 599 Suspended particulate matter within the water column, BPI = Benthic position index, DistRiver = Distance to nearest  
 600 river, IceThick = Sea ice thickness, Bathy = Bathymetry, VRM = Vector ruggedness measure, CurrVel = Current velocity  
 601 at the seafloor.

602  
 603 **Figure 4. Accumulated local effects (ALE) plots for the six predictor variables with highest importance in the**  
 604 **mud content random forest model.** ALE (distributions down by lines) gives a visual representation of the average  
 605 effect of the predictor variable on the response but does not indicate the influence of multi-way interactions which are  
 606 inherent in random forest models. Rug plots (dashed marks at bottom) indicate the distribution of each variable within  
 607 the training dataset. SPM = suspended particulate matter.

608

609 Areas with sediments dominated by mud (>75%) were predicted across the basins of many of the  
610 Pacific fjords, inlets and estuaries, and within the southern Salish Sea (Fig. 5). In the Arctic, mud  
611 dominated areas included large parts of the Canadian western Arctic as well as Hudson Bay. In  
612 the Atlantic, the Laurentian channel and deeper parts of the Scotian Shelf contained particularly  
613 high mud fractions (Fig. 5). Across the model domain, sediment in deeper areas on the continental  
614 slope was also highly dominated by mud (Fig. 5) Using robust spatial cross validation, the model  
615 was estimated to have an RMSE of 24.4% and  $R^2$  of 0.60. The cell specific upper and lower 95%  
616 CI bounds are shown in Figure E1. On average the upper CI bounds were 28% larger than the  
617 mean and the lower CI bounds 20% less.

618

619 **Figure 5. Predictive mapping of mud content (%) in subtidal marine sediments across the Canadian continental**  
620 **margin.** The main plot shows the Arctic and Atlantic regions with the Pacific region inset. The 95% confidence interval  
621 bounds around the predicted means are shown in Figure E1. Labels indicating the locations of different areas  
622 mentioned within the text are shown in Figure B3. Country outlines from World Bank Official Boundaries, available at  
623 <https://datacatalog.worldbank.org/search/dataset/0038272>.

624

625

626 **3.2 Organic carbon content predictive mapping**

627 Eleven predictor variables were selected in the optimal organic carbon content (%OC) model (Fig.  
628 6). The variables with highest importance in predicting %OC were the mud content layers  
629 constructed above (specifically the mean and lower bound), with all other predictors having less  
630 than half the relative importance of the mean mud predictions (Fig. 6). On average organic carbon  
631 content increased with predicted mud content and was generally higher in areas with low SPM  
632 concentrations, low exposure settings, close to but not directly adjacent to rivers, and at high  
633 water temperatures (Fig. 7).

634

635

636 **Figure 6. Predictor variable importance from random forest models for the organic carbon content in marine**  
637 **subtidal sediments.** The y-axis is a unitless relative variable importance score. Asterisks indicate the two initial  
638 predictors which were selected based on variable importance, with all other predictor variables selected using a forward  
639 selection process (see Appendix A5 for further details).. Mud\_min = Lower bound of 95% CI for mud content, SPM =  
640 Suspended particulate matter within the water column, Temp = Temperature, DistRiver = Distance to nearest river,  
641 IceConc = Sea ice concentration, DO = Dissolved oxygen at the seafloor, IceThick = Sea ice thickness, CurrVel =  
642 Current velocity at the seafloor.

643

644

645

646 **Figure 7. Accumulated local effects (ALE) plots for the six predictor variables with highest importance in the**  
647 **organic carbon (OC) content random forest model.** ALE (distributions down by lines) gives a visual representation  
648 of the average effect of the predictor variable on the response but does not indicate the influence of multi-way  
649 interactions which are inherent in random forest models. Rug plots (dashed marks at bottom) indicate the distribution  
650 of each variable within the training dataset. SPM = suspended particulate matter.

651 The predictions of %OC ranged from  $3 \times 10^{-5}$  to 5.6% with an overall mean of  $0.8 \pm 0.3\%$  ( $\pm$  SD).  
652 Areas with highest predicted %OC (>3%) were restricted to parts of the Pacific west coast fjords  
653 and channels, and in small parts of the inlets and bays on the east coast of Nova Scotia and  
654 around Passamaquoddy Bay in the Bay of Fundy (Fig. 8). High concentrations (i.e. >1%) were  
655 more widespread across these areas as well as covering much of the Beaufort Sea, western  
656 Baffin Bay and Foxe Basin in the Arctic, southern and central Hudson Bay, the Laurentian  
657 channel, coastal north Newfoundland and the central Scotian shelf in the Atlantic, as well as  
658 across the Salish sea and deeper areas to the south of the British Columbian Pacific continental  
659 margin (Fig. 8). Lowest %OC was predicted across shallower parts of the central Pacific shelf and  
660 near coast areas west of Vancouver Island (Fig. 8). Cross validation estimated an  $R^2$  for the model  
661 of 0.58 and an RMSE of 0.09 arcsin{%OC}. Cell specific upper and lower 95% CI bounds are  
662 shown in Figure E2. On average the upper CI bounds were 42% larger than the mean prediction,  
663 and the lower CI bounds 33% less than the mean prediction.

664  
 665 **Figure 8. Predictive mapping of organic carbon content (%) in subtidal marine sediments across the Canadian**  
 666 **continental margin.** The main plot shows the Arctic and Atlantic regions with the Pacific region inset. The continuous  
 667 variable is shown displayed in discrete colour bands to improve visualisation of highly right skewed data. The 95%  
 668 confidence interval bounds around the predicted means are shown in Figure E2. Labels indicating the locations of  
 669 different areas mentioned within the text are shown in Figure B3. Country outlines from World Bank Official Boundaries,  
 670 available at <https://datacatalog.worldbank.org/search/dataset/0038272>.

671

### 672 3.3 Dry bulk density estimation

673 The dry bulk density of sediments was estimated using the predicted values of mud content from  
 674 our random forest model, and previously published functions for conversions to porosity and dry  
 675 bulk density (Fig. 2). Estimated values ranged from  $0.67 - 1.61 \text{ g cm}^{-3}$  with a mean of  $1.04 \pm 0.21$   
 676  $\text{g cm}^{-3}$  ( $\pm \text{SD}$ ). As expected by its derivation, the spatial distribution of dry bulk density values was  
 677 very similar to the mud content values predicted above (Fig. 5), i.e. lowest dry bulk density was  
 678 estimated in mud dominated areas (Fig. 9). Cell specific upper and lower uncertainty bounds are  
 679 shown in Figure E3. On average these bounds were 6.2% larger and 6.0% lower than the cell-  
 680 specific mean estimate.

681

682 **Figure 9. Estimates of sediment dry bulk density ( $\text{g cm}^{-3}$ ) across the Canadian continental margin.** The main  
 683 plot shows the Arctic and Atlantic regions with the Pacific region inset. The estimated bounds of uncertainty around the  
 684 predicted means are shown in Figure E3. Labels indicating the locations of different areas mentioned within the text  
 685 are shown in Figure B3. Country outlines from World Bank Official Boundaries, available at  
 686 <https://datacatalog.worldbank.org/search/dataset/0038272>.

687

### 688 **3.4 Estimated organic carbon density and standing stock**

689 From combining predictions of dry bulk density and organic carbon content, organic carbon  
 690 density could be estimated across the Canadian continental margin (Fig. 2). Estimated values  
 691 ranged from  $5 \times 10^{-4}$  to  $58.4 \text{ kg m}^{-3}$  with a mean of  $8.1 \pm 2.8 \text{ kg m}^{-3}$  ( $\pm$  SD). Spatial patterns in  
 692 organic carbon density (Fig. 10) were similar to those found for organic carbon content (Fig. 8).  
 693 Areas with highest carbon density ( $> 25 \text{ kg m}^{-3}$ ) were restricted to small areas within nearshore  
 694 zones, including inlets and fjords of British Columbia (Pacific), as well as enclosed nearshore  
 695 areas of the Atlantic East Coast (Fig. 10). High carbon densities ( $> 15 \text{ kg m}^{-3}$ ) were predicted to  
 696 occur across wide parts of these areas as well as further offshore in parts of the Laurentian  
 697 channel and central Scotian Shelf, and at the edge of the continental slope off the West of  
 698 Vancouver Island (Fig. 10). In the Arctic, areas with relatively high carbon ( $> 10 \text{ kg m}^{-3}$ ) were  
 699 predicted across many nearshore areas, as well as across large parts of the Beaufort Shelf, Foxe  
 700 Basin, James Bay and the Kane Basin (Fig. 10). Cell specific upper and lower uncertainty bounds

701 are shown in Figure E4. On average the upper bounds were 50% higher than the mean prediction,  
702 and the lower bounds 37% less than their means.

703 Using a standardised sediment depth of 30 cm, the total standing stock of organic carbon in  
704 surficial sediments across the model domain is estimated at 10.9 Gt with uncertainty bounds of  
705 7.0 – 16.0 Gt. Between bioregions, total stock was predominantly related to the total areal extent,  
706 for example Hudson Bay having the largest carbon stock and largest area (Table 2). The Strait of  
707 Georgia and Southern Shelf bioregions of the Pacific had the lowest total standing stocks due  
708 their small extent, however per unit area, these regions contained the highest organic carbon  
709 stocks, along with the Gulf of St Lawrence.

710

711  
712 **Figure 10. Estimates of organic carbon density (kg m<sup>-3</sup>) across the Canadian continental margin.** The main plot  
713 shows the Arctic and Atlantic regions with the Pacific region inset. The continuous variable is shown displayed in  
714 discrete colour bands to improve visualisation of highly right skewed data. The estimated bounds of uncertainty around  
715 the predicted means are shown in Figure E4. Labels indicating the locations of different areas mentioned within the text  
716 are shown in Figure B3. Country outlines from World Bank Official Boundaries, available at  
717 <https://datacatalog.worldbank.org/search/dataset/0038272>.

718

719 **Table 2. Summary of estimated mean total organic carbon stocks in surficial seabed sediments of different**  
 720 **bioregions across the Canadian continental margin.** Organic carbon standing stocks are estimated for the top  
 721 30 cm of seabed sediments. For delineation of the different bioregions see Supplement.

<b>Bioregion</b>	<b>Model domain extent (km<sup>2</sup>)</b>	<b>OC stock (Gt)</b>	<b>Stock per unit area (kt km<sup>2</sup>)</b>
1. Offshore Pacific	53,598	0.15	2.75
2. Northern Shelf BC	96,373	0.23	2.34
3. Southern Shelf BC	28,313	0.10	3.38
4. Strait of Georgia	8,664	0.04	4.94
5. Western Arctic	526,309	1.09	2.06
6. Arctic Basin	250,178	0.42	1.69
7. Arctic Archipelago	243,425	0.47	1.92
8. Eastern Arctic	757,226	1.82	2.40
9. Hudson Bay	1,234,257	3.08	2.49
10. NL Shelves	820,462	2.04	2.49
11. Gulf of St Lawrence	235,541	0.80	3.38
12. Scotian Shelf	234,888	0.65	2.77

722 Notes: OC = Organic carbon; NL = Newfoundland-Labrador.

723

### 724 **3.5 Rock substrate distribution case studies**

725 As the predictive maps produced in this study rely on physical sediment samples alone, they are  
 726 unlikely to produce valid estimates for areas of bedrock – i.e. estimates of zero sediment carbon  
 727 density where bedrock is located. On the Scotian shelf (bioregion 12), correcting our predictive  
 728 maps with a predicted bedrock distribution map (Fig. F1) reduces total organic carbon stock  
 729 estimates in this region by between 7.7 – 7.8% leading to a value of 0.59 Gt (0.37 – 0.90 Gt). For  
 730 the Pacific British Columbian marine region (bioregions 1-4), assigning zero values to areas  
 731 covered by a predicted bedrock distribution map (Fig. F2) would reduce our estimates by 9.1 –  
 732 9.7% to a total of 0.46 Gt (0.29 – 0.71 Gt) of organic carbon.

733

### 734 **4. Code and data availability**

735 All mapped products as shown in Figures 5, 8, 9 and 10 have been made available as  
 736 georeferenced TIFF files in the Borealis data repository at  
 737 <https://borealisdata.ca/privateurl.xhtml?token=7bb00f1e-2ce3-400c-955d-e8e0d4fe3080>

738 (Epstein et al., 2023). This includes the mean predictions as well as the cell-specific uncertainty  
739 bounds as shown in Appendix E. The repository also contains all data collated within the  
740 systematic data review of organic carbon content and the georeferenced TIFF files from the rock  
741 distribution case studies (Appendix F). Additionally, all the associated code used for data  
742 manipulations, model building and predictive mapping can also be found within the above  
743 repository.

744

## 745 **5. Discussion**

746 Using best available data, we have produced the first national assessment of organic carbon in  
747 surficial seabed sediments across the Canadian continental margin, estimating the standing stock  
748 in the top 30 cm to be 10.9 Gt (7.0 – 16.0 Gt). Although comparisons to previous global studies  
749 is challenging due to differences in sediment reference depths, mapping resolutions and total  
750 spatial coverage, our estimate falls within a similar range to those previously published (e.g.  
751 2.2 Gt in the top 5 cm (Lee et al., 2019) and 48 Gt in the top meter (Atwood et al., 2020) of the  
752 Canadian EEZ). In contrast to these global studies, the national approach taken here allows for a  
753 more complete data synthesis, a finer spatial resolution, larger spatial coverage of the Canadian  
754 continental margin and spatially defined estimates of uncertainty. Similarly to other national and  
755 regional mapping studies (Smeaton et al., 2021; Diesing et al., 2017, 2021), areas of high organic  
756 carbon stocks were predominantly predicted to occur in coastal fjords, inlets, estuaries, enclosed  
757 bays and sheltered basins, as well as in deeper channels and troughs (Fig. 10). To put our  
758 estimated organic carbon standing stock into context, 10.9 Gt equates to 52% of the organic  
759 carbon estimated to be stored in all Canadian terrestrial plant live biomass and detritus (both  
760 above and below ground), and 9.8% of soil organic carbon to 30 cm across Canada (Sothe et  
761 al., 2022).

762

### 763 *Model interpretation and uncertainties*

764 The two key components of the carbon stock estimates in this study are the predictive maps for  
765 mud content and organic carbon content, which were estimated to have a map accuracy of 60%  
766 and 58% respectively ( $R^2$  0.60 and 0.58). While these values may seem relatively low when  
767 compared to some other related studies (Diesing et al., 2017, 2021; Atwood et al., 2020; Mitchell  
768 et al., 2019), the use of robust, spatial cross-validation to calculate model evaluation metrics (as

769 we did herein) has been shown to produce significantly more conservative estimates of map  
770 accuracy when compared to frequently used random cross-validation approaches (Ludwig et al.,  
771 2023; Meyer et al., 2019) such as those used in both the global seabed carbon stock studies  
772 discussed above (Atwood et al., 2020; Lee et al., 2019). Within this study, we also calculated cell  
773 specific uncertainty bounds. While there are many ways to calculate model uncertainty, therefore  
774 making comparisons between studies challenging, the uncertainty in carbon density calculated  
775 here (37-50% either side of the mean) is close to those found within similar regional (Diesing et  
776 al., 2021; 58%) and global studies (Lee et al., 2019; 49%), both of which predict carbon stocks at  
777 significantly coarser resolutions. Our bounds for total standing stock (36% lower and 47% higher  
778 than the mean) are also similar to the estimated bounds from the recently published predictive  
779 models of Canadian terrestrial vegetation and soil carbon (a 90% confidence interval 48% either  
780 side of the mean) (Sothe et al., 2022).

781 Using two case studies from British Columbia and the Scotian Shelf, we estimated that the  
782 distribution of rock substrates could reduce our estimates of carbon stock by approximately 7.7 –  
783 9.7% (Fig. F1, F2). As much of the Canadian coastline is distant from significant infrastructure,  
784 extensive surveys of the seafloor are generally lacking, especially when compared to similar  
785 regional carbon mapping studies in northwest Europe (e.g. Smeaton et al., 2021). It is therefore  
786 unclear how representative these case studies are of the entire Canadian EEZ. Improved data on  
787 the presence of bedrock across lesser studied regions of the Canadian Arctic, Hudson Bay, Gulf  
788 of St Lawrence, Newfoundland and Labrador may allow for the production of a predictive map of  
789 bedrock across the Canadian EEZ which would significantly improve the carbon estimates and  
790 spatial predictive maps produced in this study.

791 Areas of uncertainty which could not be fully quantified include the accuracy and precision of  
792 response data and predictor layers. The response data drive the model construction, and  
793 therefore sampling, processing, or recording errors can propagate into predictions. This is  
794 particularly relevant given the large temporal extent of response data which was required to gain  
795 sufficient coverage for this work (1959-2019). This large duration may also add additional variation  
796 from temporal differences between data, for example from differing anthropogenic drivers on  
797 carbon storage and/or accumulation (Keil, 2017); however, similar temporal extents have been  
798 used in related studies (Atwood et al., 2020; Lee et al., 2019; Seiter et al., 2004) and 72% of the  
799 organic carbon data within this study were sampled after 1980 and 55% after 2000. Within the  
800 response data, assumptions and/or predictions were also required regarding the distribution of  
801 mud and carbon across sediment depths. While standardising for this factor is clearly necessary,

802 especially when using a wide variety of legacy data, it does add additional uncertainty which would  
803 not be present if widescale standardised sampling methods were employed. The results from this  
804 study do however highlight, that within the top 30 cm of sediment, the spatial location of the  
805 sample is a far stronger driver of organic carbon content than the sediment sampling depth (Table  
806 C1).

807 Most of the predictor variables used in this study are also themselves modelled products, which  
808 contain their own inherent uncertainties and/or interpolations which cannot be fully quantified  
809 here. Additionally, many predictors are constructed at spatial resolutions significantly coarser than  
810 that used for modelling and prediction in this study. This meant that predictor data had to be  
811 interpolated, with significant inherent assumptions regarding variation and distribution of the data.  
812 Although best available data were used in this study, if predictor variables were available at higher  
813 native resolutions, less assumptions would be necessary and significant differences may be found  
814 in predictions, as well as their uncertainty and variability. Many of the predictor variables also  
815 have temporal components, and while the climatological mean of a 12 – 14 year timespan used  
816 in this study is expected to produce variables representative for the study region, they do not  
817 completely align with the temporal extent of the response data which could add further prediction  
818 uncertainty. Finally, due to data availability, the uncertainty bounds around our mean estimates  
819 of dry bulk density and organic carbon density were approximated from the constructed 95% CIs  
820 of mud content and %OC from the random forest models. While these provide an appropriate  
821 measure of uncertainty in our estimates in the context of this study, if large empirical datasets  
822 became available for dry bulk and organic carbon density, it would be preferable to construct  
823 predictive models, mean estimates and uncertainty bounds for these response variables directly.

824

#### 825 *Future directions and applications*

826 Improvements could be made in future iterations of these sediment carbon maps when additional  
827 response data become available. The size of the organic carbon content dataset was relatively  
828 small (2,518 point-samples) given the size of the model domain, so new data could greatly  
829 improve accuracy and reduce uncertainty in predictions. Additionally, wide-spread empirical data  
830 on sediment dry bulk density would reduce the assumptions needed in using approximate  
831 conversions from mud content, while a large geographically dispersed empirical dataset on  
832 seabed sediment organic carbon density (i.e. where OC content and dry bulk density is measured  
833 directly in each physical sample) would reduce assumptions even further, with the potential to

834 construct a single predictive map for this response alone (Diesing et al., 2021). There are also  
835 improvements to be made with the development of higher resolution or more accurate predictor  
836 layers. This would be particularly relevant for those variables with coarse resolutions and those  
837 which were seen to have highest importance within our models or from related seabed sediment  
838 mapping studies (e.g. Gregr et al., 2021; Diesing et al., 2017, 2021; Mitchell et al., 2019) – i.e.  
839 wave velocities, suspended particulate matter, exposure, current velocities and oxygen  
840 concentrations. Further validation and refinements could also be supported by numerical  
841 biogeochemical modelling products where the organic carbon densities are mathematically  
842 estimated based on oceanographic, climatological and benthic conditions, including the potential  
843 to incorporate predictions under different future climate scenarios (Ani and Robson, 2021).

844 The organic carbon predictive mapping product generated here could have many future  
845 applications. Regionalisation and prioritisation processes could identify key areas of carbon  
846 storage for further research and possible protections (Epstein and Roberts, 2022, 2023; Diesing  
847 et al., 2021). There is also potential to combine these mapped products with spatial data on  
848 human activities occurring on the seafloor to consider potential management implications, such  
849 as controlling the levels of impactful industries (e.g. mobile bottom fishing, mineral extraction,  
850 energy generation) in areas with high organic carbon (Clare et al., 2023; Epstein and Roberts,  
851 2022). The mud content predictive maps may also have applications for marine planning more  
852 widely, being a strong driver of the biological habitat type and sensitivity. Overall, these data have  
853 wide-scale relevance across marine ecology, geology and environmental management  
854 disciplines, however, the use of these products should always consider the discussed  
855 uncertainties and quantified uncertainty bounds of predictions. As with all large-scale mapping  
856 exercises, continued empirical data collection is needed for improved accuracy of mapping  
857 seabed carbon stocks across Canada.

## 858 **6. Appendices**

### 859 **Appendix A. Supplementary methods**

#### 860 A1. Analysis software

861 Analyses were primarily undertaken in R 4.2.2 (R Core Team, 2022) and Rstudio 2022.12.0.353  
862 (Posit Team, 2022), with some additional data manipulation and spatial plotting in QGIS  
863 (QGIS.org, 2021) and Python (Van Rossum and Drake, 2009). Within R, raster data were handled  
864 using the *terra* package (Hijmans, 2022), spatial vector data using the *sf* package (Pebesma,  
865 2018), netCDF data with the *stars* (Pebesma, 2022) and *tidync* (Sumner, 2022) packages, data-  
866 frames with the *dplyr* package (Wickham et al., 2019), and vector data with base R (R Core Team,  
867 2022). Random forest modelling was primarily dependent on the *ranger* package (Wright and  
868 Ziegler, 2017), however models were constructed and tuned using the *tidymodels* package (Kuhn  
869 and Wickham, 2020), with cross-validation and predictor variable selection using the *CAST*  
870 (Meyer et al., 2023) and *caret* (Kuhn, 2022) packages. Plotting utilised the above packages as  
871 well as *ggplot2* (Wickham et al., 2019) and *patchwork* (Pedersen, 2022) while parallel processing  
872 used the *doParallel* package (Microsoft Corporation and Weston, 2022).

873

#### 874 A2. Bathymetry layer construction

875 To define the maximum potential spatial coverage of this study, best available bathymetric  
876 datasets were combined across the Canadian Exclusive Economic Zone (EEZ) (Table 1). Firstly,  
877 three Digital Elevation Model (DEM) raster layers covering different extents of the Canadian EEZ  
878 were each filtered to contain only those elevations of less than or equal to 0 m. Where necessary,  
879 data were then aggregated (averaged) or disaggregated (split) to a resolution of approximately  
880 200 m, and all layers were projected onto a unified 200 m x 200 m equal area grid (co-ordinate  
881 reference system (CRS) EPSG:3573 – WGS 84 – North Pole Lambert Azimuthal Equal Area  
882 Canada). Reprojection was necessary as all three DEMs were in different co-ordinate systems,  
883 including some already being projected. The 200 m resolution was chosen as it is the median  
884 native resolution of the three DEMs, while also being considered towards the upper limit of what  
885 may be computationally possible within the scope of this study. After reprojection, the three layers  
886 were overlain, with the region-specific data given priority over global data where present. Finally,  
887 the seaward boundaries were delineated by the outer extent of the Canadian EEZ (Flanders  
888 Marine Institute, 2019).

889

890 A3. Details of ocean circulation models

891 ANHA12 is a regional configuration of the NEMO ocean and sea-ice model (Madec et al., 1998)  
892 created at the University of Alberta, covering the Arctic and northern Hemisphere Atlantic at 5 day  
893 temporal resolution, a curvilinear 1/12<sup>th</sup> degree horizontal resolution ranging from 1.93 km in the  
894 Arctic to 9.3 km at the equator, and 50 vertical levels (Hu et al., 2019). The British Columbia  
895 continental margin (BCCM) circulation model created by Fisheries and Oceans Canada (DFO)  
896 covers the entire Canadian Pacific coast and extends approximately 400 km offshore. It has a  
897 uniform horizontal resolution of 3 km, 42 vertical levels and a 3 day temporal resolution (Peña et  
898 al., 2019; Masson and Fine, 2012). As the BCCM model has higher uncertainty in nearshore and  
899 enclosed environments due to its relatively coarse resolution, data were also extracted for the  
900 enclosed Salish Sea from the Salish Sea Cast ERDDAP data server. Similarly to the ANHA12  
901 model, the Salish Sea Cast is a configuration of the NEMO circulation model developed by a  
902 consortium of Canadian Universities and government agencies and extends from Juan de Fuca  
903 Strait to Puget Sound to Johnstone Strait at 500 m horizontal resolution, 40 vertical layers and  
904 hourly temporal resolution (Soontiens and Allen, 2017; Soontiens et al., 2016). For further details  
905 on all these models, see relevant cited references. It should be noted that many of these ocean  
906 circulation models contain high uncertainty in nearshore areas. However, they are expected to be  
907 greatly improved when compared to global circulation model products (Peña et al., 2019; Hu et  
908 al., 2019; Soontiens and Allen, 2017) which are frequently used in this sort of predictive mapping  
909 work (e.g. Atwood et al., 2020; Lee et al., 2019; Assis et al., 2018).

910

911 A4. Sediment grain size data collation and processing details

912 Sediment composition point data were extracted from two sources. Firstly, all data were exported  
913 from the NRCan Expedition Database on 11<sup>th</sup> November 2022. This data repository contains  
914 information related to marine and coastal field surveys conducted by or on behalf of the Geological  
915 Survey of Canada from the 1950s to present, which deployed sampling methods including piston  
916 cores and grab samples. Data were also extracted from a recent synthesis of grain size  
917 distribution measurements from the Canadian Pacific seafloor (1951-2017), compiled by  
918 Geological Survey Of Canada and NRCan (Enkin, 2023). Although there are some duplications  
919 between these two datasets, these are accounted for in proceeding pre-processing steps. In both  
920 sources, grain size data is reported as the percentage content of mud (sometimes separated into

921 silt and clay), sand and gravel within each sample. Due to modern developments in grain size  
922 analyses (e.g. laser diffraction) older samples may have lower measurement accuracy; however,  
923 due to the relatively coarse metric being used in this study (%mud/sand/gravel) and the  
924 occurrence of a number of largescale geological surveys occurring during the 1960s, we chose  
925 to retain data from 1960 onwards. Where sampling year was not recorded within the database,  
926 the date was inferred from the expedition code or from expedition metadata. The sampling method  
927 and depth of the sediment from which the sample/sub-sample originates are also predominantly  
928 recorded within the database. Where sediment depth was absent, but the sampling method was  
929 noted as “grab” or “other”, the penetration depth was assumed to be 10 cm (a commonly assumed  
930 penetration of standard sediment sampling devices such as Van Veen Grabs and Day Grabs).

931

#### 932 A5. Details on construction and implementation of spatial cross validation and feature selection

933 For each response variable modelled in this study (mud content and organic carbon content  
934 (%OC)), the *spatialsample* package (Silge and Mahoney, 2023) was used to construct a variety  
935 of spatial CV data-fold structures and the validity of each structure was visually assessed using  
936 the *CAST.plot\_geodist* function (Meyer et al., 2023). This function creates density plots of nearest  
937 neighbour distances (Euclidean) in multivariate predictor space (using normalized variables)  
938 between response data locations and a random sample of prediction locations, and between data  
939 inside and outside each CV fold (Ludwig et al., 2023; Meyer et al., 2023; Meyer and Pebesma,  
940 2022). The suitability of a given CV structure to be representative of estimating map accuracy can  
941 be determined by visually assessing the density plots and finding the CV-distance curve being  
942 closely aligned to the density curve of response data to prediction distances (see Appendix D;  
943 Ludwig et al., 2023; Meyer and Pebesma, 2022). To approximate response-to-prediction  
944 distances, the sample size number within *plot\_geodist* was set to select 5,000 random samples  
945 across the model domain. Further, as the spatial distribution of data is a key consideration to  
946 ensure robust cross-validation (Ludwig et al., 2023; Meyer and Pebesma, 2022), for the  
947 *plot\_geodist* calculations alone, the x- and y-coordinates of each data point were included in  
948 addition to those predictor variables listed in Table 1 and described in Section 2.5.

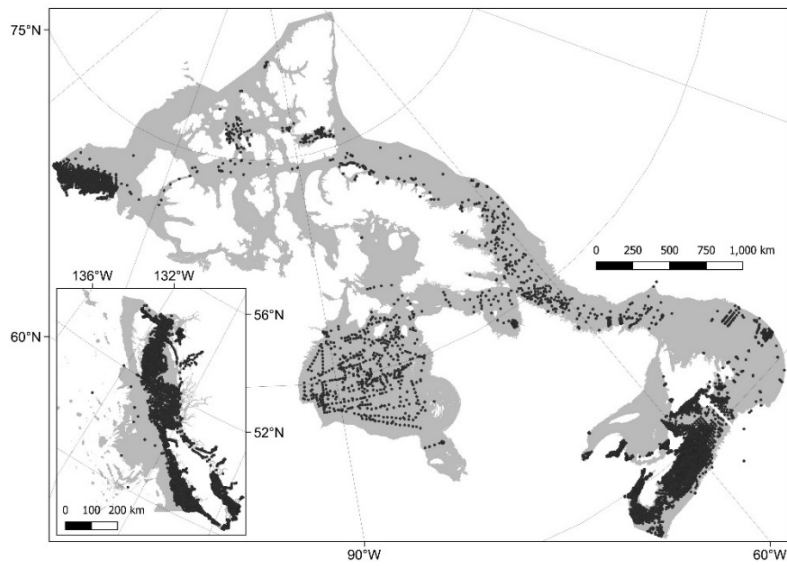

949 For the mud content data, a spatial kmeans clustering CV structure was chosen as the response  
950 data had good coverage of the model domain, contained a large number of data points, and  
951 showed relatively strong spatial clustering (Fig. B1). A range of options in the number of kmeans  
952 clusters were tested, with 35 being determined as the optimal number and each cluster being

953 assigned to its own CV fold (Fig. D1). Through visual assessment of the density plots, it was  
954 identified that the kmeans CV structure was somewhat mis-aligned from response-to-prediction  
955 distances, with the CV distances being overly conservative at including near-distance  
956 comparisons (Fig. D1). We therefore used a partially repeated CV strategy, with a small number  
957 of randomly selected data-points added to the assessment set in each kmeans spatial-CV fold  
958 (1% of mud content data randomly sampled at each fold without replacement) (Fig. D2). As the  
959 %OC response dataset was relatively small and spatially dispersed (Fig. B2), we used a spatial  
960 block CV strategy in place of the kmeans clustering to avoid clusters containing highly spatially  
961 dispersed data. We chose to use hexagonal shaped blocks, random assignment of blocks to folds,  
962 and the same number of CV folds as for the mud content data ( $v = 35$ ) – both to maintain  
963 uniformity and because varying the fold-number did not significantly influence the density plots.  
964 Instead, the diameter of the spatial blocks was altered, and an optimal block size of 100 km  
965 identified using the *plot\_geodist* function (Fig. D3).

966 The *CAST.ffs* function (Meyer et al., 2023) was used to run a forward predictor variable selection  
967 process with appropriate spatial considerations. The function fits a model with all combinations of  
968 two-way predictors, selects the best model based on a given metric, and then increases the  
969 number of predictors by one, testing all remaining variables. This iteratively continues with the  
970 process stopping if none of the tested variables increases the performance when compared to  
971 the best previous model with “n-1” predictors. The function allows models to be fit separately on  
972 each spatial CV fold (as defined above), with the overall performance of each iteration based on  
973 model accuracy across all CV folds. This therefore incorporates appropriate spatial considerations  
974 into the feature selection process. Due to the large number of variables within this study, and the  
975 relatively large datasets, this process was very computationally expensive. We therefore chose  
976 to adapt the function to initiate forward variable selection after initial identification of the first two  
977 predictor variables. These variables were identified by constructing a single random forest model  
978 with all training data and predictor variables, and the hyperparameters *mtry* (the number of  
979 variables to randomly sample as candidates at each split), *min\_n* (the number of observations  
980 needed to keep splitting nodes) and *trees* (the number of random forest trees to construct and  
981 take mean predictions across) set to 2, 5 and 1,000 respectively. Variable importance was  
982 estimated on out-of-bag samples through permutation of predictor variable values (Wright et al.,  
983 2016), and the two predictor variables with highest importance selected. The *ffs* function was then  
984 run starting with the two pre-selected variables (see Fig. 3 & 6) and performance of each iteration  
985 assessed on the root mean squared error (RMSE) of predictions across all CV folds.

993

994

**Figure B3. Map indicating the locations of different areas which are mentioned within the text.** The Canadian Pacific (blue), Arctic (grey) and Atlantic (red) regions are shown with labelled locations overlaid. BC = British Columbia; Passa' Bay = Passamaquoddy Bay; NS = Nova Scotia; NF = Newfoundland; SPMI = St Pierre and Miquelon. The locations are for guidance only and do not represent the entire extent or exact location of a given area. Country outlines are derived from World Bank Official Boundaries, available at <https://datacatalog.worldbank.org/search/dataset/0038272>.

999

1000

1001

1002

1003 **Appendix C. Organic carbon sediment depth modelling results**

1004

There was a significant effect of sampling depth on the organic carbon content in seabed sediments ( $\chi^2 = 1400.9$ ,  $p < 0.001$ ). While sample ID explained most of the variation between sub-sample carbon contents, the sampling depth was also a significant factor (Table C1). Carbon content decreased with increasing sampling depth (Fig. C1). The rate of carbon content decline generally decreased with increasing depth into the sediment, however uncertainty in this trend increased within deeper sediment layers (Fig. C1).

1010

1011

1012 **Table C1. Results from the generalised additive mixed model between the carbon content of marine sediments**  
 1013 **and sampling depth.** A basic generalised additive mixed model with a scaled-t distribution was constructed for carbon  
 1014 content in sediment sub-samples with sample ID as the random factor and sampling depth as the fixed factor.

Spline	Type	edf	Res. df	$\chi^2$	Deviance explained	p
Sampling depth (cm)	Cubic	4.28	5.36	2299	1.1%	< 0.001
ID	Random	181.94	182.00	715046	86.9%	< 0.001

1015 Notes: edf = Effective degrees of freedom. Res. df = Residual degrees of freedom

1016

1017  
 1018 **Figure C1. Regression splines indicating the effect of sediment sampling depth (a) and sample ID (b) on the**  
 1019 **organic carbon content in seabed sediment sub-samples.**

1020  
 1021 The predicted mean effect of sediment depth on carbon content was extracted from the model  
 1022 and converted into a transfer function which states the expected ratio between the carbon content  
 1023 across 30 cm compared to the cumulative mean at any given sampling depth (Figure C2). The  
 1024 ratio ranged from 89.3% when only measuring the sediment surface, to 93.7% if measuring the  
 1025 carbon content across the top 10 cm, and by 25 cm was approaching equilibrium at 98.8%.

1026

1027

1028 **Figure C2. Transfer function for cumulative mean organic carbon (OC) content at 30 cm sediment depth.** Using  
 1029 a generalised additive mixed model an estimated transfer function was constructed to standardise the cumulative mean  
 1030 carbon content at any given depth to an expected value at 30 cm.

1031

1032 **Appendix D. Results from random forest cross-validation structure selection**

1033

1034 **Figure D1. Multivariate nearest-neighbour distance density plot for mud content data with the optimal number**  
 1035 **of spatial k-means clusters across cross validation (CV) folds.** Frequency of nearest neighbour distances (x-axis)  
 1036 is shown for sample-to-sample distance (red), sample-to-prediction distance (green) and CV fold analysis-to-  
 1037 assessment distance (blue). dist = Multivariate Euclidean distance in predictor space after normalization of predictors.  
 1038 An optimal number of 35 clusters was selected to due close overlap between the CV-distance and sample-to-prediction  
 1039 curve.

1040

1041 **Figure D2. Multivariate nearest-neighbour distance density plot for mud content data with a partially repeated**  
 1042 **spatial-random mixture method for cross validation (CV) folds.** Frequency of nearest neighbour distances (x-axis)  
 1043 is shown for sample-to-sample distance (red), sample-to-prediction distance (green) and CV fold analysis-to-  
 1044 assessment distance (blue). dist = Multivariate Euclidean distance in predictor space after normalization of predictors.  
 1045 Due to the optimal spatial k-means clustering showing poor overlap at lower multivariate distances (Fig. D1), a 1%  
 1046 random sample without replacement was added to each fold.

1047

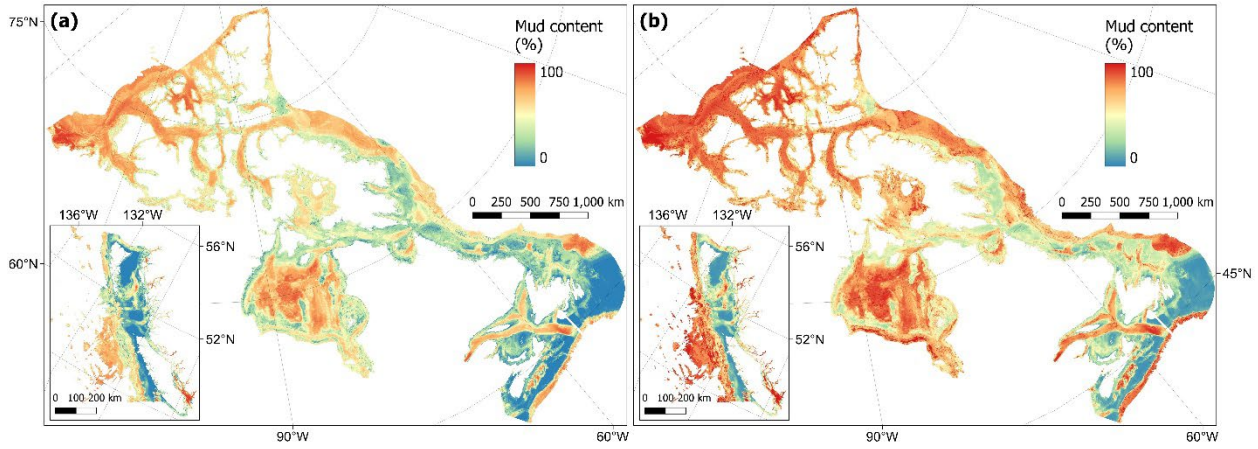

1048

1049 **Figure D3. Multivariate nearest neighbour distance density plot for organic carbon content data with the**  
 1050 **optimal block size across cross validation (CV) folds.** Frequency of nearest neighbour distances (x-axis) is shown  
 1051 for sample-to-sample distance (red), sample-to-prediction distance (green) and CV fold analysis-to-assessment  
 1052 distance (blue). dist = Multivariate Euclidean distance in predictor space after normalization of predictors. An optimal  
 1053 block size of 100 km was selected to due close overlap between the CV-distance and sample-to-prediction curve.

1091 Columbian continental margin is taken from Gregr et al. (2021).

1092 **7. Author contributions**

1093 JKB and SDF secured funding and led the management of this project. GE, SDF and JKB  
1094 conceptualised this study. GE, DH, AP, CP & PGM collated the data. GE developed the model  
1095 code and performed the investigations with input from SDF and JKB throughout. GE prepared the  
1096 manuscript with contributions from all co-authors.

1097

1098 **8. Competing interests**

1099 The authors declare that they have no conflict of interest.

1100

1101 **9. Acknowledgements**

1102 We greatly appreciate advice given across various stages of the processes from Cooper Stacey,  
1103 Markus Diesing, Sophia Johannessen, Ashley Park, Nadja Steiner, Diane Lavoie, Amber  
1104 Holdsworth, Michael Li, Kate Jarret, Javier Murillo-Perez, Ellen Kenchington, Emily Rubidge and  
1105 others within the Department for Fisheries and Oceans, and Natural Resources Canada. We  
1106 would also like to thank Randy Enkin, Sarah Paradis and Genevieve Philibert for sharing data  
1107 towards this work, as well as the constructive and insightful comments from the two referees, and  
1108 Jennifer McHenry, Matt Csordas and Brian Timmer for their ideas towards troubleshooting during  
1109 the project. This research was enabled in part by support provided by BC & Prairies Digital  
1110 Research Infrastructure and the Digital Research Alliance of Canada ([alliancecan.ca](http://alliancecan.ca)).

1111

1112 **10. Financial support**

1113 This work was funded by an Natural Sciences and Engineering Research Council (NSERC)  
1114 Alliance partnership grant #ALLRP571068 – 21 to JKB, and is publication #001 of Blue Carbon  
1115 Canada. GE is also supported by a Mitacs-Accelerate Fellowship, jointly funded by Oceans North.  
1116 PGM also gratefully acknowledge the financial and logistic support of grants from NSERC  
1117 including a Discovery Grant (rgpin 227438-09) and Climate Change and Atmospheric Research  
1118 Grants (VITALS - RGPCC433898 and the Canadian Arctic Geotraces program - RGPCC  
1119 433848), as well as support from the Marine Environmental Observation, Prediction and  
1120 Response Network (MEOPAR) Prediction Core.
