10 **Abstract.** Monitoring changes in glacial dynamics is essential for understanding the environmental response to a ccelerated climate warming in the Arctic. However, geodetic surveys in polar regions continue to present considerable challenges because of the harsh environmental conditions and the polar night. This study records a 14–year–long time series (2006–2019) of GNSS surveys of the positions of 16 ablation stakes distributed across Hansbreen, a tidewater glacier in southern Svalbard. The measurements were conducted with an exceptionally high temporal resolution, from about one week to about one month, and
15 covering altitudes ranging from 0 to 490 m asl. The position of one stake was surveyed every day. The primary data products consist of the stake coordinates and velocities. Time series of annual and seasonal velocities are also provided. This dataset may be a subject of further studies of glacier dynamics in relation to the long-term and seasonal impact of climate change on ice flow in the region. It also offers unique material for tuning numerical models of glacier dynamics and for validating satellite-derived products such as velocity and digital elevation models. The dataset described here has been made publicly available
20 through the Zenodo repository: <https://doi.org/10.5281/zenodo.8289380> (Błaszczyk et al., 2023).

1. Introduction

The study of ice mass dynamics in light of climate changes is a major research topic (Benn and Evans, 1998; Lemke et al., 2007; Strozzi et al., 2017; Meredith et al., 2019; Van Wychen et al., 2016). For more than two decades, in situ measurements of glacier surface velocities with GNSS (global navigation satellite system, Vieli et al., 2000, 2004; Stober and Hepperle, 2007;
25 Machío et al., 2017) have been among the most valuable sources of information for the study of glacier dynamics. The surface velocity is the sum of two components – ice deformation and basal slip (Nye, 1952; Weertman, 1957). The forces governing flow depend on several factors, such as ice temperature, the debris content of the ice, bed roughness and water pressure (Benn and Evans, 1998). As there are still few data on flow rates at depth, the surface velocity, the easiest component of flow to measure (Cuffey and Patterson, 2010), is used for constructing numerical models of glaciers (Vieli et al., 2004; Rückamp et al., 2010; Otero et al., 2017; Vallot et al., 2017; Koziol and Arnold, 2018; Klein et al., 2020; Rosier and Gudmundsson, 2020).
30

Few sets of long-term in situ measurements of glacier velocities in polar regions are available, as geodetic measurements are time-consuming, logistically difficult to perform, and expensive (Stober and Hepperle, 2019). Nonetheless, they are especially important for acquiring knowledge and an understanding of the mechanism of mass circulation in the glacier system. They are also useful for determining the volume of ice lost by glaciers flowing into the sea as a result of frontal ablation (Kochitzky et al., 2022). Svalbard glaciers where long-term velocity measurements have been studied are Kongsvegen (Voigt, 1965; Vivet and Lliboutry, 1978; Lefauconnier, 1987; Lefauconnier et al., 1994; Hagen et al., 2005), Kronebreen (Schellenberger et al., 2015; Vallot et al., 2017), and Nordenskiöldbreen (den Ouden et al., 2010; van Pelt et al., 2018). Other in situ velocity measurements of tidewater glaciers in Svalbard have usually been limited to just a few years, e.g. five years on Austfonna (Dunse et al., 2015), and two on Holtedahlfonna (Bahr, 2015).

This study aims to present a data set of in situ glacier surface velocities of Hansbreen (Svalbard), collected for the 14-year period 2006–2019, obtained from the mass balance stakes network surveyed using GNSS. This continuous measurement record presents velocity of an Arctic glacier with unique and exceptionally high temporal resolution, around one week for five stakes and around one month for eleven stakes. To our knowledge, Hansbreen was the first Svalbard tidewater glacier for which ice flow velocity was measured with dual-frequency GPS on a regular basis resulting in exceptionally high measurement accuracy. The presented data also fill the gap in discontinuous satellite-derived glacier flow velocities before beginning of Sentinel-1 mission in 2014. Hansbreen is one of the few well-studied tidewater glaciers in Svalbard. The Polish Polar Station Hornsund, located in the vicinity of the glacier, provides the logistics for permanent measurements. Hansbreen is also one of the key glaciers in the World Glacier Monitoring Service (WGMS, 2021; <https://wgms.ch>, latest access: 30 June 2023), and its annual mass balance has been measured since 1989. Additionally, the surface velocity near the terminus of Hansbreen was measured by terrestrial photogrammetry from 1982 to 1991 (Jania and Kolondra, 1982; Vieli et al., 2000) and GNSS surveying (Vieli et al., 2004). Therefore, as a well-studied, polythermal, non-surging tidewater glacier of medium size, Hansbreen can be representative for the entire Svalbard Archipelago. The presented velocity data set can serve as input data for numerical models of glacier dynamics and processes at glacier termini (see, e.g. Otero et al., 2017; de Andrés et al., 2018). In situ measurements are invaluable for validating satellite-derived velocities obtained with methods like differential interferometric synthetic aperture radar and SAR offset tracking (Schellenberger et al., 2015; Błaszczyk et al., 2019a; Solgaard et al., 2021). The height of the glacier can be used for validating numerous digital elevation models derived from different remote sensing techniques (Jawak and Luis, 2012; Berthier et al., 2014; Schröder et al., 2017; Błaszczyk et al., 2019b). As climate warming in Hornsund took place more than six times as fast as the global average in the period 1979–2018 (Wawrzyniak and Osuch, 2020), such long-term observations permit a better insight into glacier dynamics in a rapidly changing environment. Our understanding of the physics of glacier motion is still incomplete (Benn and Evans, 1998), especially regarding connection between ice flow and surface runoff. This study provides datasets that enable a detailed assessment of spatial and temporal changes in flow of a Svalbard tidewater glacier in the context of surface runoff, both in short-term and interannual time scale.

65 2. Study area

Hansbreen (15°37'E, 77°05'N) is a polythermal tidewater glacier terminating in the Hornsund fjord, southern Svalbard (Fig. 1). In 2015, the glacier covered an area of 51.3 km² and had an active calving front 1.7 km wide (Błaszczyk et al., 2019a). The Hansbreen system was described in detail by Grabiec et al. (2012). It consists of a main glacier trunk and four major western tributary glaciers: Staszelisén, Deileggbreen, Tuvbreen and Fuglebreen. The surface slope is 1.8° along the centreline of Hansbreen and up to 5.6° along the centrelines of the tributary glaciers. The ice divide between Hansbreen and Vrangpeisbreen is well defined and located at around 490 m a.s.l, the highest part of the main trunk. However, the boundary between Hansbreen and its eastern neighbour Paierlbreen is more difficult to define owing to the transfluence of ice from the accumulation field to Kvitungisen, a tributary of Paierlbreen. The terminus retreat has been studied by Błaszczyk et al. (2013, 2021). The terminus of Hansbreen has been retreating since 1899, although there have been sporadic episodes of advance. From 1991 to 2015, the front retreated 917 m.

Hansbreen is the westernmost glacier in Hornsund, the southernmost fjord of Svalbard Archipelago. The hydrographic conditions along the west coast of Spitsbergen are defined by the cold water of Spitsbergen Current and warmer water of West Spitsbergen Current (Promińska et al., 2018). According to Nilsen et al. (2016), in recent years warm water from the West Spitsbergen Current flows more often into the western fjords, even in winter. Further, the glaciers of southern and central Spitsbergen have the most negative climate balance on Svalbard (Schmidt et al., 2023; van Pelt et al., 2019), and models predict the greatest glacier mass loss in the southern part of the archipelago also in the 2019–2060 period (van Pelt et al., 2021). Furthermore, global mass balance models (excluding the Greenland and Antarctic ice sheets) point to Svalbard as the region with the greatest negative mass balance by the end of the 21st century (Huss and Hock, 2015). In light of these studies, understanding a response of Hansbreen dynamics to climate warming is important for predicting glacial dynamic processes in the rest of the archipelago, as well as for other Arctic areas.

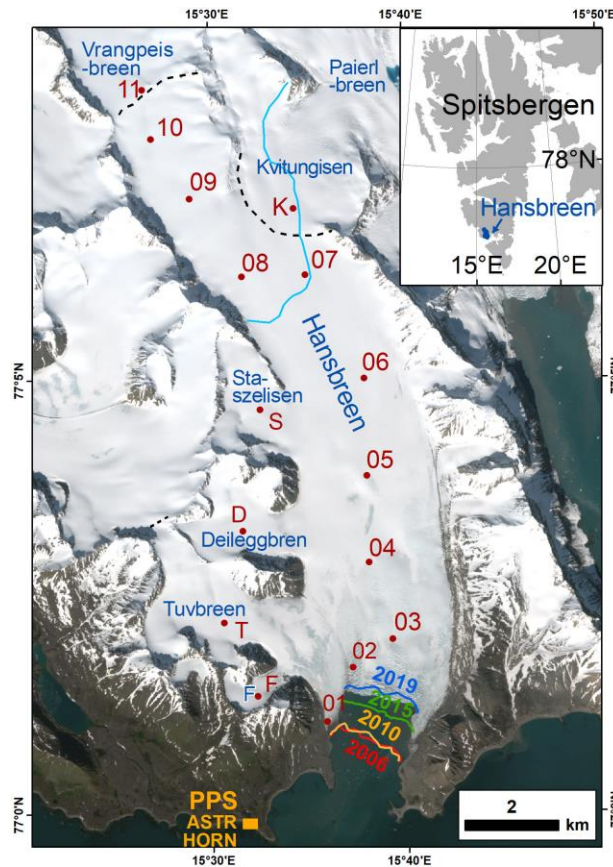

Figure 1: Location of Hansbreen. Red dots show positions of the stakes. PPS denotes the location of the Polish Polar Station. ASTR and HORN stand for GPS reference stations, F stands for Fuglebreen. Dashed black lines indicate ice divides separating Hansbreen from other ice masses. Blue line represents the average equilibrium-line altitude of Hansbreen in 2014 (after Laska et al., 2017). Terminus extent in 2006, 2010, 2015 and 2019 is determined from Blaszczyk et al. 2020, complemented. Background: Sentinel 2 (2018-07-06).

3. Instruments and methodology

3.1 Stake network

The datasets of ice surface velocities were estimated from repeated GNSS measurements of 16 aluminium stakes deployed on Hansbreen and its tributary and neighbouring glaciers (Fig. 1). The stakes were embedded up to 8 m deep in the glacier with a steam drill or Kovacs ice drill. The positioning of the stakes was selected to cover the entire elevation range of the glacier. Stakes 01–10 represent the velocity along the main trunk of Hansbreen, whereas the labelling of stakes F, T, D and S is based on the names of the tributary glaciers, i.e. Fuglebreen, Tuvbreen, Deileggbreen and Staszselisen, respectively. The positions of stake 11 on the glacier divide and stake K on Kvitungisen lie beyond the current border of Hansbreen. However, we have included the data pertaining to them, as they may be crucial for better constraining numerical models of glacier dynamics or studies of ice elevation changes. The positions of the stakes were measured from summer 2006 to summer/autumn 2019.

The speed of several grounded calving glaciers tends to increase as ice thins towards the terminus (Benn and Evans, 1998). This process has been observed on several Svalbard glaciers, e.g. Hansbreen (Vielí et al., 2000), Nordenskiöldbreen (van Pelt et al., 2018), and Kronebreen (Schellenberger et al., 2015; Vallot et al., 2017). Due to difficult polar conditions, the frequency of measurements of individual stakes varied depending on the distance from the glacier front. The stakes were surveyed in three different time intervals:

- Stakes 01, 02, 03 and 05 were normally surveyed at 7–10 day intervals, although these intervals were sometimes longer or shorter, as the measurements depended on the weather conditions. All these stakes were located in the ablation zone. Weekly intervals allowed to highlight detailed variation in the glacier velocity. The stakes 01 and 02 were installed outside the main flow line of the glacier, due to the high crevassing of the frontal part.
- Stake 04 was measured once a day in order to acquire a fuller picture of the glacier's dynamics. Seasonal changes in velocities at this point are representative of the glacier's ablation zone (3.7 km from the front of the glacier in 2006, at an altitude of 192 m asl) and daily intervals allowed to highlight very short variations in glacier velocity, e.g. speed events.
- Stakes 06–11, F, T, D, S and K were surveyed roughly once a month, generally at 25–30 day intervals, although these intervals could have been longer or shorter. For these stakes, monthly velocity significantly exceeded the estimated errors (see section 3.3 Data and accuracy), which allowed for seasonal insight in the glacier flow.

Hansbreen is a glacier with a negative climatic mass balance (-0.35 ma^{-1}) for the studied period of 2006–2019 (WGMS – <https://wgms.ch/> latest access: 30 June 2023). The thinning rate estimated from differentiation of digital elevation models for the period 2011–2017 was around 1 ma^{-1} in the upper parts the glacier, and up to 10 ma^{-1} at the glacier front (Błaszczuk et al., 2019b). Because of the lowering of the glacier surface caused by negative mass balance and the advection of the stakes towards the terminus, some stakes needed to be reinstalled. In such case, the position of the stake was shifted tens to hundreds of metres. This shift was especially common for stakes 02 and 03, which were deployed in a heavily crevassed frontal area. Moreover, some stakes were lost (broken by the wind or polar bears, or buried under heavy snowfall) and had to be replaced. Every change in the position of the stake is marked according to nomenclature described below. We differentiate each change in a stakes position using additional designations as follows:

- A, B, C – the consecutive positions of a reinstalled stake that was significantly shifted with respect to the glacier elevation and/or its position relative to the centreline;
- 1, 2, 3 – the consecutive positions of a reinstalled stake where the shift was small in comparison with the size of the glacier and the centreline (from decimetres to 290 m).

3.2 GNSS processing

Up to and including 2016, two-frequency (L1–/L2) GNSS-receivers (Leica GX1230) were used to measure the positions of the stakes in static mode. After 2016, a Leica GS14 with both GPS and GLONASS constellations was used for the

135 measurements. During the measurements, the antenna of the GNSS instrument was placed on the top of the stake. Static GNSS
surveys (15–30 minutes, but mostly 30 minutes with only a small portion being shorter) were further post-processed in Leica
GeoOffice software. The two reference points used in the post-processing were the ASTR (July 2006 to August 2009) and
HORN (September 2009 to September 2019) permanent GNSS stations in the vicinity of the Polish Polar Station, Hornsund
(Fig. 1; Węzka et al., 2010; Rajner, 2018). The baseline distance from the reference station to the stakes on the glacier ranged
140 between 2.4 and 15.5 km. The coordinates in the WGS84 system were re-projected to UTM zone 33X. The ellipsoidal heights
of the antenna were converted to geoidal heights using the EGM96 geoid and reduced to the glacier surface using field
measurements of the stake height. When the tip of the stake had frozen so that the antenna could not be placed on top, the
antenna was placed at the side of the stake and the offset was measured and compensated for by the observer in a pre-processing
procedure. In the final step, artefacts were identified manually and removed from the dataset.

145

One GNSS-receiver (Leica GX1230) was permanently deployed on stake 04, working in wake-up mode. This GNSS
instrument was continuously battery-powered and recorded data during most of the study period with some gaps of several
days (128 data gaps of four days or longer) due to lack of power or poor positional accuracy after post-processing. Stake 04
was located in the main flow line of the glacier and outside the highly crevassed zone, which allowed for a safe maintenance
150 and replacement of the battery, ensuring a continuous measurements of the stake position. The position of stake 04 was
surveyed daily for 30 minutes at midnight (00:00 hrs UTC), although in 2010, 2017 and 2018, these measurements were also
made at 22:00, 23:00 or 01:00 hrs. As mentioned above, daily measurements enabled observation of very short changes in
glacier velocity.

3.3 Data and accuracy

155 The accuracy of the geodetically determined position of a stake is influenced by the accuracy of the static DGPS (Differential
Global Positioning System) measurement (horizontal component 0.02–0.03 m; Stober and Hepperle, 2007; Bahr, 2015) and
the accuracy of the survey. The survey accuracy includes slight changes in the method of measuring a given stake, related to
the frozen tip of the stake, as described above. Contrary to Rückamp et al. (2010) or Machío et al. (2017) we made no correction
for the tilt of the stakes. Our measurements were much more frequent, therefore, tilt of the stake could be neglected. Following
160 Stocker-Waldhuber et al. (2019) and Anderson et al. (2018) we used the measurement accuracy of a stake's position $e_x=0.12$
m. The error e_x of stake 04 was assumed to be 0.03 m, as the antenna was not removed between measurements.

The displacement error Δx was estimated as:

$$\Delta x = \sqrt{(e_{xi})^2 + (e_{xi+1})^2} , \quad (1)$$

165 where e_{xi} and e_{xi+1} are the positioning errors of two stake positions.

The relative error of the measured short-term ice surface velocity was estimated using the method of Rückamp et al. (2010) to be the sum of the relative error of the displacement and time:

$$\frac{\Delta v}{v} = \frac{\Delta x}{x} + \frac{\Delta t}{t}, \quad (2)$$

170 where $\Delta v/v$ is the relative error of the velocity V , Δx is the error of the displacement, x is the calculated displacement of the aluminium stake, Δt is the precision of the time observation and t is the time between stake measurements. The time accuracy is 6 hours, as the observer did not always measure the stakes in the same order. In the case of stake 04, the time is accurate to the nearest second, so $\Delta t/t$ is negligible here.

175 In addition to the horizontal velocity, we estimated the geoidal heights of the glacier surface at the position of each stake. The accuracy of the vertical component of static DGPS measurements is 0.03 m (Stober and Hepperle, 2007). However, there may be additional errors in the height reduction from the top of the stake, where the antenna was mounted, to the snow or ice horizon. As the ice horizon is difficult to define during the ablation season, we assessed the height accuracy to 0.1 m. Apart from estimated horizontal velocities of the stakes between GNSS measurements, we provide annual and seasonal ice
180 velocity records. These records are based on the hydrological year, here defined as the period from 1 October to 30 September the following year (Cogley et al., 2011), with summer identified as the period from 1 June to 30 September, and winter from 1 October to 31 May.

4. Results

4.1 Horizontal velocities

185 Figure 2 shows the locations of each stake and the field observations. The time series of the horizontal velocity calculated for each stake, together with the estimated accuracy of measurements, are given in Fig. 3. The measurements of the stakes started between 3 July and 2 August 2006. The continuous measurements of the stake positions ended at different times between June and October 2019. Stakes 02 and 03 were surveyed only until November 2018, as they were approaching the terminus of the glacier and the ice surface was too heavily crevassed for measurements to be conducted safely. There are some gaps in the
190 data sets because a stake was lost or inaccessible, or the accuracy of the GNSS measurement was poor. Therefore, some velocities were estimated for periods longer than described above (i.e. longer than daily, weekly or monthly). The longest data gaps were 330 days for stake 02 and 304 days for stake 11. Although the longer observation period assures higher accuracy of measurements (see formula 2), it can cause some short speed changes to remain unnoticed in the observation.

Figure 2. Location of all surveyed stakes. Black dots represent the first position of each new dataset and light red dots show all measurements. Dashed navy blue lines indicate ice divides separating Hansbreen from other ice masses. Background: Pleiades (2017-08-20; Blaszczyk et al. 2019b).

200 **Figure 3. Time series of horizontal velocities for all stakes from 2006 to 2019. Shaded areas indicate accuracy ranges. Note different y axis for stake 02.**

The median values of velocities estimated from all the observations on each stake are listed in Fig. 4. Stake 01 was situated near the glacier terminus, on stagnant ice, i.e. part of a glacier that does not flow at a detectable rate (Cogley et al., 2011). This stake moved very slowly towards the front until 2013 (stakes 01A.1 – 01A.5). Since the end of 2013, this stake has been almost stationary, strongly influenced by the retreating ice front. Surveys repeated every few days yielded distances between consecutive measurements of the order of one to a few centimetres, which is well below the accuracy of the measurements (Fig. 3). Owing to the small displacements and the short times between the measurements, the relative velocity error at stake 01 could have been as high as $\pm 2600\%$. Similarly, the velocities of stakes 02A (up to 2013), 11 and F are lower than the accuracy of surveys. The relative velocity error for these stakes was as high as 200%, and those stakes were mostly surveyed every few days. Therefore, we wish to stress that these data should be used with a monthly or annual temporal resolution.

Figure 4. A box-and-whisker plot of measured ice velocities at Hansbreen in 2006-2019: a horizontal line is the median ice velocity, box edges represent the first and third quartiles, the whiskers correspond to a minimum and maximum velocity excluding outliers, and the outliers are presented as dots.

The highest velocity was recorded for stakes 02C, 03A, 03B and 03C (Fig. 4). The variability of the velocity was also the highest at these stakes. Their positions changed significantly a few times after reinstallation. Additionally, terminus of Hansbreen retreated by c. 1 km during the study period. Hence we stress here, that especially in the case of those stakes close to the front, caution is advised when drawing long-term conclusions, which should be analysed in relation to increasing surface flow velocities towards the calving front (Pillewizer, 1939; Krimmel, 1992; Vieli et al., 2000).

The velocities of stake 04 represent a unique dataset with a very high temporal resolution (Fig. 3d). The time series capture several short speed-up events, representing a considerable increase in glacier velocity (Kamb et al., 1994; Meier et al., 1994; Vieli et al., 2004). Such speed-up events were apparent not only at stake 04 measured every 24 h, but also at the other stakes
225 measured every few days (stakes 02, 03 and 05), and even at monthly intervals when the acceleration was higher than the accuracy of the measurements (stakes 06 to 09). However, there are some gaps in the dataset due to the poor accuracy of GNSS measurements, the lack of power or instrument failure. Continuous monitoring of stake 04 started on 3 July 2006 and ended on 29 September 2019. There are no observations for a total of 1256 days, i.e. 26% of the entire period. In the majority of cases, the data gaps are no longer than one to a few days. There are 50 data gaps of 6 days or longer, mainly in 2013 and 2014.
230 The longest interruptions in the data measurements were 38 days in October-November 2013 and 48 days in March-April 2014. Owing to terminus retreat and glacier movement, the distance of stake 04 from the front decreased from c. 3.7 km in 2006 to c. 2.7 km in 2019. Hence, as in the case of stakes 02 and 03, long-term conclusions should be analysed in the light of increases of surface flow velocities towards the calving front.

4.2 Accuracy assessment at stake 01

235 Stake 01 was deployed on stagnant ice (Cogley et al., 2011) that had terminated on the land and remained almost motionless since the end of 2013; hence, velocity measurements provide an excellent source for assessing the accuracy of measurements of stake positions (Fig. 5). Stake 01A.6 moved very slowly to the east, shifting 0.23 m between November 2013 and September 2014. Stake 01A.7 moved northwards, in the opposite direction to that of the glacier, shifting 0.46 m between October 2014 and July 2016. It is difficult to separate the slow movement of a stake from its tilting over a longer period or from the influence
240 of the direct vicinity of the steep front of the glacier, and therefore from the influence of tensions due to intensive surface melting, dry calving (Cogley et al., 2011) and surface cracking. The distribution of measurements of stakes 01A.6 and 01A.7 (Fig. 5) shows that the distances between consecutive measurements, usually carried out every few days, were within the measurement error assessed in this paper. This confirms the accuracy of the positional measurements used in this paper (0.12 m). The accuracy includes the accuracy of the GNSS measurements (0.02–0.03 m; Stober and Hepperle, 2007; Bahr, 2015),
245 together with all the other uncertainties related to the antenna offset compensation and stake tilting over a short time period. The data for stake 01A.8 cannot be used for such a quality assessment, as the glacier front melted and retreated considerably from 2016 to 2019, so the distance from the stake to the front decreased from about 200 to 100 m, and the exceptionally high velocity (Fig. 3a) was due to the noise caused by surface melt, opening of crevasses and dry calving of the glacier (Cogley et al., 2011).

250

Figure 5. Position changes of the stake 01A.6 and 01A.7. The numbers and colours (from red to dark green) indicates subsequent measurements.

4.3 Annual and seasonal velocities

In order to encourage the wider use of the data presented in this paper, we also give the annual (hydrological year) and seasonal velocities derived from continuous measurements. These velocities were estimated as the weighted average of all measurements, the weights being proportional to the duration of the measurement interval. The most common problems experienced were discontinuities in the stake position surveys, due to instrument failure or logistical problems with reaching the stake (e.g. safety reasons related to crevasses, insufficient light during the polar night, or harsh weather conditions). We therefore estimated the annual and seasonal velocities only for periods with continuous datasets. The timing of a seasons was established according to calendar dates, whereas conducting field measurements was limited by the weather and snow conditions. Therefore, if the beginning/end of the year or if the season fell in between two field measurements, the velocity was calculated as weighted in proportion to the length of the period falling within a particular season.

Data series prepared in this way can be used to assess the spatiotemporal pattern of the Hansbreen flow. The spatial pattern of the Hansbreen velocity and the increase in velocity towards the calving front has been the subject of previous studies (Pillewizer, 1939; Jania, 1988; Vieli et al., 2004). Here, to exemplify the dataset, we show the mean annual horizontal velocities for all the stakes in the hydrological year 2006–2007 (Fig. 6). The velocity increases from the upper parts of Hansbreen (stakes 09A and 10A) towards the terminus. The highest annual velocity (in 2006/2007) was recorded at stakes 03A and 04A, i.e. those nearest to the front. The stakes deployed on the tributary glaciers revealed very slow movement, typically of the order of just a few metres per year. A similar velocity was calculated for stake 11, which flows in the opposite direction, away from the main tongue of Hansbreen, i.e. towards Vrangpeisbreen. The ice at stake K flows towards Kvitungisen into the neighbouring Paierlbreen glacier system. Although stakes 11 and K are located outside the Hansbreen basin, they can help in a broader understanding of changes in glacier dynamics and the surface height at the catchment divide, particularly the possible ice flow piracy (McCormack et al., 2023) between Hansbreen and Paierlbreen.

275

Figure 6. Mean annual horizontal velocities for the hydrological year 2006-2007, as an example of the spatial pattern of Hansbreen velocity. The stakes 11 and K flow into other ice masses. Vr. stands for Vrangpeisbreen. Background: Sentinel2 (2018-07-06).

The data show a homogeneous pattern of annual and seasonal increases and decreases in velocities recorded at all the stakes, although the maximum and minimum velocities at particular stakes were noted in different years (Fig. 7). For example, the largest annual velocity was recorded in 2009 and 2017–2018 (stakes 04–08) and in 2011 and 2017 (stakes 10, K, SA, TA – no data for 2018). The lowest annual velocities were noted in 2006/2007 and 2013/2014 at stakes 04 and 05. The lowest velocities at stakes farther up the glacier were in 2006/2007–2008/2009 and 2013/2014. The highest summer velocities were generally recorded in the 2013/2014 and 2017/2018–2018/2019. A positive trend in velocities at both the annual and seasonal scales (Fig. 7) can be inferred for stakes that did not shift significantly during the measurement period (see Fig. 2). There was a similar positive trend in velocities at stake K, which is beyond the current border of Hansbreen where the ice flows into the Paierlbreen glacier. There was a similar increase at stake K, which is beyond the border of Hansbreen, where this flows into the Paierlbreen glacier.

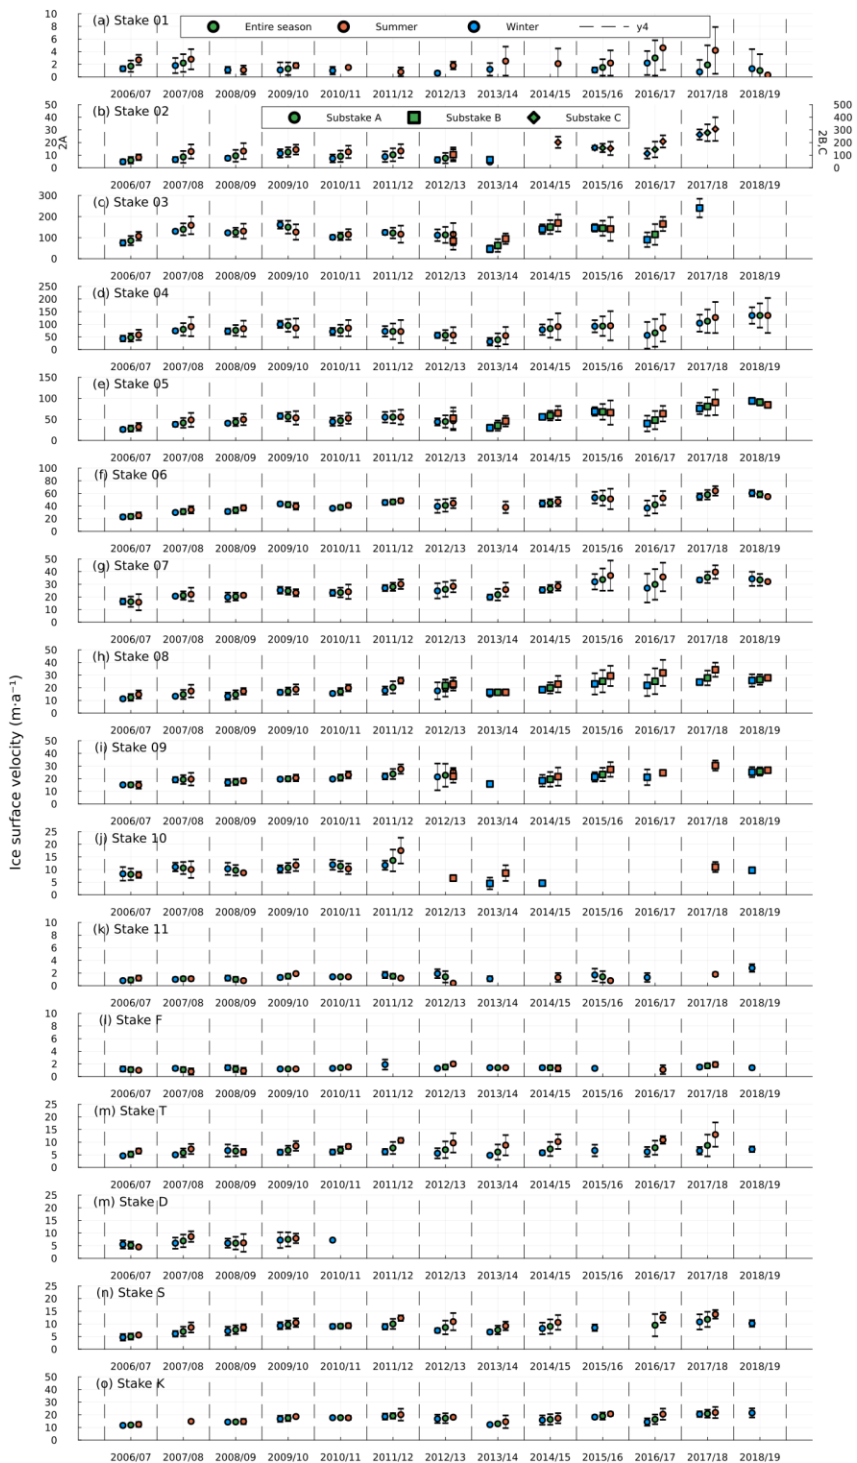

Figure 7. Annual and seasonal velocities determined for hydrological years, together with standard deviations.

There was high variability in both the annual and seasonal velocities of all the stakes between the years. At particular stakes, the velocities between the fastest and slowest years differed by a factor of two, or even three in some cases. The data also show the differences between the annual, summer and winter velocities in particular years. Generally, the glacier speed exhibits a clear annual cycle, and the velocity is the highest in summer and the lowest in winter (Meier et al., 1985; Van der Veen, 1995). In some cases, however, the winter velocities are either higher (e.g. stakes 03A, 04A, 05A, 06A, 07A in 2010) or very similar to the summer and annual velocities (e.g. stakes 08A, 09A, KA, SA in 2010). Relatively small variations between the annual and seasonal velocities are also apparent in 2014 and 2015 for the majority of stakes, and also in other years at particular stakes. Importantly, the dates of the seasons were established according to calendar dates. As glacier acceleration can also occur after the summer period, seasonal velocities should be analysed in light of such events and the meteorological and hydrological conditions (Krimmel and Vaughn, 1987; Walters and Dunlap, 1987). The largest variations between the annual and seasonal velocities were recorded at stakes 02 and 03, i.e. those nearest to the front. But, as already mentioned, the positions of stakes shifted a few times, and fluctuations of velocities are affected by their changing distance to the glacier front (Pillewizer, 1939; Vieli et al., 2004).

4.4 Glacier elevation

Besides the horizontal position and velocity, the datasets include the elevation of the glacier surface. Representative datasets of glacier surface elevation measurements at stakes 01, 05 and 10 are shown in Fig. 8, which depicts the change in surface elevation of different parts of the glacier over time. Note that these data correspond not only with emerging or submerging ice flow but also take account of changes resulting from snow accumulation and glacier ablation. This time series is not continuous, as outliers due to incorrect field measurements of the stake height were filtered from the datasets.

Figure 8. Representative dataset of height measurements of stake 01, 05, 10.

5. Data structure and availability

315 All the data have been made publicly available through the Zenodo repository: <https://doi.org/10.5281/zenodo.8289380>
 (Błaszczyk et al., 2023). There are two .csv files for each of the 16 ablation stakes (01–11, F, T, D, S and K). The first one
 (e.g. *Stake_01_position.csv*) contains a time series of GNSS-derived position measurements in the UTM (zone 33X) coordinate
 system. This file has the following columns: sub-stake label, date of measurements, easting, northing, geoidal height (EGM96).
 The second one (e.g. *Stake_01_velocity.csv*) is a time series of surface ice flow velocity, and is divided into the following
 320 columns: sub-stake label, date of the first measurement, date of the second measurement, surface ice flow velocity and accuracy
 of the surface ice flow velocity measurement. Additionally, we provide three files with annual, summer and winter velocities
 estimated for a hydrological year (*Stakes_annual_velocity.csv*, *Stakes_summer_velocity.csv* and *Stakes_winter_velocity.csv*,
 respectively). These files are divided into the following columns: hydrological year, velocity for each consecutive sub-stake
 and standard deviation of velocity for each sub-stake. The file *Hansbreen_preprocessing_code_stakes.zip* includes the code
 325 used for velocity estimation and data preprocessing. This code was written in the Bash and Julia programming languages.

6. Summary

This paper presents the velocity datasets resulting from an in situ monitoring survey of the Hansbreen glacier (Svalbard) during the period 2006–2019 using the GNSS system. The dataset includes high-temporal resolution velocities at 16 stakes with accuracy assessments, as well as mean annual and seasonal velocities. This dataset is one of the longest datasets documenting glacier movement on Svalbard. The data exhibit a pattern of velocities characteristic of tidewater glaciers (Pillewizer, 1939; Krimmel, 1992; O’Neel et al., 2001), where an ice flow increases from the ice divides towards the calving terminus. Further, the glacier typically accelerates during the summer months (Kamb et al., 1994; Meier et al., 1994), although higher velocities were occasionally also recorded in autumn and winter.

The shortcoming of this dataset is that it does not allow for an easy analysis of dynamic responses to climate changes, as the velocities were measured at stakes that change their position with time and represent a Lagrangian velocity field (Machío et al., 2017). Furthermore, the glacier terminus retreated about one kilometre during the study period. Thus, to investigate the relation between intraseasonal or interannual velocities and climate forcing, stake velocity should be corrected to the same position in space, and to the same distance from the glacier termini. Nevertheless, after such correction, these data might be further investigated with regard to changes in the glacier dynamics in light of climate change in the region (Wawrzyniak and Osuch, 2020), together with changes in the terminus position at different timescales (Ultee et al., 2020). Overall, these in situ ice flow velocity datasets can be used for tuning numerical models of glacier dynamics, e.g. modelling of flow of a grounded calving glacier (Vieli et al., 2000), developing glacier-plume and glacier-fjord circulation coupled models to simulate glacier-ocean system (De Andres et al., 2021), numerical simulation of the ice flow velocity in the future (e.g. Ai et al., 2019a), and changes of strain rate between neighbouring stakes (Ai et al., 2019b). Further, the data set is an invaluable source of information on short-term processes such as speed events and seasonal velocity changes (van Pelt et al., 2018). Moreover, such a data set can be of great importance for validating satellite-derived ice flow fields with in situ velocity measurements (Schellenberger et al., 2015; Fahnestock et al., 2016; Friedl et al., 2021) and digital elevation models derived from different remote sensing techniques, as previously used by Błaszczyk et al. (2019b).

350 Author contributions

JJ, DP and PG conceived the project. DP, MP, MB, BL, DI, and ML maintained the stake network and the instrumentation. Data curation were provided by MB, BL, MP. Conceptualization of the paper were performed by MB, MP, JJ and BL. MB, DP and MP led data processing and analysis. MB and MP wrote the original draft, and co-authors contributed text and edits. Funding acquisition was performed by PG, BL, MP, and JJ.

355 **Competing Interests.** The authors declare that they have no conflict of interest.

Acknowledgements

The data were collected within the framework of the glaciological monitoring of the Polish Polar Station Hornsund managed by the Institute of the Geophysics Polish Academy of Sciences, subsidized by the Polish Ministry of Education and Science (Decision No. 3/524698/SPUB/SP/2022). Special thanks are due to the staff of the Institute of Geophysics PAS, the Polish
360 Polar Station, Hornsund, and the participants of the University of Silesia's expeditions to Spitsbergen for maintaining the glaciological monitoring and conducting the fieldwork. The Pléiades used in the figures were provided by the Pléiades Glacier Observatory (PGO) programme of the French Space Agency (CNES), and Sentinel-2 was obtained from Copernicus Sentinel data (2018). The research and logistical equipment of the Polar Laboratory of the University of Silesia in Katowice was used during the fieldwork. The publication was created as part of a project co-financed by the Minister of Education and Science
365 under contract No. 2023/WK/02. BL was supported by a subsidy from the Polish Ministry of Education and Science for the Institute of Geophysics, Polish Academy of Sciences. MP was supported by a grant from the Priority Research Area (Anthropocene) under the Strategic Programme Excellence Initiative at the Jagiellonian University. Publication co-financed by funds allocated under the Research Excellence Initiative of the University of Silesia in Katowice. The research leading to these results has received funding from the EEA Financial Mechanism 2014-2021, predefined project no:
370 2022/43/7/ST10/00001.
