21

22 **Abstract.** Non-floodplain wetlands – those located outside the floodplains – have emerged as integral
23 components to watershed resilience, contributing hydrologic and biogeochemical functions affecting
24 watershed-scale flooding extent, drought magnitude, and water-quality maintenance. However, the
25 absence of a global dataset of non-floodplain wetlands limits their necessary incorporation into water

26 quality and quantity management decisions and affects wetland-focused wildlife habitat conservation
27 outcomes. We addressed this critical need by developing a publicly available Global NFW (non-
28 floodplain wetland) dataset, comprised of a global river-floodplain map at 90 m resolution coupled with a
29 global ensemble wetland map incorporating multiple wetland-focused data layers. The floodplain,
30 wetland, and non-floodplain wetland spatial data developed here were successfully validated within 21
31 large and heterogenous basins across the conterminous United States. We identified nearly 33 million
32 potential non-floodplain wetlands with an estimated global extent of over 16 million km². Non-floodplain
33 wetland pixels comprised 53% of globally identified wetland pixels, meaning the majority of the globe's
34 wetlands likely occur external to river floodplains and coastal habitats. The identified Global NFWs were
35 typically small (median 0.039 km²), with a global median size ranging from 0.018-0.138 km². This novel
36 geospatial Global NFW static dataset advances wetland conservation and resource-management goals
37 while providing a foundation for global non-floodplain wetland functional assessments, facilitating non-
38 floodplain wetland inclusion in hydrological, biogeochemical, and biological model development. The
39 data are freely available through the United States Environmental Protection Agency's Environmental
40 Dataset Gateway (https://gaftp.epa.gov/EPADDataCommons/ORD/Global_NonFloodplain_Wetlands/) and
41 through <https://doi.org/10.23719/1528331> (Lane et al., 2023).

42

43 **1 Introduction**

44

45 Wetlands are recognized as globally important ecosystems providing functions leading to critical
46 provisioning (e.g., food, fresh water for domestic, agricultural, and industrial use) and regulating services
47 (e.g., flood and drought mitigation, water purification and waste treatment, and habitat; Millennium
48 Ecosystem Assessment, 2005). Despite their functional importance, wetlands are threatened worldwide by
49 myriad anthropogenic disturbances, including sea-level rise (IPCC, 2014), drainage and filling (Davidson
50 et al., 2014), water abstraction (Liu et al., 2017), consolidation (McCauley et al., 2015), invasive species
51 (Zedler and Kercher, 2004), and changing precipitation and temperature patterns (Winter, 2000). These

52 widespread and globally prevalent alterations to wetlands affect their functioning, resulting in increased
53 downgradient flooding (Golden et al., 2021), modified stream baseflows (Buttle, 2018), reduced pollution
54 mitigation (Evenson et al., 2018a), and habitat loss (Uden et al., 2015).

55
56 Watershed-scale wetland management is currently hampered by the paucity of accurate and fine-grained
57 maps of wetland location (Creed et al., 2017; Christensen et al., 2022). However, methods to identify
58 existing aquatic systems, including wetlands, that provide functions at global scales have recently
59 emerged, such as the Landsat-based 30 m global surface-water inundation data (Pekel et al., 2016), finer-
60 resolution satellite-based landcover maps (e.g., Zanaga et al., 2021), and groundwater-driven aquatic
61 system characterizations (Fan et al., 2013). In addition, methods utilizing digital elevation models to
62 identify topographic depressions likely to support aquatic systems with characteristic wetland features,
63 such as saturated soils and/or ponded waters, have also regionally proliferated (Wu et al., 2019a; Wu et
64 al., 2019b; Christensen et al., 2022).

65
66 These advancements in mapping wetland location, such as those located within the river floodplain or
67 geographically distal from floodplains, allow resource managers to better incorporate wetland
68 biogeochemical, hydrological, and biological functions and concomitantly ecosystem services into their
69 decision-making efforts. For instance, incorporating *floodplain* wetlands into decision-making advances
70 the wise management and conservation of mapped riparian ecosystems (Tullos, 2018; Kundzewicz et al.,
71 2018). Thus, recognizing the importance of wetlands located within active river floodplains, land-
72 management decisions are being made to quantify the functions and ecosystem services of these wetlands
73 and incorporate them into watershed-scale hydro-ecological decisions (e.g., Makungu and Hughes, 2021;
74 Rajib et al., 2021).

75
76 However, *non-floodplain wetlands* are typically not incorporated into watershed-scale conservation and
77 management planning (e.g., Sullivan et al., 2019), thereby ignoring their contributions to watershed-scale

78 resilience in response to biogeochemical and hydrological disturbances (Rains et al., 2016; Golden et al.,
79 2021; Lane et al., 2022). Non-floodplain wetlands are abundant inland [freshwater](#) wetlands located
80 distally from the floodplains of rivers and lakes (Lane and D'Amico, 2016; Lane et al., 2018). Though
81 typically small (Cohen et al., 2016), high biogeochemical processing rates within non-floodplain wetlands
82 have resulted in these systems being termed bioreactors (Marton et al., 2015). Indeed, a literature review
83 of over 600 articles found that the highest reactivity rates (pollutant mass removal per unit time) were
84 found in the smallest water bodies and wetlands (Cheng and Basu, 2017). Further, the high reactivity of
85 individual non-floodplain wetlands can cumulatively improve downgradient water quality conditions
86 (Golden et al., 2019; Evenson et al., 2021). Non-floodplain wetlands may therefore have an outsized
87 impact on a watershed's water quality.

88

89 Non-floodplain wetlands are also important ecosystems affecting water quantity (i.e., for storing and
90 gradually releasing water to downgradient rivers and streams). Specifically, precipitation is captured and
91 stored in non-floodplain wetlands prior to being discharged downgradient. During this storage period,
92 water can infiltrate to recharge aquifers, evaporate or transpire, or eventually “spill” overland and be
93 transported downstream (Jones et al., 2018; Buttle, 2018). These non-floodplain wetland water storage
94 functions attenuate storm flows (Shaw et al., 2012; Fossey and Rousseau, 2016; Blanchette et al., 2022)
95 and recharge groundwaters (Bam et al., 2020), thereby mitigating flood-hazards (Mclaughlin et al., 2014)
96 and ameliorating drought conditions by maintaining baseflow (Ameli and Creed, 2019).

97

98 Despite the important functions provided by non-floodplain wetlands (Biggs et al., 2017; Chen et al.,
99 2022) a substantive data gap remains: no global maps or datasets exist identifying the geospatial location
100 of non-floodplain wetlands and open waters. Regionally focused efforts, such as the recent work by Lane
101 and D'Amico (2016) and Lane et al. (2022) mapped the extent of non-floodplain wetlands (also known as
102 geographically isolated wetlands, Leibowitz, 2015; Mushet et al., 2015) across the geospatially data-rich
103 conterminous United States (CONUS, see abbreviation list [in](#) Appendix A). They found that 16-23 % of

104 freshwater systems were potential non-floodplain wetlands, suggesting a substantial yet hitherto unknown
105 portion of the globe's wetlands are likely also this vulnerable water resource.

106

107 Fortunately, geospatial data for identifying aquatic systems, including wetlands, are burgeoning (~~Khare et~~
108 ~~al., in review~~). Global land cover and land use geospatial datasets that include a wetland cover class
109 continue to propagate (Hu et al., 2017a), taking advantage of both lengthy time-series Landsat data
110 (Homer et al., 2020) as well as recently launched advanced high-resolution and/or synthetic aperture radar
111 (SAR) equipped satellites (e.g., Sentinel-1, Sentinel-2, plus many commercially available platforms;
112 Martinis et al., 2022) and topographic data sources and analyses (e.g., Wu et al., 2019b). Examples
113 include the GlobeLand30 (Chen et al., 2015), the European Space Agency (ESA) WorldCover 2020
114 (ESA, 2020), the Dynamic World (Brown et al., 2022), as well as consortiums focusing on annual land
115 cover change mapping (e.g., Tsendbazar et al., 2021). Several recent publications review the available
116 wetland-focused datasets, including Hu et al. (2017a, their Table 1), Davidson et al. (2018, their Table
117 S1), Tootchi et al. (2019, their Table 1), and Zhang et al. (2023, their Table 1). We summarize additional
118 emerging global land cover data sets related to surface water and wetlands in Appendix Table B1.

119

120 Lehner and Döll (2004) were amongst the first to publish a geospatially explicit global map focusing on
121 wetland extents. Their Global Lakes and Wetlands Database provides 1 km estimates of wetland
122 abundance. More recent and/or higher resolution wetland-focused datasets have emerged, including the 1
123 km global dataset from Hu et al. (2017b) that incorporates precipitation and a topographic wetness index,
124 and the multi-sourced 500 m composite maps of regularly flooded and groundwater-driven wetlands by
125 Tootchi et al. (2019). Tootchi et al.'s (2019) approach identified small and scattered wetlands. However,
126 they recognized the limitations inherent in their global product (ca. 500 m per pixel resolution) resulted in
127 omission errors for many wetland systems, especially those smaller than their 500 x 500 m (25 ha) data
128 resolution. This suggests, and Tootchi et al. (2019) acknowledged, that many (non-floodplain) wetlands
129 were omitted in the Tootchi et al. (2019) 500 m global product. Cohen et al. (2016) determined non-

130 floodplain wetlands in the CONUS are “unambiguously small”, e.g., their average non-floodplain wetland
131 area was just over two hectares (2.1 ha). Based on the “all or nothing” methodological approach in
132 Tootchi et al. (2019), > 12.5 ha of a given 25.0 ha cell [one homogenous pixel] ~~cell~~ would have to be
133 identified as wetland in their resampling of the finer-scale data – much larger than the average 2.1 ha
134 wetlands found in Cohen et al. (2016).

135
136 Concurrent with increasingly available global land cover and wetland data, there is an increasing global
137 focus on deriving floodplain and flood ~~hazard~~-prone areal extents within river networks based on high-
138 resolution topographic data coupled with hydrologic and/or hydraulic modeling (Tullos, 2018;
139 Kundzewicz et al., 2018; ~~Rajib et al., in review~~). The past decade has seen development of multiple
140 regional to continental flood models that span physically based approaches (e.g., 1-,2-, and 3-D
141 hydrodynamic models) to empirical models (including machine-learning approaches and statistical
142 models) (see review by Mudashiru et al. 2021). On the global scale, openly accessible global flood
143 models include those reviewed by Hoch and Trigg (2019), namely CaMa-Flood (Yamazaki et al. 2011),
144 GLOFRIS (Winsemius et al. 2013), JRC (Dottori et al. 2016), CIMA-UNEP (Rudari et al. 2015), Fathom
145 (Sampson et al. 2015), and ECMWF (Papperberger et al. 2012). For instance, Sampson et al. (2015)
146 created a global 90 m map of flood-prone areas between 60° N and 56° S using a regional flood-frequency
147 model. More recently, Nardi et al. (2019) ~~developed-published~~ a global floodplain dataset at 250 m
148 resolution that extended from 60° N to 60° S, ~~based-developed through a~~ on-geomorphic or terrain-based
149 analyses of floodplain elevations and maximum flood-prone areas using ~~on~~ a drainage-area scaling
150 variable (Rajib et al. 2021). The evolution of the MERIT Hydro 90 m global hydrography dataset by
151 Yamazaki et al. (2019) and machine-learning approaches (e.g., Zhao et al. 2021) has created additional
152 opportunities to further advance the derivation of global floodplains, with improved identification of flow
153 accumulation area, river-basin shape, and river channel location.

154

155 These wetland-location and floodplain-extent data are critical for watershed-scale sustainable aquatic
156 resource policy decisions (Creed et al., 2017; Golden et al., 2017). The lack of these data can result in
157 disproportionately large model errors and potentially misguided management decisions when non-
158 floodplain wetlands are not incorporated in hydrological and biogeochemical models, ignoring their
159 watershed-scale impacts on flooding, drought, and water quality (Evenson et al., 2018a; Rajib et al., 2020;
160 Golden et al., 2021).

161
162 Here, we provide the first global geospatial dataset of non-floodplain wetlands. We incorporate the recent
163 development of a high-resolution global floodplain mapping algorithm based on digital terrain models by
164 Nardi et al. (2019). We couple these spatial floodplain data with higher-resolution modifications to the
165 gridded global wetland and open water data layers developed by Tootchi et al. (2019) that incorporate the
166 Pekel et al. (2016) satellite-based inundation product, modeled groundwater-driven wetland extent (Fan et
167 al. (2013), and ancillary satellite landcover data from Herold et al. (2015). We test the applicability of our
168 global dataset of non-floodplain wetlands in 21 large and spatial-data rich watersheds spanning nearly
169 700,000 km² across the CONUS. This novel global product identifying non-floodplain wetlands provides
170 for the quantification and estimation of the locations and extent of important aquatic systems with
171 abundant hydrological, biogeochemical, and biological functions, filling a noted research gap while
172 delivering useful data for informed natural resource decision-making and management (Creed et al.,
173 2017; Lane et al., 2022).

174

175 **2 Methodology and data**

176

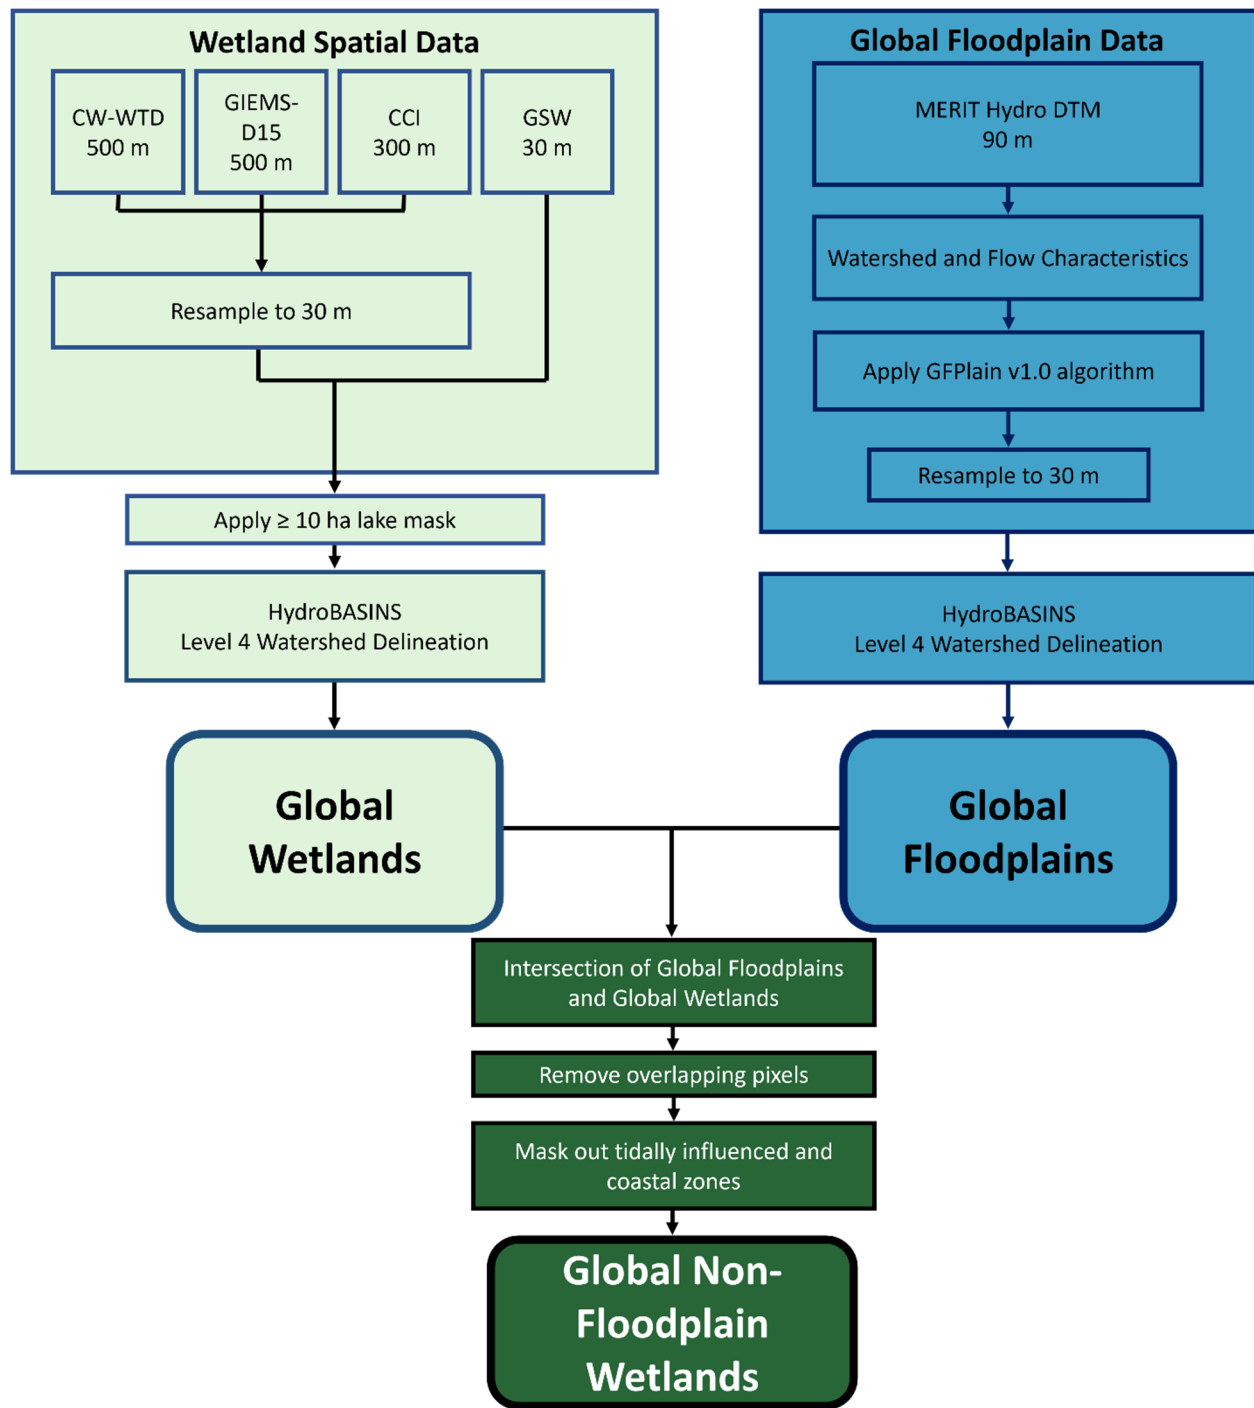

177 Identifying global non-floodplain wetlands required the following steps: 1) determination of global
178 floodplain extent, 2) identification of the global distribution of wetlands, 3) spatial overlay (masking) of
179 floodplains and wetlands to derive a non-floodplain wetland data layer, and 4) data verification and
180 accuracy assessment. Steps 1-3 are outlined in a flow chart given in Figure-Fig. 1.

181

182 **~~2.1 Global floodplain data~~**

183

184 ~~Nardi et al. (2019) combined space-borne elevation data and terrain analysis with a novel open-source~~
185 ~~algorithm to delineate the geomorphic floodplains across the globe between 60°N and 60°S latitudes.~~
186 ~~Conceptually, Nardi et al. (2019) identified floodplains from surrounding hillslopes as those low-lying~~
187 ~~landscape features that have been naturally shaped by accumulated geomorphic effects of past flood~~
188 ~~events. The original Nardi et al. (2019) dataset was limited in its spatial extent (60°N–60°S) and~~
189 ~~resolution (250 m); this study sought to delineate global floodplain extent while concurrently identifying~~
190 ~~floodplain features further up the river network than possible with 250 m pixels. Hence, we utilized the~~
191 ~~freely available Nardi et al. (2019) GFPlain v1.0 algorithm and coupled this with the MERIT Hydro~~
192 ~~(Multi-Error Removed Improved Terrain, Yamazaki et al., 2019), global raster digital terrain model data~~
193 ~~to develop a higher resolution (90 m) geomorphic riverine floodplain for the globe, termed hereafter~~
194 ~~GFPlain90.~~

195
 196 **Figure 1.** Data flow chart identifying the main data sets and processes involved in deriving the Global Floodplain
 197 and Global Wetland data layers, as well as the intersection of those data to create the Global Non-floodplain
 198 Wetlands data product. Curved boxes represent final products, and abbreviations may be found in the text and
 199 Appendix A.

2.1 Global floodplain data

Nardi et al. (2019) combined space-borne elevation data and terrain analysis with a novel open-source algorithm to delineate the geomorphic floodplains across the globe between 60° N and 60° S latitudes. Conceptually, Nardi et al. (2019) identified floodplains from surrounding hillslopes as those low-lying landscape features that have been naturally shaped by accumulated geomorphic effects of past flood events. The original Nardi et al. (2019) dataset was limited in its spatial extent (60° N-60° S) and resolution (250 m); this study sought to delineate global floodplain extent while concurrently identifying floodplain features further up the river network than possible with 250 m pixels. Hence, we utilized the freely available Nardi et al. (2019) GFPlain v1.0 algorithm and coupled this with the MERIT Hydro (Multi-Error Removed Improved Terrain, Yamazaki et al., 2019), global raster digital terrain model data to develop a higher resolution (90 m) geomorphic riverine floodplain for the globe, termed hereafter GFPlain90.

The development of GFPlain90 required multiple steps. We first extracted elevation data from MERIT Hydro ~~and~~ reprojected the data in UTM zones to prevent distortion when using the GFPlain algorithm. ~~We then~~ ~~and then~~ developed the drainage network, drainage area, flow accumulation and flow direction data from these data using the ~~established~~ scaling parameters in Nardi et al. (2019; ~~power-law coefficient (a) of 0.01 and dimensionless exponent (b) = 0.30~~). We established 20 km² as the minimum contributing-area threshold required to create the drainage network, balancing the development of a global stream-network distribution and extent with computational requirements. We then globally organized the data by HydroBASINS Level 4 basins (Lehner and Grill, 2013). HydroBASINS provides seamless watershed boundaries and subbasin delineations at global scales; there are 1,342 Level 4 HydroBASINS globally. The floodplain extent resolution of GFPlain90 was resampled (using nearest neighbor) to 30 m for subsequent performance assessment and overlap analyses with the wetland spatial data. All spatial

225 analyses in this study were conducted using ArcGIS Pro v.2.9.x (ESRI, Redlands, California) and GRASS
226 GIS v 7.4.4 (OSGEO, Beaverton, Oregon).

227

228 **2.2 Global Wetland data**

229

230 Tootchi et al. (2019) developed a widely used composite global wetland map at ~500 m by combining
231 multiple data sources, including both satellite-based surface-water inundation mapping and vegetation
232 classification coupled with model-based approaches capturing important groundwater-driven wetland
233 systems. We specifically used the Tootchi et al. (2019) composite map consisting of both regularly
234 surface-water flooded wetlands (“regularly flooded wetlands,” RFWs) and groundwater discharge-
235 maintained wetlands (“groundwater-driven wetlands,” GDWs) as the foundation for our global wetland
236 map. Tootchi et al. (2019) merged the RFW and GDW maps, described below, to form a union product
237 used here that demonstrated a high correlation with available evaluation data, called the composite
238 wetland-water table depth (or CW-WTD).

239

240 **2.2.1 Original composite wetland data**

241

242 Regularly flooded wetlands (RFWs) derived by Tootchi et al. (2019) were based on three data sources: 30
243 m resolution Global Surface Water (GSW) by Pekel et al. (2016), 300 m Climate Change Initiative (CCI)
244 land cover data by Herold et al. (2015), and 500 m GIEMS-D15 wetland extent data by Fluet-Chouinard
245 et al. (2015). GSW data used by Tootchi et al. (2019) were developed from Landsat satellite imagery
246 analyses of pixels identified as inundated at least once during the 32-year period of record by Pekel et al.
247 (2016). CCI input wetland data for Tootchi et al. (2019) included both inundated and wetland vegetation-
248 classed pixels assessed during the period 2008-2012 by Herold et al. (2015). For GIEMS-D15, data
249 included were the mean annual maximum extent of pixels identified as wetlands using multi-sensor
250 satellite data by Prigent et al. (2007), downscaled to ~500 m resolution by Fluet-Chouinard et al. (2015).

251 GSW and CCI input data were resampled to ~500 m resolution using an “all or nothing” approach by
252 Tootchi et al. (2019). This means that a pixel categorization of “wetland” at 500 m resolution was given
253 by Tootchi et al. (2019) only if the majority of resampled finer-resolution input pixels were classed as
254 wetlands. The upward resampling from 30 m and 300 m to 500 m resulted in a loss of informative spatial
255 data on wetland extent from GSW and CCI. Tootchi et al. (2019) calculated that RFWs cover
256 approximately 9.7 % of the global land area (excluding lakes [sourced from (Messenger et al., 2016)],
257 Antarctica, and the Greenland ice sheet).

258
259 Groundwater-driven wetlands (GDWs in the analysis of Tootchi et al., 2019) used in this study were
260 based on the water-table depth estimates by Fan et al. (2013). Fan et al. (2013) developed a 1 km
261 resolution groundwater map based on climate and terrain variables that was validated by over 1 million
262 government-recorded and published observations. Fan et al. (2013) estimated that shallow groundwater
263 influenced nearly 15 % of groundwater-fed surface features, explaining important wetland patterning at
264 global scales (as well as vegetation classes at local and regional scales). A water-table depth threshold of
265 ≤ 20 cm was used by Tootchi et al. (2019) to identify groundwater-driven wetlands and they resampled
266 these data to ~500 m cell resolution. The GDW distribution based on water table depths covered
267 approximately 15 % of the global land mass (including large portions of the Amazon basin, coastal zones,
268 and North American and Siberian peatlands).

269
270 Tootchi et al. (2019) created a merged “final” product, ~~which that called the composite wetland-water~~
271 table depth (CW-WTD) map, which is based on the union of the ~~merged the~~ RFW and GDW maps ~~to~~
272 form a union product with a high correlation with available evaluation data, which they called the
273 composite wetland water table depth (hereafter CW-WTD). They measured an approximately 3.8 %
274 overlap between the total land pixels identified as wetlands in both the RFW and GDW maps that
275 comprise the CW-WTD, suggesting the different input maps capture different wetland types. At the

276 global scale, Tootchi et al. (2019) reported spatial Pearson correlations between CW-WTD (wetland
277 fractions at 3 arcmin, or ~4.9 km grids) and wetlands within GLWD (Lehner and Döll, 2004) and Hu et
278 al. (2017b) as $r=0.34$ and $r=0.43$, respectively. Tootchi et al. (2019, their Table 5 and S1) provided
279 additional analysis of the correlations between their global wetland product and existing benchmark data.
280 The total CW-WTD global wetland estimate was ~ 21.1 % of the land mass, or approximately 27.5
281 million km² (excluding large lakes, Antarctica, and the Greenland ice sheet; Tootchi et al., 2019).

282

283 2.2.2 Derived global wetland data

284

285 To account for the acknowledged limitations of the Tootchi et al. (2019) data and to accurately identify
286 more of the existing small and, specifically, non-floodplain wetlands across the globe (e.g., those <25 ha),
287 we improved upon and augmented the CW-WTD (Tootchi et al., 2019) global wetland data layer with the
288 30 m native-resolution GSW (Pekel et al., 2016) and 300 m native-resolution CCI (Herold et al., 2015)
289 data. The inclusive wetland categories of Tootchi et al. (2019) were maintained, namely at least one
290 inundation event over a 32 year range (for GSW data) and CCI pixels defined as “...mixed classes of
291 flooded areas with tree covers, shrubs, or herbaceous covers plus inland water bodies...” (Tootchi et al.,
292 2019, p. 193). However, for our analysis we resampled the 500 m CW-WTD product to 30 m using the
293 nearest-neighbor approach and then added any identified wetland pixel from the CCI data (resampled
294 from 300 m to 30 m) and inundated pixel from the GSW data (30 m resolution). Resampling to a finer
295 resolution (as we did in our analysis-) does not result in data losses-: the same data are retained but are
296 divided into equal, smaller parts. However, moving from a finer resolution to coarser resolution causes
297 data losses: fine scale data are necessarily aggregated (often by averaging) to a larger grid cell size, and
298 therefore less information is retained. However, moving from a finer resolution to coarser resolution (as
299 in the CW-WTD dataset’s “all-or-nothing” approach) does cause data losses: fine-scale data are
300 necessarily aggregated (often by averaging) to a larger grid cell size, and therefore less information is
301 retained. To compensate for this data loss in the CW-WTD dataset, the finer resolution JRCGSW data-(30

302 ~~m) and CCI (300 m) data was were added back into the dataset. Resampling to a finer resolution does not~~
303 ~~result in a loss of any data whereas resampling from a finer resolution to a coarser resolution results in the~~
304 ~~loss of any data smaller than the chosen resolution.~~ This resulted in a novel and encompassing wetland
305 ensemble end-product, hereafter termed the Global Wetlands dataset. This new dataset is inclusive of both
306 finer-resolution (30 m and 300 m) data, thereby accounting for a wide range of wetland sizes – such as
307 smaller non-floodplain wetlands (Cohen et al., 2016) – that remained unmapped by Tootchi et al. (2019).

308

309 **2.3 Global Non-Floodplain Wetlands (Global NFWs)**

310

311 To identify non-floodplain wetlands specifically, we overlaid our GFPlain90 floodplain data with our
312 mapped Global Wetlands data to mask wetland pixels collocated on the floodplain. Then, to avoid tidally
313 influenced wetlands, we conducted a region-group analysis to identify connected pixels abutting coastal
314 shorelines in order to mask wetlands in coastal areas (e.g., those directly abutting the shoreline and
315 spatially connected to tidally influenced areas). We used a four-directional contagion criterion to identify
316 connected pixels (i.e., those connected in cardinal directions). Subsequently, we applied a 1 km buffer to
317 the HydroBASINS (Lehner and Grill, 2013) coastline area and removed from our analyses any wetland
318 region-group partially or completely overlain by the 1 km coastline buffer. In addition, Tootchi et al.
319 (2019) removed lake systems (≥ 10 ha) from their wetland-focused data by masking aquatic layers using
320 HydroLAKES (Messenger et al., 2016). To avoid including large lakes in our emerging non-floodplain
321 wetland geospatial data, we also applied the HydroLAKES mask and removed lake systems ≥ 10 ha
322 (Messenger et al., 2016) from our Global Wetlands dataset. Thus, our final global non-floodplain wetland
323 data product (hereafter Global NFWs) did not include fluvial floodplain wetlands nor coastal wetland
324 complexes and large open water lacustrine (lake-like, Cowardin et al., 1979) systems.

325

326 **2.4 Data verification and assessment**

327

328 We evaluated the global products developed here through comparison of high-resolution floodplain and
329 wetland extent data from 21 basins representing disparate climatic (according to the Köppen-Geiger
330 classification, Beck et al., 2018), elevation, and land-use gradients within the CONUS (Fig. 2;
331 summarized in Table [B4B2](#)). We specifically focused on the CONUS for product assessment because of
332 its wide-ranging data availability and diversity of physiographic and climatic regions.

333

334 **2.4.1 Verifying floodplain extent**

335

336 We used a recently developed machine learning (ML)-based 30 m resolution CONUS floodplain dataset
337 (Woznicki et al., 2019) as the benchmark to evaluate our GFPlain90 global floodplain data. Specifically,
338 the ML model by Woznicki et al. (2019) used the U.S. Federal Emergency Management Agency (FEMA)
339 100 yr floodplain (i.e., a 1 % chance of coastal or fluvial flood-inundation in a given year; Jakubínský et
340 al., 2021) as the training data, and subsequently used soil and topographic characteristic along with land
341 cover to identify potential floodplain grid cells across CONUS at 30 m resolution. Woznicki et al. (2019)
342 reported that their ML approach correctly identified ~79 % of the FEMA 100 yr coastal and fluvial
343 floodplains, providing spatially complete 100 yr floodplain coverage totaling 980,450 km² across the
344 CONUS.

345

346 **2.4.2 Verifying wetland and non-floodplain wetland extent**

347

348 We evaluated our inclusive Global Wetlands and Global NFWs datasets in 21 basins covering ~680,000
349 km² (Fig. 2). We contrasted our products to the 2016 National Land Cover Database (NLCD, Dewitz,
350 2019). The NLCD is a 30 m Landsat satellite-based geospatial product with an overall accuracy of 86 %
351 that incorporates high-resolution aerial imagery of wetland location for model parameterization and
352 calibration (Jin et al., 2019; Wickham et al., 2021). Three NLCD classes were selected for comparison
353 with the Global Wetland product: woody wetlands, emergent herbaceous wetlands, and open water. To

354

355

356

357

358

359

360

Figure 2. Twenty-one validation watersheds were selected from across CONUS to capture the breadth and extent of land use (top, [NLCD 2019](#)) and climate and physiographic regions (bottom) within CONUS according to the Köppen-Geiger classification (Beck et al., 2018); also summarized in Table [B4B2](#)). [Land cover data are from NLCD \(2019\) and the Hydrologic Unit Code \(HUC\) classifications are sourced from USGS Watershed Boundary Dataset \(2022\).](#)

361
 362 assess the relative improvement of our 30 m Global Wetlands and Global NFWs dataset with the 500 m
 363 Tootchi et al. (2019) data, we also contrasted the CW-WTD with the NLCD classes within the
 364 verification watersheds. For equal comparisons, following Tootchi et al. (2019) we used the Messenger et
 365 al. (2016) HydroLAKES to mask out large lake systems (≥ 10 ha) from both the Global Wetlands and the
 366 NLCD data within the 21 verification watersheds.

367

368 **2.4.3 Standard performance measures**

369

370 We evaluated the floodplain and wetland spatial data within the 21 validation watersheds using
 371 commonly employed performance measures. Following Wing et al. (2017), we first created a contingency
 372 table for our performance assessment (Table 1). As noted, we selected 20 km² as the minimum
 373 contributing area to develop stream networks in our global floodplain analysis, a reasonable area for flow-
 374 accumulation that balances computational efficiency for global geospatial model development. Woznicki
 375 et al. (2019), our benchmark floodplain dataset, used a 4.5 km² contributing area in their high-resolution
 376 ~~CONUS analysis. To appropriately compare between datasets of two varying resolutions, we removed~~
 377 ~~stream and river network components from the Woznicki et al. (2019) validation dataset developed with~~
 378 ~~contributing areas < 20 km², as our model did not discern landscape data at that granularity.~~

379

380 **Table 1.** Contingency table of possible outcomes for each cell used in assessing the performance of either the
 381 floodplain or wetland geospatially modeled data. We contrasted published benchmark data from Woznicki et al.
 382 (2019) for floodplain extent against modeled GFPlain90 data. Wetland comparisons contrasted NLCD wetlands
 383 (Dewitz, 2019, open water and wetland classes) against both Global Wetlands and Global NFWs data. Table is
 384 modified from Wing et al. (2017). The subscript “1” equates to a positive outcome or overlapping extent for either
 385 the modeled (M) or benchmark (B) data whereas a zero means no data overlap or a negative outcome.

	Floodplain [or Wetland] in Benchmark data	Not Floodplain [or Wetland] in Benchmark data
--	--	--

Floodplain [or Wetland] in Modeled data	M ₁ B ₁	M ₁ B ₀
Not Floodplain [or Wetland] in Modeled data	M ₀ B ₁	M ₀ B ₀

386

387 CONUS analysis. To appropriately compare between datasets of two varying resolutions, we removed
 388 stream and river network components from the Woznicki et al. (2019) validation dataset developed with
 389 contributing areas <20 km², as our model did not discern landscape data at that granularity.

390

391 To provide a full assessment of our geospatial modeling performance, we contrasted our GFPlain90
 392 floodplain dataset across the 21 validation watersheds using the approaches described below following
 393 Sampson et al. (2015), Wing et al. (2017), and others (e.g., Bates and De Roo, 2000; Alfieri et al., 2014;
 394 Sangwan and Merwade, 2015; Jafarzadegan et al., 2018; Woznicki et al., 2019). We first contrasted our
 395 GFPlain90 floodplains to Woznicki et al. (2019), our benchmark floodplain data. We then analyzed the
 396 watershed-scale comparison of our Global Wetlands product versus the NLCD wetlands (combined open
 397 water and wetland classes), our benchmark wetlands data. We followed with a comparison focusing only
 398 on our Global NFWs data and those NLCD wetlands and open water pixels that were determined to be
 399 non-floodplain systems (i.e., NLCD data that also do not overlap the GFPlain90 data nor coastal waters
 400 and with lakes >10 ha removed). These NLCD wetlands were our benchmark non-floodplain wetland
 401 data. Lastly, we assessed the mean and aggregate error bias of our analyses by exploring results at coarser
 402 spatial granularity (i.e., 1 km pixel size) along the riverine network (for floodplain assessment) and, for
 403 wetland metrics, throughout the entirety of our 21 performance assessment watersheds (Sampson et al.,
 404 2015; Wing et al., 2017). The metrics described below and in Table 2 were used in our analyses.

405

406

407 Hit Rate (Bates and De Roo, 2000; Horritt and Bates, 2002; Tayefi et al., 2007) also referred to as Recall
 408 (Woznicki et al., 2019) and Correct (Sangwan and Merwade, 2015), measures how well a geospatial
 409 model classification replicates the benchmark data but does not penalize for overprediction. *H* varies from

0, where there is no overlap between the modeled data and the benchmark data, to 1 where the modeled data completely contain the benchmark data. *Precision* (Woznicki et al., 2019), also known as *Spatial Coincidence* (Tootchi et al., 2019), indicates the proportion of the benchmark data that are correctly predicted and mapped in the modeled data. This metric, *P*, also ranges from 0 to 1 with higher values

Table 2. Performance metrics used in validation assessments of floodplain and wetland data layers. Data for assessment (e.g., M_1B_1) follow that given in Table 1 and modified from Wing et al. (2017), with the exception of equations 7 and 8 (see text).

Equation Number	Metrics	Equation	Range
1	Hit Rate (H)	$Hit\ Rate\ (H) = \frac{M_1B_1}{M_1B_1 + M_0B_1}$	0 - 1, higher is “better”
2	Precision (P)	$Precision\ (P) = \frac{M_1B_1}{M_1B_1 + M_1B_0}$	0 - 1, higher is “better”
3	False Alarm Ratio (FA)	$False\ Alarm\ Ratio\ (FA) = \frac{M_1B_0}{M_1B_0 + M_1B_1}$	0 - 1, lower is “better”
4	Critical Success Index (CSI)	$Critical\ Success\ Index\ (CSI) = \frac{M_1B_1}{M_1B_1 + M_0B_1 + M_1B_0}$	0 - 1, higher is “better”
5	F1	$F1 = 2 \left(\frac{H \times P}{H + P} \right)$	0 - 1, higher is “better”
6	Error Bias (EB)	$Error\ Bias\ (EB) = \frac{M_1B_0}{M_0B_1}$	0 - ∞; <1 underprediction, 1 = no bias, >1 indicate overprediction
7	Mean Absolute Error (E _A)	$Mean\ Absolute\ Error\ (E_A) = \frac{\sum_{i=1}^N M-B }{N}$	0 - 1, lower is “better”
8	Aggregate Error Bias (B _A)	$Aggregate\ Error\ Bias\ (B_A) = \frac{\sum_{i=1}^N M-B}{N}$	-1 to 1, negative values indicate underprediction, positive values overprediction

—indicating better performance. The *False Alarm Ratio* (Sampson et al., 2015; Wing et al., 2017) also known as the *False Discovery Ratio*, quantifies modeled data overprediction relative to the benchmark *Hit Rate* (Bates and De Roo, 2000; Horritt and Bates, 2002; Tayefi et al., 2007; Alfieri et al., 2014; Sampson et al., 2015; Wing et al., 2017; Jafarzadegan et al., 2018) also referred to as *Recall* (Woznicki et al., 2019) and *Correct* (Sangwan and Merwade, 2015), measures how well a geospatial model classification replicates the benchmark data but does not penalize for overprediction. *H* varies from 0,

424 where there is no overlap between the modeled data and the benchmark data, to 1 where the modeled data
425 completely contain the benchmark data.

$$426 \text{ Hit Rate } (H) = \frac{M_1 B_1}{M_1 B_1 + M_0 B_1} \quad (1)$$

427
428 *Precision* (Woznicki et al., 2019), also known as *Spatial Coincidence* (Tootchi et al., 2019), indicates the
429 proportion of the benchmark data that are correctly predicted and mapped in the modeled data. This
430 metric, *P*, also ranges from 0 to 1 with higher values indicating better performance.

$$431 \text{ Precision } (P) = \frac{M_1 B_1}{M_1 B_1 + M_1 B_0} \quad (2)$$

432
433 The *False Alarm Ratio* (Sampson et al., 2015; Wing et al., 2017) also known as the *False Discovery*
434 *Ratio*, quantifies modeled data overprediction relative to the benchmark data. *F* varies from 0 (zero false
435 alarms) to 1 (all false alarms); lower values are considered better performance. The False Alarm Ratio can
436 also be calculated as 1 - *Precision* (Woznicki et al., 2019).

$$437 \text{ False Alarm Ratio } (FA) = \frac{M_1 B_0}{M_1 B_0 + M_1 B_1} \quad (3)$$

438
439 The *Critical Success Index* (CSI, Bates and De Roo, 2000; Aronica et al., 2002; Werner et al., 2005;
440 Fewtrell et al., 2008; Alfieri et al., 2014; Sampson et al., 2015; Wing et al., 2017), also known as
441 Jaccard's Index (Tootchi et al., 2019), and Fit (Sangwan and Merwade, 2015), penalizes for both over-
442 and under-prediction, ranging from 0 (no match) to 1 (perfect match).

$$443 \text{ Critical Success Index } (CSI) = \frac{M_1 B_1}{M_1 B_1 + M_0 B_1 + M_1 B_0} \quad (4)$$

444
445 Woznicki et al. (2019) utilized a performance metric, *F1*, which combines the *Hit Rate* (called Recall by
446 Woznicki et al. 2019) and *Precision* using their harmonic mean. *F1* also varies from 0 to 1, with higher
447 values indicating better performance.

$$448 \text{ F1} = 2 \left(\frac{H \times P}{H + P} \right) \quad (5)$$

449

450 *Error Bias (EB)* characterizes the tendency of the model towards under- or over-prediction (Sampson et
 451 al., 2015). Values of 1 indicate no bias, $0 \leq EB < 1$ indicates underprediction whereas $1 < EB \leq \infty$
 452 indicates the model is tending towards overprediction.

$$453 \quad \text{Error Bias (EB)} = \frac{M_1 B_0}{M_0 B_1} \quad (6)$$

454
 455 Lastly, two additional metrics were calculated that assessed performance at the 30 arc-sec (~1 km) scale.
 456 These measures, *Mean Absolute Error* and *Aggregate Error Bias* (Sampson et al., 2015; Wing et al.,
 457 2017), characterize the data accuracy across large spatial extents. Large spatial extents are areas where 30
 458 m data and overlap accuracy is less a concern than general dataset performance for broad-scale end-user
 459 applications (e.g., when coarser, watershed-scale “lumped” hydrologic characterizations of water storage
 460 are all that is required). For these metrics, both estimated and benchmark data were resampled to 1 km
 461 resolution across the whole of each watershed; values within each 1 km pixel ranged from 0 to 1 and
 462 represented the fraction of the 30 m resolution estimates and benchmark data. We assessed floodplain
 463 estimates after calculating the fractional abundance comprising each 1 km² pixel within a 1 km buffer
 464 around the Woznicki et al. (2019) floodplain data. We additionally analyzed all wetlands at the
 465 watershed-scale as well as focusing on non-floodplain wetlands (e.g., wetlands exclusive of the
 466 GFPlain90 floodplain or coastal connections, our target aquatic system). In Eq. 7 and 8 (given in Table 2),

$$467 \quad (7) \quad \text{Mean Absolute Error (E}_A\text{)} = \frac{\sum_{i=1}^N |M-B|}{N}$$

$$469 \quad \text{Aggregate Error Bias (B}_A\text{)} = \frac{\sum_{i=1}^N M-B}{N} \quad (8)$$

470
 471 ~~Where~~ *M* is the area estimated as floodplain (or wetland), *B* is the benchmark floodplain (or wetland)
 472 area, and *N* is the number of 1 km cells with data. *Mean Absolute Error* and *Aggregate Error Bias* were
 473 calculated for each of the 21 HUCs, following Wing et al. (2017).

474

475

476 3 Results

477

478 3.1 Floodplain data performance

479

480 The GFPlain90 floodplain data (Fig. 3) performed well when contrasted with the 100 yr coastal and
481 fluvial floodplain extent data from Woznicki et al. (2019), even though our analyses do not map coastal
482 floodplains. A median Hit Rate of 0.77 suggests that nearly 80% of the benchmark floodplain from
483 Woznicki et al. (2019) was similarly captured by the GFPlain90 floodplain data ([see Appendix Table](#)
484 [2B3](#)). In addition, the median False Alarm of 0.26 indicates that for every three pixels correctly identified
485 as within the Woznicki et al. (2019) floodplain, one pixel was incorrectly identified as such (i.e., a
486 commission error measure); this is evident in wider GFPlain90 floodplains in lower river reaches than
487 predicted by Woznicki et al. (2019). These performance values are similar to those reported by Woznicki
488 et al. (2019, False Alarm 0.22) and Wing et al. (2017, False Alarm 0.34-0.37). Critical Success Index
489 (CSI) scores penalize for over-prediction; our median value of 0.53 approximates previously published
490 regional (e.g., Sangwan and Merwade, 2015, CSI values ranging from 0.44-0.89) and continental flood-
491 extent approaches (e.g., Sampson et al., 2015, CSI values from 0.43-0.67; Wing et al., 2017; CSI values
492 between 0.50 and 0.55 reported). Median Precision (0.74) and F1 (0.70) values approximate those in the
493 literature as well (e.g., Woznicki et al., 2017 reported values of 0.78 for both). [Median Error Bias values](#)
494 [of 1.0 suggests the model neither over-estimates nor under-estimates floodplain extents \(Wing et al.](#)
495 [2017\)](#). -Mean Absolute Error of 0.08 reported here indicates an approximate 8 % difference between our
496 GFPlain90 model and that of Woznicki et al. (2017) at the 1 km cell resolution.

497

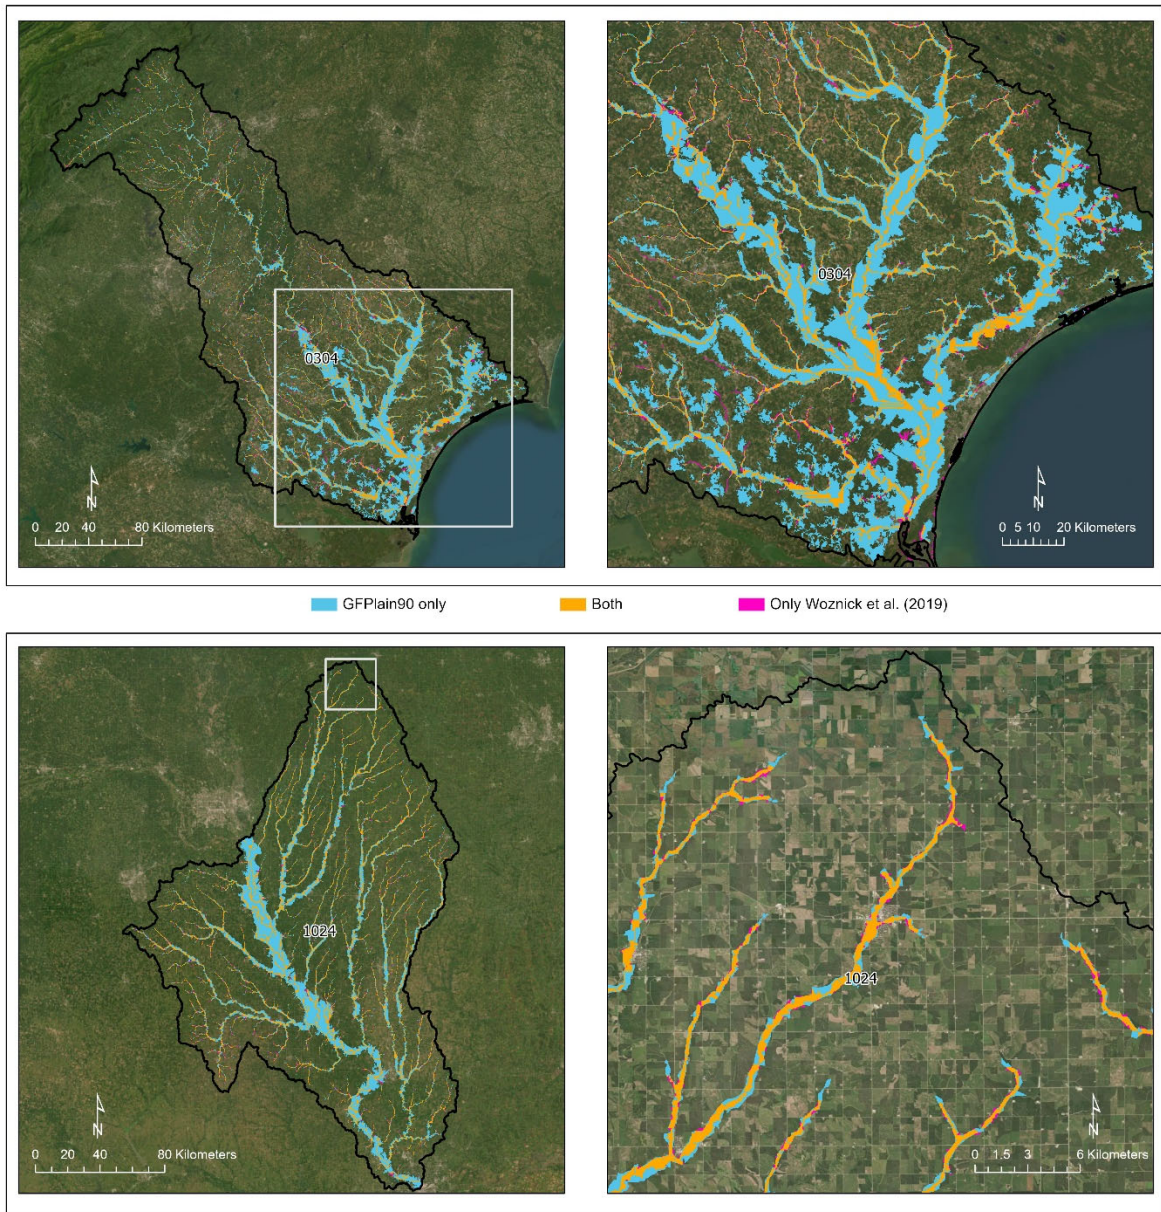

498 3.2 Wetland data performance

499

500 3.2.1 Global Wetland dataset

501
502
503
504
505
506
507
508
509
510
511
512

The novel ensemble Global Wetlands approach improved upon the previously published Tootchi et al. (2019) research product, the CW-WTD (Table 3) when contrasted with CONUS data. A median Hit Rate value of 0.24 indicates that both the inclusive Global Wetlands and CW-WTD captured ~one-quarter of the high-resolution, 30-m pixel size NLCD wetlands and open waters in the validation dataset. However, across the 21 validation watersheds the Global Wetlands dataset developed here correctly identified more wetlands than the CW-WTD alone, as indicated by an 8% mean increase in Precision, 43 % increase in Critical Success Index, 38 % increase in F1, a -8 % decrease in the False Alarm ratio, and a 21 % decrease in Error Bias. At coarser, 1 km² scales, there was a slight decrease in the Mean Absolute Error associated with the Global Wetlands, and no difference in Aggregate Error Bias between the data products.

513
 514 **Figure 3.** The robust performance of GFPlain90 relative to the benchmark Woznicki et al. (2019) floodplain data is
 515 evident in the two rows, with the top panels (HUC_0304) a coastal watershed spanning North and South Carolina,
 516 USA, and the bottom two panels different spatial extents of a midwestern USA watershed (HUC_1024). The
 517 mainstem of the river network appeared wider in the GFPlain90 data in both examples, especially in the lower
 518 reaches, though the complete network was well represented (i.e., floodplains were identified to the furthest extent of
 519 the stream network's headwaters). Satellite imagery ~~is are~~ sourced from ESRI (2022).

520 decrease in Error Bias. At coarser, 1 km² scales, there was a slight decrease in the Mean Absolute Error
521 associated with the Global Wetlands, and no difference in Aggregate Error Bias between the data
522 products. **Table 2.** Floodplain performance assessment of the GFPlain90-derived floodplain and the benchmark
523 floodplain from Woznicki et al. (2019). The first six equations directly assess the spatial concordance and overlap
524 between the two datasets, whereas Mean Absolute Error (Eq. 7) and Aggregate Error Bias (Eq. 8) are coarser
525 fractional analyses (i.e., the fraction of a 1 km² cell predicted correctly) as measured along the riverine network.

529 ~~3.2 Wetland data performance~~

531 ~~3.2.1 Global Wetland dataset~~

532
533 ~~The novel ensemble Global Wetlands approach improved upon the previously published Tootehi et al.~~
534 ~~(2019) research product, the CW-WTD (Table 3) when contrasted with CONUS data. A median Hit Rate~~
535 ~~value of 0.24 indicates that both the inclusive Global Wetlands and CW-WTD captured one-quarter of~~
536 ~~the high-resolution, 30-m pixel size NLCD wetlands and open waters in the validation dataset. However,~~
537 ~~across the 21 validation watersheds the Global Wetlands dataset developed here correctly identified more~~
538 ~~wetlands than the CW-WTD alone, as indicated by an 8% mean increase in Precision, 43% increase in~~
539 ~~Critical Success Index, 38% increase in F1, a 8% decrease in the False Alarm ratio, and a 21%~~
540 ~~decrease in Error Bias. At coarser, 1 km² scales, there was a slight decrease in the Mean Absolute Error~~
541 ~~associated with the Global Wetlands, and no difference in Aggregate Error Bias between the data~~
542 ~~products.~~

544 3.2.2 Global Non-Floodplain Wetland (Global NFW) dataset

546 Non-floodplain wetland identification using the Global Wetlands data (i.e., Global NFWs) similarly
547 improved upon the CW-WTD product (Fig. 4). For instance, though the Hit Rate values were low (e.g.,
548 median values ≤ 0.10), underscoring both the difficulty in mapping non-floodplain wetlands and the
549 challenge of assessing performance using high-resolution data, Global NFW analyses correctly identified
550 50 % more non-floodplain wetlands than the CW-WTD (Table 4, Tootchi et al., 2019). Improvements
551 when focusing on non-floodplain wetlands were found in every category with the Global NFWs dataset,
552 demonstrating increased non-floodplain wetland accuracy versus the original CW-WTD across the
553 median metric values for Precision, Critical Success Index, F1, False Alarms, and Error Bias (e.g., 33 %
554 increase in Precision, 20 % increase in Critical Success Index, 10 % increase in F1 scores, and a 12 %
555 decrease in False Alarms and a 19 % decrease in Error Bias). There was no difference between the
556 datasets with median values for Mean Absolute Error (median values for both = 0.09) or Aggregate Error
557 Bias (median values for both = 0.07). Thus, at the 1 km² cell size, there was <10 % difference between
558 both the CW-WTD and the Global NFWs and the benchmark NLCD non-floodplain wetlands and open
559 waters (with the difference mostly stemming from an increase in identified wetlands with both CW-WTD
560 and Global NFWs, as indicated with the positive Aggregate Error Bias values).

561

562

563

564

565 **Table 3.** Spatial performance assessment of both the Global Wetland (abbreviated here as GW) and CW-WTD
566 (abbreviated here as WTD, Tootchi et al., 2019) datasets when contrasted with the benchmark NLCD wetlands
567 (Dewitz, 2019). The first six equations directly assess the spatial concordance and overlap between each spatial
568 dataset and the benchmark (e.g., CW-WTD contrasted with the NLCD), whereas Mean Absolute Error (MAE, Eq.
569 7) and Aggregate Error Bias (AEB, Eq. 8) are coarser fractional analyses measured throughout each watershed (e.g.,
570 the proportional abundance NLCD within each 1 km² cell is contrasted with the proportional abundance of Global
571 Wetlands predicted correctly within that cell).

Hydrologic Unit Code (HUC) ID	Hit Rate		Precision		False Alarm		Critical Success

Figure 4. Demonstration of the relative accuracy of the Global NFWs in identifying non-floodplain wetlands using a Prairie Pothole Region watershed (HUC_1016, see Fig. 2) replete with abundant non-floodplain wetlands. Correctly identified wetlands occur in both wetland sources (magenta color). Omission errors (NLCD non-floodplain wetlands, smaller systems in yellow) and commission errors (Global NFWs, green) are evident as a result of the higher resolution of the NLCD validation dataset. Satellite imagery is sourced from ESRI (2022). Note the scale increasing from left panel to right panel (i.e., the orange box in the first panel is shown in the second panel at a higher resolution, and the box in the second panel is shown in the last panel at an even higher resolution).

584 **Table 4.** Non-floodplain wetland performance metrics contrasting both the Global NFWs (abbreviated here as
585 GNFW) and CW-WTD (abbreviated here as WTD, Tootchi et al., 2019) non-floodplain wetland spatial data with the
586 benchmark NLCD wetlands (Dewitz, 2019). Descriptions of the metrics are the same as in Table 3, though the focus
587 here is on wetlands outside the GFPlain90-derived floodplain.

591

592 ~~decrease in False Alarms and a 19 % decrease in Error Bias). There was no difference between the~~
593 ~~datasets with median values for Mean Absolute Error (median values for both = 0.09) or Aggregate Error~~
594 ~~Bias (median values for both = 0.07). Thus, at the 1 km² cell size, there was <10 % difference between~~
595 ~~both the CW-WTD and the Global NFWs and the benchmark NLCD non-floodplain wetlands and open~~
596 ~~waters (with the difference mostly stemming from an increase in identified wetlands with both CW-WTD~~
597 ~~and Global NFWs, as indicated with the positive Aggregate Error Bias values).~~

599 **3.3 Global extent analyses and synthesis**

600

601 **3.3.1 Floodplains**

602

603 Floodplains were estimated to cover 26.6 million km² (Table 5), or 19.7 % of the global landmass.

604 Approximately 23-24 % of the African and Australasian land masses were categorized as occurring

605 within a floodplain, the greatest percentage of global areas so categorized. Conversely, the Arctic

606 (northern Canada and Alaska) and Greenland (excluding the ice sheet) had the least land mass categorized

607 as floodplain (13-14 %). In comparison, Nardi et al. (2019) calculated a global floodplain extent of

608 13,394,139 km², using a 250-m pixel size, a 1000 km² minimum contributing area, and bounding their

609 study between 60° N and 60° S latitudes. Our analyses using the same latitudinal bounds but with a higher

610 resolution dataset (90 m) and a 20 km² minimum contributing area identified 24,185,775 km², an 81 %

611 areal increase (Fig. B1). The relative percent composition of each HydroBASIN that is comprised of

612 GFPlain90 floodplains is given in Fig. 5.

613

614

615 Figure 5. Floodplain extents derived from GFPlain90 as a proportion of each of the Level 4 HydroBASINS
616 (Lehrner and Grill, 2013). The data range demonstrated that up to ~90 % of a given watershed was comprised of
617 floodplain area, as evidenced by HydroBASINS in south central Africa and central South America. The basemap
618 layer is the ESRI World Terrain Base (2022).

619

620

621
 622 **Table 5.** Calculated floodplain area for each HydroBASINS at the global scale. Our analyses found 19.7 % of the
 623 landmass occurs within a floodplain.

HydroBASINS Region	Floodplain (km ²)	Floodplain Percent of Landmass
Africa	6,990,859	23.3 %
Arctic (northern Canada & Alaska)	894,594	14.2 %
Asia	4,283,991	20.6 %
Australasia	2,649,395	23.8 %
Europe and Middle East	3,415,308	19.1 %
Greenland (excl. ice sheet)	270,813	12.6 %
North & Central America (excl. Alaska)	2,713,346	17.0 %
Siberian Russia	2,051,305	15.8 %
South America	3,368,778	18.9 %
Total	26,638,389	19.7 %

624

625

626 3.3.2 Wetlands

627

628 Global Wetland extent covered 30.5 million km² (Table 6). With a focus on smaller systems compared to
 629 those presented by Tootchi et al. (2019), our Global Wetland dataset identified 11-% more potential
 630 global wetlands (3 million km² additional wetlands).

631

632 Australasia had the greatest proportional wetland abundance (see also Zhu et al., 2022), with wetlands
 633 covering 38 % of the landmass (driven, in part, by island abundance and fringing estuarine wetlands [Fan
 634 et al., 2013]). Greenland (3 %) and Africa (12 %) had the least wetlands identified on the land mass.

635

636 **Table 6.** Estimated Global Wetlands areal extent for each of the nine regional HydroBASINS (Lehner and Grill,
 637 2013). As described in the text, Global Wetlands extent incorporates the CW-WTD (Tootchi et al., 2019), CCI
 638 (Herold et al., 2015), and GSW (Pekel et al., 2016); lakes of ≥ 10 ha have been removed (Messenger et al., 2016).

HydroBASINS Region	Wetlands (km ²)	Wetland Percent of Landmass
Africa	3,524,917	11.8 %
Arctic (northern Canada & Alaska)	1,807,830	28.6 %
Asia	5,543,333	26.6 %

Australasia	4,283,996	38.4 %
Europe and Middle East	2,465,074	13.8 %
Greenland (excl. ice sheet)	60,761	2.8 %
North & Central America (excl. Alaska)	4,107,333	25.8 %
Siberian Russia	3,578,868	27.6 %
South America	5,140,139	28.8 %
Total	30,512,251	22.6 %

639

640

641 3.3.3 Non-floodplain wetlands (Global NFW)

642

643 Approximately 16.0 million km² of potential non-floodplain wetlands were identified globally (Global
644 NFWs, Fig. 56), meaning that 11.9 % of the global landmass is estimated to be covered by non-floodplain
645 wetlands (Table 7). This represents ~53 % of the total global wetlands found in the dataset used in this
646 analysis (see Methods: Wetland Data, above). The global distribution of non-floodplain wetlands is
647 widespread, though they were found to comprise a higher proportion of wetlands within more northern
648 HydroBASINS watersheds (i.e., higher abundances in formerly glaciated basins), as demonstrated in Fig.
649 67. The Arctic portion of northern Canada and Alaska (21.7 %), and Siberian Russia (17.4 %), typically
650 underlain by permafrost and frequently inundated or saturated due to poor drainage evolution
651 (Kremenetski et al., 2003; Robarts et al., 2013; Olefeldt et al., 2021), had the greatest percent non-

652

653

654

655

656

657

658

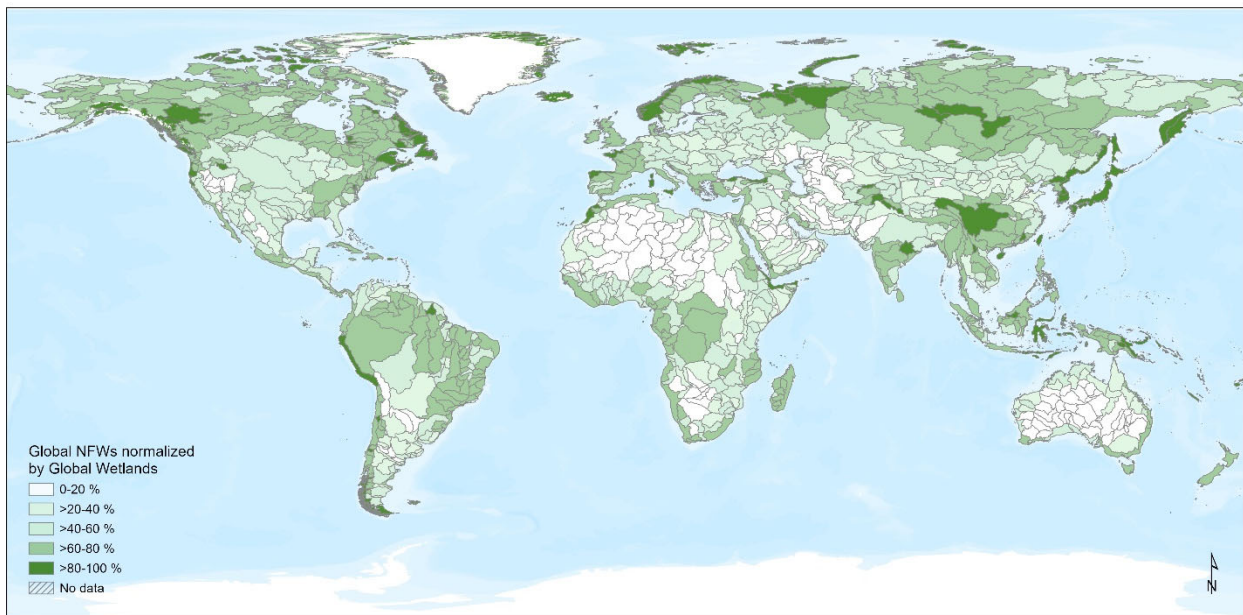

659

660

Figure 56. Non-floodplain wetlands, Global NFWs, are found worldwide, with a greater abundance in formerly glaciated landscapes of northern climates (e.g., northern North America and Siberian Russia) as well as within the Amazon basin (South America). This density map was created using the Focal Statistics tool in ArcGIS Pro 2.9.1. The basemap layer is the ESRI World Terrain Base (2022).

661

662

663 **Figure 67.** The proportion of non-floodplain wetlands, Global NFWs, within a given HydroBASINS watershed
 664 (Lehrner and Grill, 2013), ranging up to 100 %, varied globally. The impacts or effects of non-floodplain wetlands
 665 on biological, biogeochemical, and hydrological functions will vary based on their relative abundance, location
 666 within the watershed, and hydrologic characteristics (Lane et al., 2018). The basemap layer is the ESRI World
 667 Terrain Base (2022).

668

669

670 floodplain wetlands. Africa (5.4 %) and Greenland (1.0 %, excluding ice sheets) had the least abundance
671 of non-floodplain wetlands. A four-direction region-group (contagion) analysis conducted to identify
672 adjacent pixels considered as contiguous units or non-floodplain wetland systems identified 32.8 million
673 individual non-floodplain wetlands. Non-floodplain wetlands are typically small aquatic systems (see
674 Table 7): the median size differed across the HydroBASINS regions from 0.018 km² (1.8 ha) to 0.138
675 km² (13.8 ha) with a global median of 0.039 km² (3.87 ha).

676 **Table 7.** Global NFW data further described by HydroBASINS region.

HydroBASINS Region	Global NFW Extent (km ²)	Count of Global NFWs (#)	Global NFW Percent of Landmass	Global NFW Median Area (km ²)
Africa	1,611,225	2,698,465	5.4 %	0.138
Arctic (northern Canada & Alaska)	1,371,937	5,956,081	21.7 %	0.018
Asia	2,924,900	4,564,172	14.0 %	0.049
Australasia	850,402	1,448,315	7.6 %	0.054
Europe and Middle East	1,475,355	3,740,961	8.3 %	0.054
Greenland (excl. ice sheet)	21,747	180,726	1.0 %	0.018
North & Central America (excl. Alaska)	2,608,158	5,740,066	16.4 %	0.025
Siberian Russia	2,255,689	4,864,577	17.4 %	0.063
South America	2,891,604	3,572,294	16.2 %	0.096
Total	16,011,018	32,765,657	11.9 %	0.039

677

678 **4 Discussion**

679

680 We report here for the first time the global abundance of non-floodplain wetlands, a functionally
 681 important and imperiled resource (Creed et al., 2017). Our estimate of 16.0 million km² suggests that
 682 approximately 53 % of the ~~global population of Earth's~~ wetlands are likely non-floodplain wetland
 683 systems. These aquatic systems are small, with a range from 0.018-0.138 km² (1.8-13.8 ha) across the
 684 globe and a global median size of 0.039 km² (3.87 ha, see Table 7).

685

686 The global abundance of non-floodplain wetlands is a reasonable first approximation of the total non-
 687 floodplain wetland extent. For instance, non-floodplain wetland estimates in the CONUS were conducted
 688 by Lane et al. (2022) using high-resolution aerial-sourced spatial data layers developed by the National
 689 Wetlands Inventory (U.S. Fish and Wildlife Service, various dates). Lane et al. (2022) reported
 690 approximately 23% of the area of freshwater wetlands to be non-floodplain wetland systems. Yet the
 691 CONUS has lost nearly half of its wetlands since the European colonization (Dahl, 1990), with smaller
 692 and shallower non-floodplain wetlands likely being disproportionately lost (Van Meter and Basu, 2015;
 693 Serran et al., 2017).

694

695 Tootchi et al. (2019) – our base input geospatial data layer – calculated that the global wetland extent
696 identified from incorporating both regularly flooded wetland systems (surface-water and precipitation-
697 sourced) and groundwater-driven wetland systems (e.g., Fan et al., 2013; Hu et al., 2017b) resulted in
698 approximately 27.5 million km² of wetlands, a value towards the higher-end of previously published
699 geospatial wetland datasets (Hu et al., 2017a). In their synthesis, Tootchi et al. (2019) explained their
700 values as particularly influenced by groundwater-driven wetlands, especially those in the tropics (10° N-
701 10° S latitudes, Zhu et al., 2022), following recent studies acknowledging the under-estimation of those
702 wetland systems (e.g. Wania et al., 2013; Gumbrecht et al., 2017).

703
704 It follows that incorporating additional higher-resolution satellite inundation data (Pekel et al., 2016) as
705 well as groundwater-driven wetland systems data (e.g., Fan et al., 2013; Tootchi et al., 2019), as
706 conducted in this study, would similarly maintain the trend towards the higher end in global estimates as
707 found by Hu et al. (2017a) and Tootchi et al. (2019). This is meted out in the simple contrast between the
708 proportional abundance of non-floodplain wetland systems identified here against the 30 m NLCD data
709 product described above (Dewitz, 2019) across the 21 CONUS watersheds in this study. The calculated
710 median watershed abundance of non-floodplain wetlands in both the Global NFWs (9.4 %) and the
711 Tootchi et al. (2019) CW-WTD (9.1 %) datasets from our validation watersheds are nearly 5-fold the
712 abundance of the benchmark data from the NLCD (Table [78](#)). However, this is contrasted with a 7-fold
713 *under-representation* of non-floodplain wetlands as derived from the satellite based GSW data (Table 8,
714 Pekel et al., 2016). This suggests that our first approximation of global non-floodplain wetland estimates
715 may be high, primarily due to the resolution of the input data layers. However, as we discuss below,
716 additional factors than just resolution are likely at play.

717
718 It is apparent that the GSW alone is insufficient to map non-floodplain wetlands (this study, Vanderhoof
719 and Lane, 2019). Though useful as a satellite-based input data layer, the GSW by itself appears
720 inadequate for identifying non-floodplain wetlands because it relies on surface-water inundation and

721 ignores saturated wetland systems and those driven by groundwater discharge and upwelling (Winter et
 722 al., 1998). Fan et al. (2013) found that groundwater drivers of aquatic system state were important and
 723 underrepresented in global datasets. Relying on surface water inundation captured during satellite
 724 overflights depends not only on an unobstructed view of the waterbody (e.g., not obscured by trees) but
 725 also fortuitous timing regarding inundation status. For example, in an analysis of non-floodplain wetlands
 726 of the CONUS as derived by distance from an aquatic system, Lane and D'Amico (2016) reported that
 727 just over 50 % of the non-floodplain wetlands were classified as seasonally or temporarily flooded –
 728 meaning that cloud-free and unobscured overflights would only potentially identify these systems at
 729

730 **Table 8.** A comparison of the non-floodplain wetland distribution within the 21 HUCs contrasting across NLCD
 731 (the benchmark data layer, Dewitz, 2019), Global NFW (this study), CW-WTD (Tootchi et al., 2019), and GSW
 732 (Pekel et al., 2016). The CW-WTD (at 500 m) and the Global NFW (coupling 500 m, 300 m, and 30 m data),
 733 derived from the CW-WTD, identified 5-fold the abundance of non-floodplain wetlands whereas the GSW under-
 734 estimated non-floodplain wetlands nearly 7-fold.

HUC ID	Percent HUC as			
	NLCD NFW	Global NFW	CW-WTD NFW	GSW NFW
HUC_0101	10.4 %	19.2 %	18.9 %	0.1 %

Median	2.0 %	9.4 %	9.1 %	0.3 %

735

736 ~~underrepresented in global datasets. Relying on surface water inundation captured during satellite~~
737 ~~overflights depends not only on an unobstructed view of the waterbody (e.g., not obscured by trees) but~~
738 ~~also fortuitous timing regarding inundation status. For example, in an analysis of non-floodplain wetlands~~
739 ~~of the CONUS as derived by distance from an aquatic system, Lane and D'Amico (2016) reported that~~
740 ~~just over 50% of the non-floodplain wetlands were classified as seasonally or temporarily flooded~~
741 ~~meaning that cloud-free and unobscured overflights would only potentially identify these systems at~~
742 certain inundated times of the year. Additionally, Lane and D'Amico (2016) identified another 6% of
743 CONUS non-floodplain wetlands as saturated (i.e., wetlands with saturated substrates but with surface
744 water seldom present). These wetlands would not be identified by the GSW (Pekel et al., 2016) resulting
745 in a further under-representation of the global resource. Similarly, Hamunyela et al. (2022), analyzing
746 ~150,000 km² in southeastern Africa, found that the GSW underestimated surface water extent (i.e.,
747 omission errors) by nearly 65%. Vanderhoof and Lane (2019) found approximately 42% omission rates
748 when contrasting the GSW data to surface-water extent in non-floodplain wetlands ranging from 0.2-17.6
749 ha in area in the Midwestern US. While the GSW is an outstanding dataset that is continuing to be
750 managed and updated, the GSW and its derived product have limitations in their stand-alone utility in
751 global non-floodplain wetland analyses.

752
753 While solely using satellite-based surface-water data products omits groundwater-driven and saturated
754 wetlands and likely results in non-floodplain wetland underestimations, our Global Wetland data
755 incorporated the finer-resolution CCI (Herold et al., 2015) and GSW (Pekel et al., 2016) products into the
756 Tootchi et al. (2019) base map, substantially improving ~~the wetland~~ identification ~~of non-floodplain~~
757 ~~wetlands~~ (see Table 3). These improvements, as indicated by performance indices increasing from 10-50
758 % in the derived Global ~~Wetland-NFW~~ data (see Table 44), support the inclusion of these higher-
759 resolution satellite-based data (Herold et al., 2015; Pekel et al., 2016) with groundwater datasets (Fan et
760 al., 2013), especially when focused on smaller and non-floodplain wetland systems. Similarly, at a coarser
761 scale of 1 km, there was a difference in Mean Absolute Error value of 0.09 (see Table 4) between the

762 Global NFWs and the benchmark NLCD. This ~9 % difference between the two datasets at a 1 km
763 resolution (the former originating at 500 m and the latter at 30 m) further suggest substantive potential
764 utility in these global non-floodplain wetland data for effective natural resource management and
765 decision-making.

766

767

768 **5 Implications**

769

770 Non-floodplain wetlands remain vulnerable waters (Creed et al., 2017), despite the fact that the
771 hydrological, biogeochemical, and biological functions performed by non-floodplain wetlands are
772 increasingly noted in the literature (e.g., Leibowitz, 2003; Creed et al., 2017; Lane et al., 2018; Lane et
773 al., 2022), incorporated into eco-hydrological models by the scientific community (e.g., Fossey and
774 Rousseau, 2016; Golden et al., 2017; Golden et al., 2021; Leibowitz et al., ~~In-Review~~2023), and
775 considered by policy makers (e.g., Biggs et al., 2017; Drenkhan et al., 2022). Their global fate has
776 important implications for watershed-scale resilience to changing climatic conditions (Mckenna et al.,
777 2017; Lane et al., 2022) affecting the measured benefits humans receive from biogeochemical processing,
778 stormwater attenuation, and drought mitigation functions provided by non-floodplain wetlands.

779

780 Global attention to functions of non-floodplain wetlands has increased in the United States (Marton et al.,
781 2015; Rains et al., 2016; Cohen et al., 2016), Europe (Biggs et al., 2017; Nitzsche et al., 2017; Rodríguez-
782 Rodríguez et al., 2021), Asia (Kam, 2010; Van Meter et al., 2014), Australia (Adame et al., 2019), Africa
783 (Merken et al., 2015; Samways et al., 2020), South America (Rodrigues et al., 2012; Cunha et al., 2019)
784 and elsewhere (see extensive review in Chen et al., 2022). This includes analyses of non-floodplain
785 wetlands both as individual systems (e.g., assessing the functions of a single wetland or wetland complex;
786 Badiou et al., 2018) as well as agglomerated, watershed-scale functioning systems (e.g., answering
787 questions on the functional contributions of all non-floodplain wetlands at larger spatial extents; Golden
788 et al., 2016; Blanchette et al., 2022). Previous studies found that non-floodplain wetlands are
789 overwhelmingly important contributors to biogeochemical and hydrological functions affecting
790 downgradient (i.e., down-stream) water quality and streamflow (e.g., McLaughlin et al., 2014; Marton et
791 al., 2015; Cohen et al., 2016; Rains et al., 2016; Golden et al., 2019; Cheng et al., 2020). Hence, with the
792 development of this publicly available dataset, and subsequent improvements by others, it is hoped that

793 these important aquatic systems will be incorporated into resource management and decision-making
794 across the globe.

795
796 Recently, Lane et al. (2022) identified global-scale geospatial data of the spatial extent and spatial
797 configuration of vulnerable waters – non-floodplain wetlands and headwater stream systems (e.g.,
798 ephemeral, intermittent, and perennial low-order waters [Strahler, 1957]) – as a critical scientific gap.
799 Discounting their significance in watershed-scale hydrology and nutrient biogeochemistry analyses – as
800 well as their importance in biological processes (Schofield et al., 2018; Smith et al., 2019; Mushet et al.,
801 2019) – affects quantification of the myriad ecosystem services they provide (De Groot, 2006; Colvin et
802 al., 2019). For instance, Golden et al. (2021) provide a tangible example of the functional effects and
803 influence of non-floodplain wetlands once incorporated into watershed-scale hydrologic models (Fig. 78):
804 ignoring non-floodplain wetlands in the model resulted in projected critical flood-stage return intervals
805 (e.g., 50 yr and 100 yr floods) being reached within a given modeled time frame. Conversely,
806 incorporating non-floodplain wetlands and their storage capacities into a river basin model (e.g., Rajib et
807 al., 2020) demonstrated that non-floodplain wetlands significantly attenuate storm flows, for when non-
808 floodplain wetlands are “...integrated into the model, those simulated *flood stages are not reached*”
809 (Golden et al., 2021, p. 3, emphasis added). The hydrological functions and concomitantly the associated
810 biogeochemical functions (e.g., Marton et al., 2015) of non-floodplain wetlands demand an effective
811 accounting of their spatial extent and configuration, as demonstrated in this novel global dataset.

812

813 **6 Global Non-Floodplain Wetlands: Continuing advancements and conclusion**

814

815 Noting the challenges in accurately identifying non-floodplain wetlands – including small size, frequent
816 non-perennial hydrological inundation, soil saturation rather than overlying surface water, and canopy or
817 cloud cover obstructing satellite or airborne detection – recommendations for advanced analyses of non-
818 floodplain wetland extent hinge initially on the use of ancillary data sources. For instance, global

819 assessments will be improved through wall-to-wall high resolution digital elevation models that are used
 820 to identify depressions on the landscape (e.g., Wu et al., 2019b). Though not all landscape depressions are
 821 non-floodplain wetlands (or wetlands at all), analyses that include depressions may find improved
 822 performance when used in combination with vegetation-based assessments or spectral analyses
 823 identifying water (Devries et al., 2017; Evenson et al., 2018b). Similarly, emerging synthetic aperture
 824 radar-based landscape classifications (e.g., Huang et al., 2018; Martinis et al., 2022; Brown et al., 2022)
 825 and both airborne and satellite-borne hyperspectral and advanced analyses, including LiDAR, as well as
 826
 827

828
 829 **Figure 78.** Non-floodplain wetlands attenuate storm flows and decrease flooding hazards. In this example from
 830 Golden et al. (2021, used by permission under Creative Commons Attribution 4.0 license), incorporating the
 831 floodwater storage and attenuation functions of non-floodplain wetlands (NFWs, here) resulted in substantive
 832 decreases in flood-stage heights (i.e., modeled stream outcomes incorporating non-floodplain wetlands reached
 833 neither 50 yr nor 100 yr floods extents). The example data from Golden et al. (2021) is of USGS Pipestem Creek
 834 gage 06469400, draining approximately 1,800 km².

835 analytical capabilities (e.g., machine-learning approaches, object-oriented classifications, Berhane et al.,
836 2018); topographically based models, Xi et al., 2022; see Table B1) hold great promise for improved
837 resolution and performance in identifying non-floodplain wetlands (Christensen et al., 2022).

838 ~~6 — Global Non-Floodplain Wetlands: Continuing advancements and conclusion~~

839
840 ~~Noting the challenges in accurately identifying non-floodplain wetlands—including small size, frequent~~
841 ~~non-perennial hydrological inundation, soil saturation rather than overlying surface water, and canopy or~~
842 ~~cloud cover obstructing satellite or airborne detection—recommendations for advanced analyses of non-~~
843 ~~floodplain wetland extent hinge initially on the use of ancillary data sources. For instance, global~~
844 ~~assessments will be improved through wall-to-wall high-resolution digital elevation models that are used~~
845 ~~to identify depressions on the landscape (e.g., Wu et al., 2019b). Though not all landscape depressions are~~
846 ~~non-floodplain wetlands (or wetlands at all), analyses that include depressions may find improved~~
847 ~~performance when used in combination with vegetation-based assessments or spectral analyses~~
848 ~~identifying water (Devries et al., 2017; Evenson et al., 2018b). Similarly, emerging synthetic aperture~~

850 ~~and both airborne and satellite-borne hyperspectral and advanced analyses, including LiDAR, as well as~~
851 ~~analytical capabilities (e.g., machine-learning approaches, object-oriented classifications, Berhane et al.,~~
852 ~~2018); topographically based models, Xi et al., 2022) hold great promise for improved resolution and~~
853 ~~performance in identifying non-floodplain wetlands (Christensen et al., 2022).~~

854
855 The Global NFW dataset is not perfect, yet it incrementally advances the current understanding of the
856 potential extent of this important aquatic resource. Limitations of the global dataset (see also Section 4)
857 include the error-propagation and imperfections of the input data layers, including the relatively coarse
858 nature of four of the main input data layers (i.e., the 1000 m groundwater data from Fan et al. (2013), 500
859 m CW-WTD from Tootchi et al. (2019), 500 m GIEMS-D15 from Fluet-Chouinard et al. (2015), and the
860 300 m CCI from Herold et al. (2015)) relative to the target wetland size as clearly evident in Fig. 4. We

861 additionally acknowledge that omission and commission errors remain within this global data product.
862 For instance, our floodplain-masking process may have inadvertently misassigned pixels derived at 500 m
863 into either non-floodplain or floodplain groups. Though data were not lost when we resampled
864 downwards to 30 m from 500 m, the topological relationships were not necessarily maintained, adding
865 error to the determination of floodplain or non-floodplain pixel status (especially as it relates to those
866 pixels proximate to floodplains). Though imperfect, we suggest Global NFW data should be cautiously
867 incorporated into hydrological, biogeochemical, and biological models to account for the important
868 functions non-floodplain wetlands perform.

869
870 Similarly, though this Global NFW is a static data layer, land use, development, and climate changes
871 continue to affect the prevalence of wetlands worldwide. Fluet-Chouinard et al. (2023) recently noted a
872 global wetland loss of 21% since 1700, with rapid increases from 1950s onwards. Returning to the
873 identification of wetlands and their spatial location vis-à-vis floodplains, using the preponderance of
874 higher-resolution (i.e., < 30 m) and high-return interval sensors will improve both the spatial and
875 temporal accuracy of these data, decreasing commission and omission errors (e.g., Table 8) while
876 increasing the accurate identification of smaller aquatic features that occasional cease to hold standing
877 water.

878
879 The keys to quantifying the functional contributions, ecosystem services, and watershed-scale resilience
880 conferred by non-floodplain wetlands through hydrological, biogeochemical, and biological processes are
881 found through, as a first principle, identifying the spatial extent and configuration of this disappearing and
882 imperiled aquatic system (Creed et al., 2017; Lane et al., 2022). This novel geospatial dataset, freely
883 available (https://gaftp.epa.gov/EPADDataCommons/ORD/Global_NonFloodplain_Wetlands/, Lane et al.,
884 2023), provides for sustainable management of an important aquatic resource and advances the global
885 assessment of non-floodplain wetland functions by facilitating non-floodplain wetland inclusion in both
886 existing models and those under development (Golden et al., 2021).

887

888 **7 Data availability**

889

890 The data are available on the United State Environmental Protection Agency’s Environmental Dataset
891 Gateway (DOI: <https://doi.org/10.23719/1528331>, Lane et al., 2023) or
892 https://gaftp.epa.gov/EPADDataCommons/ORD/Global_NonFloodplain_Wetlands/, (last accessed
893 12/06/2022). Here, we provide global gridded floodplain (90 m, GFPLain90, ~/Global_Floodplains),
894 global gridded wetlands (30 m, Global Wetlands, ~/Global_Wetlands), and global gridded non-floodplain
895 wetlands (30 m, Global NFWs, ~/Global_NFWs) for each of the 3142 HydroBASINS, organized by
896 HydroBASINS region (see, e.g., Table 7).

897

898 **Author contributions.** CL, JC, HG, and ED conceptualized the study, developed the formal analysis, and
899 conducted and/or assisted the data validation. CL wrote and edited the manuscript, while JC and HG
900 reviewed and edited the manuscript. ED also developed the methodology, curated the data, conducted the
901 formal spatial analysis, validated the data, visualized the data, and reviewed and edited the manuscript.
902 QW and AR assisted in methodology development, validated the study outputs, conducted formal
903 analyses, and reviewed and edited the manuscript.

904

905 **Competing interests.** The corresponding authors have declared that none of the authors have any
906 competing interests.

907

908 **Disclaimer.** Publisher’s note: Copernicus Publications remains neutral with regard to jurisdictional
909 claims in published maps and institutional affiliations.

910

911 **Acknowledgements.** We greatly appreciate the scientific contributions and stimulative discussions in the
912 papers led by Ardalan Tootchi, Sean Woznicki, Fernando Nardi, Oliver Wing, Paul Bates, and their co-

913 authors that inspired us to complete these analyses. Jeremy Baynes and John Johnston conducted critical
914 reviews to improve this manuscript, and their efforts are acknowledged. This paper has been reviewed in
915 accordance with the US Environmental Protection Agency’s peer and administrative review policies and
916 approved for publication. Mention of trade names or commercial products does not constitute
917 endorsement or recommendation for use. Statements in this publication reflect the authors’ professional
918 views and opinions and should not be construed to represent any determination or policy of the US
919 Environmental Protection Agency.

972 **Table B21.** Descriptive characteristics of the 21 verification basins located throughout the CONUS (see Fig. 2).
973 Majority Köppen-Geiger classification follows Beck et al. (2018). Climatological data were acquired from the
974 PRISM Climate Group (Parameter-elevation Regressions on Independent Slopes Model, prism.oregonstate.edu/,
975 accessed 09/26/2022) using the 30-year annual normals for each watershed. Land use data and descriptions are from
976 the 2019 NLCD (www.mrlc.gov/data, accessed 09/26/2022) and represent the land use class with the greatest areal
977 abundance. Average elevation was derived from the USGS National Elevation Dataset (https://www.usgs.gov/3d-
978 elevation-program, accessed 01/13/2022). Global Wetland Count are the counts of wetlands from the derived Global
979 Wetland database within each watershed after region-grouping the data using a four-direction contagion criterion
980 (i.e., pixels immediately adjacent in any of the four cardinal directions are considered part of a unique, multi-pixel
981 wetland, ArcGIS Pro v.2.9.1, Redlands, California).

988

989 **Table B23.** Floodplain performance assessment of the GFPlain90-derived floodplain and the benchmark floodplain
 990 from Woznicki et al. (2019). The first six equations directly assess the spatial concordance and overlap between the
 991 two datasets, whereas Mean Absolute Error (Eq. 7) and Aggregate Error Bias (Eq. 8) are coarser fractional analyses
 992 (i.e., the fraction of a 1 km² cell predicted correctly) as measured along the riverine network.

<u>Hydrologic Unit Code (HUC) ID</u>	<u>Hit Rate</u> (Eq. 1)	<u>Precision</u> (Eq. 2)	<u>False Alarm</u> (Eq. 3)	<u>CSI</u> (Eq. 4)	<u>F1</u> (Eq. 5)	<u>Error Bias</u> (Eq. 6)	<u>Mean Absolute Error</u> (Eq. 7)	<u>Aggregate Error Bias</u> (Eq. 8)

993

994

995
 996 **Figure B1.** Comparison of floodplain extents derived from GFPlain90 (this study) and GFPlain250 (Nardi et al.,
 997 2019). The right-hand panels are the inset area outlined in the orange box on the left panels; the top panels represent
 998 an eastern coastal watershed (HUC_0304) whereas the bottom panels are from a midwestern US watershed
 999 (HUC_1024). The full extent of the riverine network is evident in the GFPlain90 dataset, which was derived from 90
 1000 m resolution DEMs in contrast to the 250 m pixel size of the GFPlain250. Satellite imagery sourced from ESRI
 1001 (2022).
