21 **Abstract**

22 Wildfires are increasingly impacting social and environmental systems in the United States.
23 The ability to mitigate the adverse effects of wildfires increases with understanding of the
24 social, physical, and biological conditions that co-occurred with or caused the wildfire
25 ignitions and contributed to the wildfire impacts. To this end, we developed the FPA FOD-
26 Attributes dataset, which augments the sixth version of the Fire Program Analysis-Fire
27 Occurrence Database (FPA FOD v6) with nearly 270 attributes that coincide with the date
28 and location of each wildfire ignition in the United States. FPA FOD v6 contains information
29 on location, jurisdiction, discovery time, cause, and final size of >2.3 million wildfires from
30 1992-2020 in the United States. For each wildfire, we added physical (e.g., weather, climate,
31 topography, infrastructure), biological (e.g., land cover, normalized difference vegetation
32 index), social (e.g., population density, social vulnerability index), and administrative (e.g.,
33 national and regional preparedness level, jurisdiction) attributes. This publicly available
34 dataset can be used to answer numerous questions about the covariates associated with
35 human- and lightning-caused wildfires. Furthermore, the FPA FOD-Attributes dataset can
36 support descriptive, diagnostic, predictive, and prescriptive wildfire analytics, including
37 development of machine learning models. The FPA FOD-Attributes dataset is available at
38 <https://zenodo.org/record/8381129> (Pourmohamad et al. 2023).

39

40

41 **1. Introduction**

42 Wildfire (hereafter, fire) hazards have increased across many regions of the world in recent
43 decades, increasing the burden on fire prevention and suppression efforts (Alizadeh et al.,
44 2021; Modaresi Rad et al., 2023; Rad et al., 2023). Changes in climate have decreased the
45 moisture content of living and dead vegetation, lengthened the fire season, and contributed to
46 a significant increase in the number of critical fire danger days across much of the United
47 States (Westerling, 2016; Dennison et al., 2014; Bowman et al., 2011). These changes have
48 overlapped with the impacts of fire suppression policies, fire deficits, and high fuel loads in
49 many regions, especially low-elevation forests in the western United States (Bowman et al.,
50 2009). Human-caused ignitions compound the fire burden, particularly near the wildland-
51 urban interface (WUI), where wildlands intermingle with human settlements (Stephens et al.,
52 2013; Committee, 2013). Moreover, increases in the area and density of human settlement
53 and infrastructure in the WUI have further increased exposure to fire hazards across the
54 United States (Scott et al., 2012). The intersection of changes in the number and timing of
55 ignitions and changing environmental conditions has resulted in several fires that caused
56 substantial loss of life (e.g., Miller and Ager, 2012).

57 Studies have focused on understanding the patterns and drivers of human-caused ignitions
58 given the potential for reducing the number of such ignitions and the negative impacts
59 associated with the resulting fires, particularly near the WUI (Short, 2014; Balch et al., 2017).
60 The primary factors that are often included in models of human-caused ignitions are social
61 and economic (e.g., demographics), environmental (e.g., vegetation, meteorology,
62 topography), anthropogenic (e.g., land ownership, distance to roads), and timing metrics (e.g.,
63 holidays, weekends) (Short, 2022). Similarly, advances in predictive understanding of
64 lightning-ignited fires have improved the speed and effectiveness of suppression responses
65 (Ronchi et al., 2017; McGee et al., 2015). Soil moisture (Viegas et al., 1992; Meisner et al.,
66 1993; Pineda et al., 2022), vegetation type and condition (Dissing and Verbyla, 2003;
67 Wierzchowski et al., 2002), weather (Wierzchowski et al., 2002; Hély et al., 2001), pre-fire-
68 season snowpack (Chen and Jin, 2022), duration of lightning contact with fuel (Fuquay et al.,
69 1979; Latham and Williams, 2001), number of lightning strikes (Flannigan and Wotton,
70 1991), and topography (Hessilt et al., 2022) are the main cited factors that affect natural fires.
71 However, the confluence of factors that shape spatial and temporal patterns of ignitions,
72 especially human-caused ignitions, confounds efforts to predict, prevent, and prepare for the
73 impacts of fires.

74 The most comprehensive source of georeferenced fire ignition data in the United States is the
75 Fire Program Analysis Fire Occurrence Database (Short, 2014), which aggregates fire reports
76 from federal, state, and local entities with fire protection and reporting responsibilities. All
77 fires in the FPA FOD database are referenced to a discovery date, final fire size (area within
78 the fire perimeter), and a point location at least as precise as a Public Land Survey System
79 section (i.e., 1 square mile grid). Most fire records are also associated with attributes

80 including fire name, discovery time, reporting agency information, ignition cause, and
81 containment date and time. The 13 cause classes, as determined by the reporting agency, are
82 natural; recreation and ceremony; equipment and vehicle use; debris and open burning;
83 smoking, arson or incendiarism; railroad operations and maintenance; misuse of fire by a
84 minor; power generation, transmission, or distribution; fireworks, firearms and explosives
85 use; other causes; and missing data, not specified, or undetermined (Short, 2021). FPA FOD
86 also includes incident identification numbers that can be referenced to other fire databases,
87 such as Monitoring Trends in Burn Severity (Eidenshink et al., 2007) and All-hazards dataset
88 (St. Denis et al., 2023). The sixth version of FPA FOD includes more than 2.3 million fire
89 records that correspond to a total of more than 72.8 million ha (180 million acres) burned
90 from 1992-2020 across the United States (Short, 2022).

91 To enable stronger inferences about factors that affect and predict fire ignitions and
92 outcomes, we augmented the sixth version of FPA FOD (FPA FOD v6) with 267 attributes
93 associated with the date and location of ignition across the United States. Major classes of
94 these attributes encompass climate, weather and fire danger, topography, land cover and
95 vegetation, jurisdiction and management, infrastructure, and social context. Although the
96 attributes are associated with the date and point of ignition, we also included summary
97 statistics within a temporal buffer (e.g., 5 days centered on the ignition date) and a spatial
98 buffer (e.g., 1 km) around the ignition point. Additionally, we included monthly, satellite-
99 derived vegetation indices during the 12 months prior to the ignition. The resultant FPA
100 FOD-Attributes dataset includes a total of 310 attributes associated with more than 2.3
101 million fire incidents across the United States from 1992-2020. This rich, tabular dataset can
102 be used in a variety of hypothesis-driven or data-exploration applications.

103 **2. Methods**

104 **2.1. Data Sources**

105 The FPA FOD-Attributes dataset brings together 267 attributes associated with fire ignitions
106 from 24 data sources (Tables 1 and S1). The accuracy, precision, and uncertainty of each
107 attribute, including spatial and temporal resolution, depends on the source data. Availability
108 of attributes for individual fire incidents also depends on the spatial and temporal coverage of
109 the source data. Table 1 lists general categories of attributes, their resolution and coverage,
110 and their sources. Table S1 lists more detail about individual attributes that are included in
111 the FPA FOD-Attributes dataset.

112 Source data were either in raster or vector/point formats. For raster data, we selected the
113 attribute value of the grid cell that contained the ignition point recorded in the FPA FOD
114 dataset. Similarly, for vector/shapfile formatted data, we selected the attribute value of the
115 area associated with the ignition point. When distance from the fire location to a vector was
116 of interest, we estimated the nearest perpendicular distance. We conducted all analyses with
117 Python libraries xarray and GDAL (raster data) or GeoPandas (vector data). Source code is
118 provided along with the FPA FOD-Attributes dataset to support future use (see Code
119 Availability and Data Availability sections).

120 Table 1. Variables in the FPA FOD-Attributes dataset and their data sources. See Table S1
 121 for a detailed description of all variables and sources.

130 **2.2. Data Compilation**

131 Here, we briefly discuss the data compilation process and assumptions. Table S1 provides a
132 detailed description of the variables, their units, and sources. Unless otherwise specified, the
133 FPA FOD-Attributes dataset provides a complete record of values of each variable for all fire
134 events from 1992-2020.

135 **2.2.1. Weather and climate**

136 Our main source of weather and climate data was gridMET (Abatzoglou, 2013), which
137 merged gridded climate and reanalysis data with gauge-based precipitation data to provide
138 spatially and temporally complete, high-resolution (4 km) gridded data on surface
139 meteorological variables. gridMET also provides daily fire danger indices based on Fuel
140 Model G from the National Fire Danger Rating System 77 (Cohen and Deeming, 1985).
141 gridMET is widely used in fire-related studies (Alizadeh et al., 2021, 2023).

- 142 • Weather and fire danger indices

143 Attributes associated with each fire ignition in the FPA FOD-Attributes dataset include daily
144 precipitation, maximum and minimum temperature (2 m above ground), relative humidity,
145 specific humidity, wind velocity (10 m above ground), surface downward shortwave
146 radiation, reference evapotranspiration, and vapor pressure deficit; all data are for the date
147 and point of fire ignition. We also derived the following fire danger indices for the date and
148 point of fire ignition: 100-hour and 1000-hour dead fuel moisture, energy release component
149 (ERC), and burning index. Additionally, we derived maximum, minimum, and average
150 values of these variables within a 5-day window centered on the fire ignition date (i.e., from 2
151 days prior to 2 days after the ignition date).

- 152 • Climate normals

153 A climate normal is defined as the long-term (1990-2020) average of daily surface
154 meteorological variables. Climate normals characterize average weather conditions. The
155 attributes include climate normals of all meteorological and fire danger indices listed above
156 for the location and day of year of fire ignition.

- 157 • Climate percentiles

158 We calculated the percentile range for meteorological and fire danger indices for the location
159 and the day of year of fire ignition, relative to values from the same day of the year from
160 1979-2020. The percentile range enables the user to compare the attribute with long-term
161 records. We report the data in discrete ranges of <10%, 10%-30%, 30%-50%, 50%-70%,
162 70%-90%, and >90%. Depending on the attribute, a higher percentile range might be
163 associated with higher (e.g., ERC) or lower (e.g., 1000-hr dead fuel moisture) fire danger.

164 **2.2.2. Land cover and topography**

165 We used data from the U.S. Forest Service (USFS), U.S. Geological Survey (USGS),
166 LANDFIRE, National Oceanic and Atmospheric Administration (NOAA), National
167 Aeronautics and Space Administration (NASA), and U.S. Environmental Protection Agency
168 (EPA) to derive attributes associated with land surface conditions at the location and time of
169 fire ignition. We provide multiple land-cover data sources to allow users to select the source
170 that best suits their needs.

171 Given the potential biases in reporting of the ignition location, statistics of variables within a
172 1-km radius around the ignition location, especially variables derived from 30-m or other
173 fine-resolution products, are likely a more accurate representation of the ground conditions
174 than values specifically at the point of ignition. For fires that burn large areas, note that land
175 cover can vary widely and thus may differ from that at the point of ignition,

- 176 • Omernik ecoregions

177 Ecoregions denote areas with similar biotic and abiotic attributes (Omernik, 1987). Ecoregion
178 shapefiles (i.e., vector data) are available at four levels: 15 Level 1 ecoregions, 50 Level 2
179 ecoregions, and 182 Level 3 ecoregions across North America, and 967 Level 4 ecoregions in
180 the CONUS. Many fire-related studies used Level II or III ecoregions (Dennison et al., 2014;
181 Alizadeh et al., 2021, 2023), and we provide these two ecoregion classifications at the
182 ignition point of each fire.

- 183 • Pyrome

184 Pyromes are regions with relatively homogeneous contemporary fire regimes (e.g., start and
185 end date of fire season, frequency of fire, modality and large-fire size); 128 pyromes have
186 been identified in CONUS (Short et al., 2020). We provide the pyrome associated with the
187 ignition point of each fire.

- 188 • Topography

189 Topography affects the likelihood of fire ignition and fire behavior. We derived elevation,
190 slope, aspect, the Topographic Position Index (TPI), and Terrain Ruggedness Index (TRI).
191 Positive and negative TPI values represent locations that are higher and lower, respectively,
192 than their neighboring grid cells (Weiss, 2001). TRI indicates the magnitude of elevation
193 change between neighboring grid cells (Riley et al., 1999). We derived elevation (above
194 mean sea level), slope, and aspect from LANDFIRE products (30-m resolution). We derived
195 TPI and TRI from the LANDFIRE digital elevation model with the GDAL library in Python.

196 The FPA FOD-Attributes dataset includes these variables at the fire ignition point, and also
197 averaged across a 1-km radius around the fire ignition point.

198 • Existing vegetation

199 We used Existing Vegetation Cover (EVC), Existing Vegetation Height (EVH), and Existing
200 Vegetation Type (EVT) data from LANDFIRE (30-m resolution) to represent vegetation as
201 close as possible to the point and date of fire ignition. EVC, EVH, and EVT are available for
202 2001, 2012, 2014, 2016 and 2020. For each fire ignition, we used the most recent prior data
203 product. For all fires prior to 2001, we used the 2001 product. We used the codes for
204 vegetation variables as in the original dataset (<https://landfire.gov/vegetation.php>). We also
205 report the most frequently occurring EVC, EVH, and EVT classification within a 1-km radius
206 around each fire ignition point.

207 • Fire regime group

208 Fire regime group (FRG) characterizes the presumed historical fire regime in a given
209 location. We report the most frequently occurring FRG within the 1-km radius around each
210 ignition point, for the prior year closest to the date of ignition. Data on FRG are available
211 through LANDFIRE for 2001, 2012, 2014, and 2016. We used the 2001 product for all
212 ignitions prior to 2001. FRG codes in FPA FOD-Attributes correspond to those in
213 LANDFIRE (<https://landfire.gov/CSV/FRG.csv>).

214 • Normalized Difference Vegetation Index (NDVI) and Enhanced Vegetation Index
215 (EVI) from NASA's MODIS sensor

216 NDVI is an index of vegetation greenness (Rouse et al., 1974) that is closely related to
217 primary productivity and leaf cover. EVI is a similar index that generally is more accurate in
218 regions with high vegetation biomass (Huete et al., 2002). We obtained NDVI and EVI from
219 NASA's MOD13C2 v6.1 product (5.6 km resolution), which provides monthly NDVI and
220 EVI indices from 2000 to present. We derived NDVI and EVI at the point of ignition in the
221 month prior to the ignition date and the 11 previous months. The FPA FOD-Attributes dataset
222 does not include NDVI and EVI values for ignitions prior to 2000.

223 • NDVI from NOAA

224 We also obtained NDVI from NOAA's daily gridded NDVI product (5.55 km resolution),
225 which was derived from the Surface Reflectance Climate Data Record based on Advanced
226 Very High Resolution Radiometer (AVHRR) and Visible Infrared Imaging Radiometer Suite
227 (VIIRS) images (Vermote, 2019). We acquired the NDVI value associated with the location
228 of ignition on the day prior to the fire discovery date. FPA FOD-Attributes also includes
229 monthly mean, maximum, and minimum NDVI for the 12 months prior to the ignition date.

230 • Land cover

231 We used the National Land Cover Database (NLCD) to derive the most recent prior land-
232 cover type associated with each point and date of fire ignition. These data are similar to EVC,

233 and users may opt to select one or the other. NLCD data are available for 1992, 2001, 2004,
234 2006, 2008, 2011, 2013, 2016, and 2019. Land cover classes and the method used to classify
235 land cover from Landsat images differed between 1992 and all other years (Dewitz, 2019).
236 The attributes include land-cover type at the point of ignition and the three land-cover types
237 with the greatest percentage of cover within a 1-km radius around the ignition point.

238 • Rangeland production

239 The rangeland production metric quantifies annual plant biomass production on 268 million
240 hectares (662 million acres) of rangeland across the CONUS from 1984 to present at 30 m
241 resolution. We derived rangeland production values at the ignition point and within a 1-km
242 radius around the ignition point for the year of fire. Values of rangeland production are only
243 provided for ignitions within the domain of the Rangeland Production Monitoring Service
244 (Reeves et al., 2021).

245 • Exotic annual and native perennial grasses

246 We used annual fractional cover maps (30-m resolution) for (1) a group of 17 exotic annual
247 grasses, (2) cheatgrass (*Bromus tectorum*), (3) medusahead (*Taeniatherum caput-medusae*),
248 and (4) Sandberg bluegrass (*Poa secunda*) from 2016-2021 (USGS, 2023). These data are
249 generated from on-the-ground observations by the U.S. Bureau of Land Management and
250 application of a machine learning model to Harmonized Landsat and Sentinel images (Dahal
251 et al., 2022). The FPA FOD-Attributes dataset provides percent cover for each of the four
252 above-mentioned categories of grasses on the date and for the location of ignition from 2016-
253 2020, within the spatial domain of the source data (extended western United States).

254 **2.2.3. Social and economic context**

255 We used a variety of government and academic data sources to derive social and economic
256 attributes associated with the location of fire ignitions. Many of these sources are based on
257 the United States or, in some cases, global census data.

258 • Climate and economic justice screening tool

259 We used the U.S. Council on Environmental Quality's Climate and Economic Justice
260 Screening Tool (CEJST) v.0 to derive metrics associated with community-level burdens
261 related to climate change, energy, health, housing, legacy pollution, transportation, water and
262 wastewater, and workforce development. Because values of CEJST's 107 variables currently
263 are static, we assigned values to all fire ignitions in the entire period of record on the basis of
264 location. CEJST is derived from 2010 U.S. census data and values of variables are available
265 at the tract level. CEJST classifies a community as disadvantaged if it is "(1) at or above the
266 threshold for one or more environmental, climate, or other burdens, and (2) at or above the
267 threshold for an associated socioeconomic burden" (<https://screeningtool.geoplatform.gov/>).

268 • Social vulnerability index

269 We used the U.S. Centers for Disease Control and Prevention’s nested hierarchical social
270 vulnerability index (SVI), which provides a measure of vulnerability for each census tract in
271 terms of overall vulnerability, four general dimensions of vulnerability (socioeconomic
272 status, household composition and disability, housing type and transportation, minority status
273 and language), and 15 subdimensions of vulnerability (e.g., income, age, minority, no
274 vehicles). Values of the SVI range from 0 (low vulnerability) to 1 (high vulnerability). SVI
275 estimates are available for 2000, 2010, 2014, 2016, 2018, and 2020. The FPA FOD-
276 Attributes dataset includes the overall SVI value and values of the dimensions and
277 subdimensions of vulnerability for the location and year of each fire ignition. We used the
278 most recent SVI prior to the ignition date. We assigned vulnerability attributes to ignitions
279 prior to 2000 from the 2000 SVI data.

- 280 • Population density

281 We obtained population density and its average within a 1-km radius around the point of
282 ignition from the WorldPop dataset (Tatem, 2017), which provides annual global population
283 data from 2000-present at 100-m resolution. We did not assign a population density value to
284 fire ignitions prior to 2000.

- 285 • Gross domestic product

286 We derived per capita gross domestic product (GDP) at the location of each ignition in the
287 most recent year prior to the ignition date. Our global data source (Kummu et al., 2018)
288 provides subnational GDP per capita for 1990, 2000, 2015 at 5 arc-min resolution.

- 289 • Global human modification

290 We assigned a static global human modification (GHM) index, which indicates the
291 cumulative human modification of lands, to each fire ignition on the basis of its location. We
292 derived GHM values from data provided by the NASA Socioeconomic Data and Applications
293 Center (1-km resolution at the global level), which were originally developed by (Kennedy et
294 al., 2019).

295 **2.2.4. Administrative**

296 We used a variety of data sources, mostly from the U.S. government, to acquire attributes
297 associated with management.

- 298 • Risk management assistance program

299 We used the two static, raster-formatted risk maps provided by the Risk Management
300 Assistance program to acquire evacuation time from the fire ignition location to a medical
301 care facility and the suppression difficulty index (SDI; Silva et al., 2020) for the fire ignition
302 point. SDI is a measure of relative difficulty of fire control given topography, fuels, expected
303 severe weather fire behavior, firefighter line production rates in various vegetation types, and
304 accessibility (e.g., distance from roads or trails).

- 305 • Fire stations

306 We derived the number of fire stations within a 1-, 5-, 10-, and 20-km radius around each fire
307 ignition point. The location of fire stations comes from the static Homeland Infrastructure
308 Foundation-Level Data.

- 309 • Geographic area coordination centers (GACC) preparedness level

310 The nine GACCs in CONUS also have preparedness levels that are based on the regional
311 availability of wildland firefighting resources and fire activity. We obtained the GACC
312 preparedness level for all fire ignitions over the period 2007-2020 (Nguyen et al., 2023). Data
313 are not available for fire ignitions prior to 2007.

- 314 • National preparedness level (NPL)

315 National preparedness level indicates suppression resource availability for emerging fires on
316 the basis of fuel and weather conditions, current fire activity, and resource commitments;
317 there is a single NPL reflecting the entire nation. We acquired the NPL associated with the
318 date of all fire ignitions from the National Interagency Fire Center (NIFC). NPLs are
319 determined by the National Multiagency Coordination Group or the National Interagency
320 Coordination Center (NICC) daily during the fire season and are published by NICC as a part
321 of the daily Incident Management Situation Report (IMSR; Nguyen et al., 2023).

- 322 • Conservation status

323 The Gap Analysis Project (GAP) is a USGS-based program that evaluates whether common
324 species of plants and animals are adequately protected and tracks the conservation status of
325 lands and waters nationwide. From GAP's vector-based static data, we obtained management
326 jurisdiction and agency (e.g., U.S. Fish and Wildlife Service), land management designation
327 (e.g., Wilderness Area, National Recreation Area), and GAP status code and priority (extent
328 to which conservation of biological diversity is prioritized) for all fire ignition points.

- 329 • Distance to road

330 We used the vector-based, static Topologically Integrated Geographic Encoding and
331 Referencing (TIGER) database to derive the minimum distance (perpendicular) from the
332 point of fire ignition to primary, secondary, local, and other roads and to all-terrain vehicle
333 and non-motorized vehicle trails.

334 **3. Data validation**

335 The FPA FOD-Attributes dataset is a derivative dataset, and hence the accuracy, precision
336 and uncertainty of the fire attributes reflect those of the source data. We selected reliable
337 source data to ensure the quality of attribute data associated with each fire. Our validation
338 process was focused on ensuring the attributes are consistent with the source. We followed
339 four steps to validate our data:

- 340 1. Manual comparison of attribute values for selected fires from the source data to those
341 in the FPA FOD-Attributes dataset.

- 342 2. Comparison of the attributes in the FPA FOD-Attributes dataset and another
343 published study.
344 3. Investigation of the temporal evolution of attributes associated with selected fires and
345 those in the FPA FOD-Attributes dataset.
346 4. Comparison of attributes from the FPA FOD-Attributes dataset with those reported by
347 the news media.

348 **3.1. Manual comparison**

349 We compared values of attributes of 100 randomly selected fires that spanned the spatial and
350 temporal domain from the FPA FOD-Attributes dataset and manually extracted source data in
351 QGIS (raster and vector-based data) or Excel (tabular data). We assumed that manual
352 comparison would detect any systematic errors in the Python code used to develop the FPA
353 FOD-Attributes dataset. All attribute values for all selected fire ignitions matched those of the
354 source data.

355 **3.2. Comparison with the literature**

356 We compared the meteorological and fire danger indices associated with seven fires in
357 Southern California listed in Table S6 of (Khorshidi et al., 2020) with those in the FPA FOD-
358 Attributes dataset. Because (Khorshidi et al., 2020) also used gridMET, we expected the two
359 sets of values to match. With the exception of rounding errors, values of vapor pressure
360 deficit (VPD), 100-hr and 1000-hr dead fuel moisture (FM100 and FM1000, respectively),
361 and burning index (BI) from the two sources matched (Figure 1, Table S2).

362

363 Figure 1. Comparison of values of meteorological and fire danger indices associated with
364 seven fires from FPA FOD-Attributes and (Khorshidi et al., 2020).

365

366 3.3. Temporal evolution of fire attributes

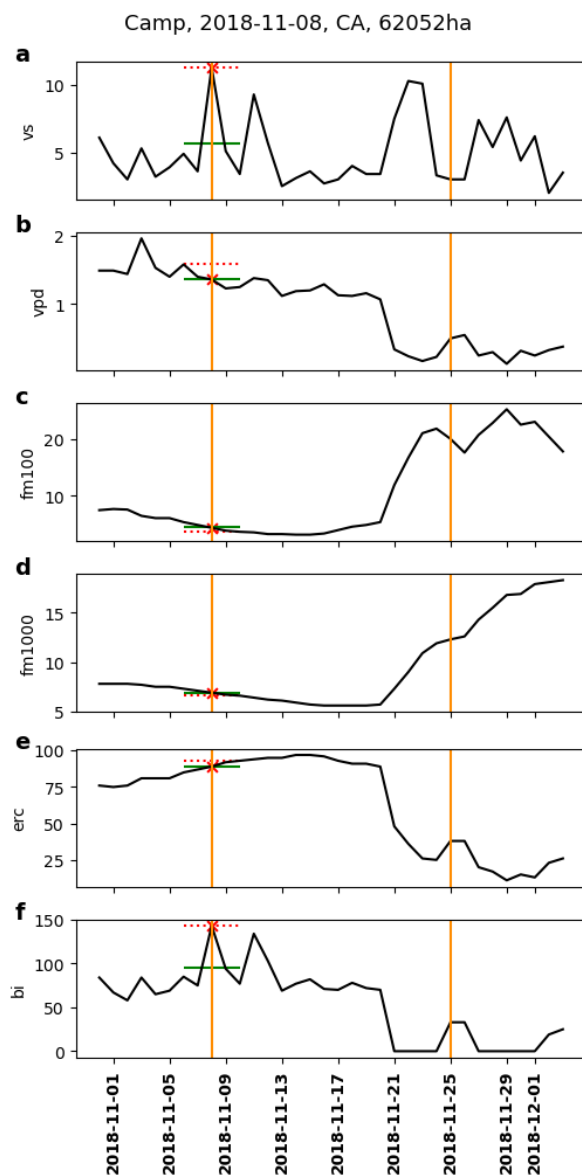

367 We analyzed the temporal evolution of meteorological and fire danger indices at the point of
368 ignition between the fire discovery and containment dates of seven high-impact fires (Table
369 S3, Figure 2, Figures S1-S6) distributed across CONUS. The FPA FOD-Attributes dataset
370 provides these attributes on the ignition date and in a 5-day window centered around the
371 ignition data. Here, we present the results for the Camp Fire, which started on November 8,
372 2018, near Paradise, California. This fire claimed 85 lives and destroyed more than 18,000
373 structures. Camp fire was ignited by power transmission lines in the coniferous forests of

374 Butte County, California, and spread quickly due to strong easterly downslope winds. The
375 FPA FOD-Attributes dataset indicates that the fire was ignited in an evergreen forest (NLCD
376 classification) and that the land cover within a 1-km radius was 50% evergreen forest, 41%
377 shrub/scrub, and 6% “developed, open space”. The three most prevalent existing vegetation
378 heights within a 1-km radius of the ignition point were 18 m (trees; 43%), 38 m (trees; 23%),
379 and 0.8 m (herbaceous plants; 9% herb). These data match the official reports and news
380 accounts of the fire (e.g., Maranghides et al., 2021, and references therein). The elevation of
381 the fire ignition in the FPA FOD-Attributes dataset, 608 m, is consistent with the downslope
382 spread of the fire from the ignition point to the city of Paradise (elevation 542 m).

383 We extracted wind velocity (VS), VPD, FM100, FM1000, energy release component (ERC),
384 and BI from late October to early December 2018 at the ignition point of the Camp Fire from
385 gridMET and the FPA FOD-Attributes dataset. Values of the two sets of variables matched
386 (Figure 2). Furthermore, the evolution of meteorological and fire danger variables followed
387 the known pattern: the Camp Fire started on a windy day (Figures 2a,f) concurrent with dry
388 vegetation (Figures 2b-e), and it was contained by the first rainstorm of the water year on
389 November 25. The arrival of the storm decreased fire danger and increased fuel moisture
390 (Figures 2b-f).

391

392

393 Figure 2. Evolution of meteorological and fire danger indices from late October to early
394 December 2018 at the ignition point of the Camp Fire. Fire discovery and containment dates
395 are indicated with vertical orange lines, the attribute value at the date of ignition is indicated
396 with red asterisks, and the attributes' five-day average and maximum (VS, VPD, ERC, BI) or
397 minimum (FM100, FM1000) values are indicated with green and red horizontal lines.

398

399 Figures S1-S6 show the evolution of meteorological and fire danger attributes associated with
400 six additional fires across the CONUS, also providing evidence of the validity of the FPA
401 FOD-Attributes dataset.

402 **3.4. Comparison with the news**

403 We also compared the fire attributes from the FPA FOD-Attributes dataset with news
404 accounts of two major fires, the Martin and East Troublesome fires. The 2018 Martin fire
405 burned more than 168,680 ha of shrublands and grasslands in Paradise Valley, Nevada. High
406 winds and high cover of cheatgrass are believed to have contributed to the quick spread of
407 this fire (Rothberg, 2018). The FPA FOD-Attributes dataset indicated that the prevalent land
408 cover (derived from NLCD) in a 1-km radius around the ignition point was shrub/scrub or
409 grassland/herbaceous; and that the majority of existing vegetation height (derived from
410 LANDFIRE) was 0.3 m (herbaceous), 0.2 m (herbaceous), and 0.8 m (shrubs). Furthermore,
411 land cover at the point of ignition included 21% cheatgrass and 27% other exotic annual
412 grasses, and daily average wind speed was in the 70%-90% range of historical records for the
413 day of the year, which is consistent with news reports (Rothberg, 2018). The FPA FOD-
414 Attributes dataset indicates an elevation of 1,415 m at the point of ignition, which is
415 comparable to the Paradise Valley, Nevada, elevation of 1,389 m.

416 The 2020 East Troublesome Fire burned 78,430 ha in the high elevations of the central Rocky
417 Mountains of Colorado (above 2,740 m). Low relative humidity and high winds enabled the
418 fire to spread rapidly through coniferous forest, kill two people, and destroy more than 400
419 structures (Colorado Encyclopedia, 2023). The FPA FOD-Attributes dataset indicates that
420 VPD and VS on the date of ignition were high relative to their historical range on the same
421 day of the year (80%-90% and >90%, respectively), and that the fire ignited at an elevation of
422 2,757 m. Land cover (derived from NLCD) within a 1-km radius around the ignition point
423 included evergreen forest (61%), shrub/scrub (32%), and deciduous forest (6%). Cheatgrass
424 is uncommon at such high elevations, and the FPA FOD-Attributes dataset did not assign any
425 cheatgrass cover to the ignition point. These metrics are consistent with the news records.

426

427 **4. Results**

428 Decadal trends and interannual variability in the number of wildfires are apparent over the
429 1992-2020 time period covered by the FPA FOD dataset. Human-caused fires increased,
430 while lightning-ignited (hereafter “natural”) fires decreased (Figure 3). Interannual variability
431 of fire ignitions is partially explained by seasonal climate and weather conditions, for
432 example modulated through fuel receptiveness to ignitions and abundance of outdoor
433 activities (Noonan-Wright et al., 2011; Finney et al., 2011). Decadal trends are mainly
434 attributable to fire prevention strategies and climatic changes (e.g., increases in the number of
435 critical fire danger days) (Noonan-Wright et al., 2011; Khorshidi et al., 2020; Alizadeh et al.,
436 2023). Importantly, fire ignitions have temporal and spatial structures, enabling development
437 of targeted fire prevention and response strategies (Douglas et al., 2001). Figure 4, for

438 example, shows a clear spatial pattern in both human-caused and natural ignitions across the
439 contiguous United States (CONUS). Human-caused fires are close to human settlements and
440 roads (which can be partially explained by reporting biases; Figure 4a); whereas natural fires
441 are associated with mountains in the western and southeastern CONUS (Figure 4b). Figures
442 S7-S19 display the spatial distribution of ignitions associated with 13 specific fire causes
443 (subcategories of natural and human-caused fires).

444

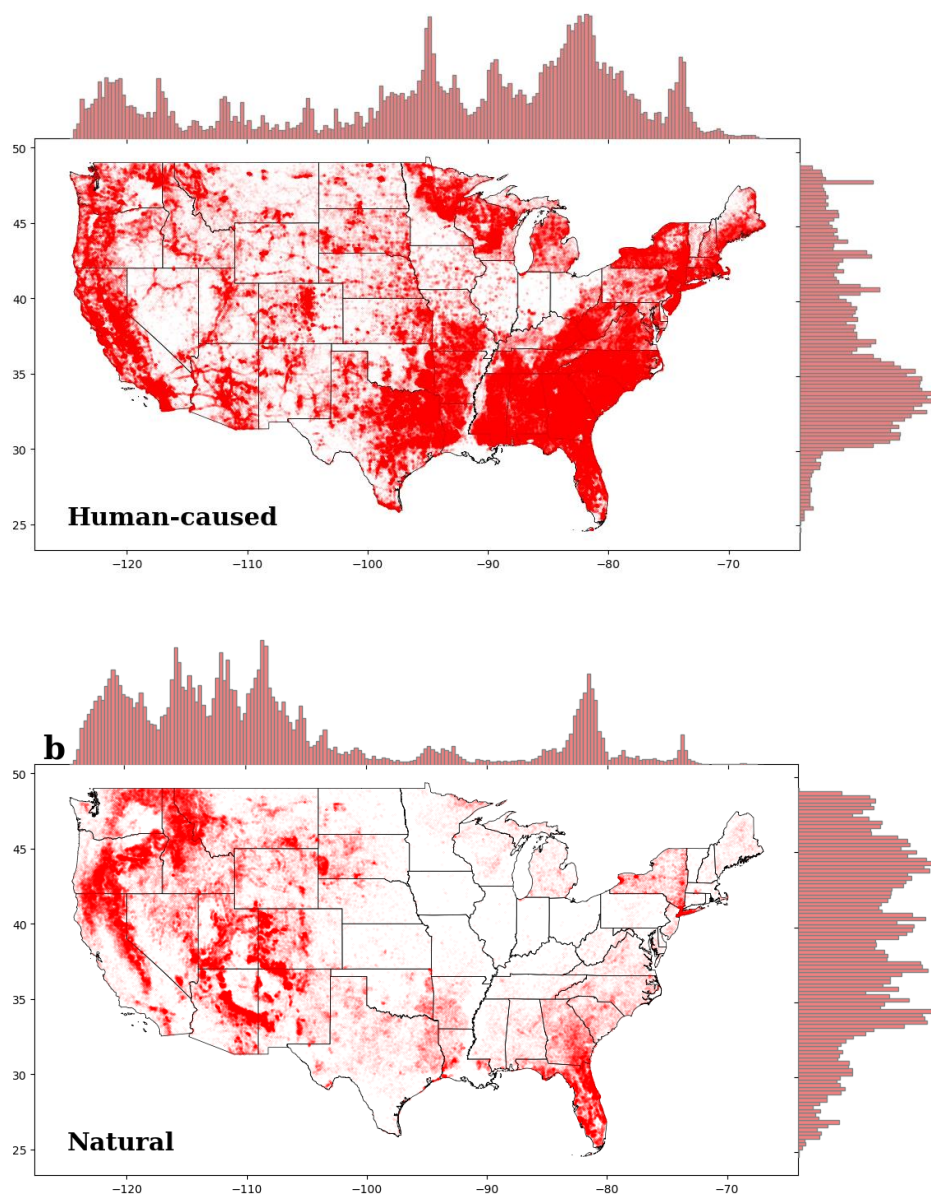

445

446 Figure 3. Trends in the annual number of natural and human-caused fires in the contiguous
447 United States from 1992-2020.

448

449

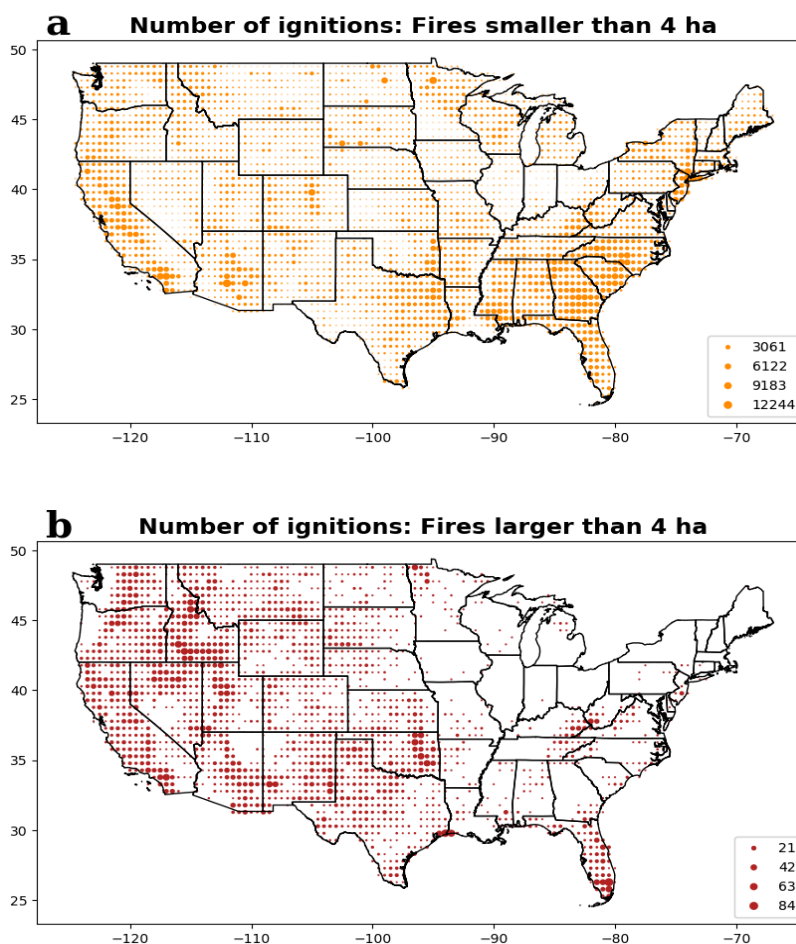

450 Figure 4. Spatial distribution of human-caused and natural fire ignitions in the contiguous
451 United States from 1992-2020. Bars on the x- and y-axes are histograms of the longitudinal
452 and latitudinal of ignitions, respectively.

453

454

455 We also visualized selected attributes associated with CONUS fires. Figure 5 shows the total
456 number of fires from 1992-2020 in 0.5-degree grids across CONUS. We differentiated small
457 fires (less than 4 ha) and large fires (greater than or equal to 4 ha). Eighty-nine percent of
458 fires were smaller than 4 ha. Fifty-nine percent of all fires were smaller than 0.4 ha, and 97%
459 were smaller than 40 ha, accounting for 0.08% and 2.28% of total burned area across
460 CONUS, respectively. The number of small fires (< 4 ha) in the eastern United States and
461 California was greater than that elsewhere in the western United States (Figure 5a). The
462 number of fires larger than 4 ha, however, was markedly greater in the western United
463 States, southern Great Plains, and Florida (Figure 5b).

464

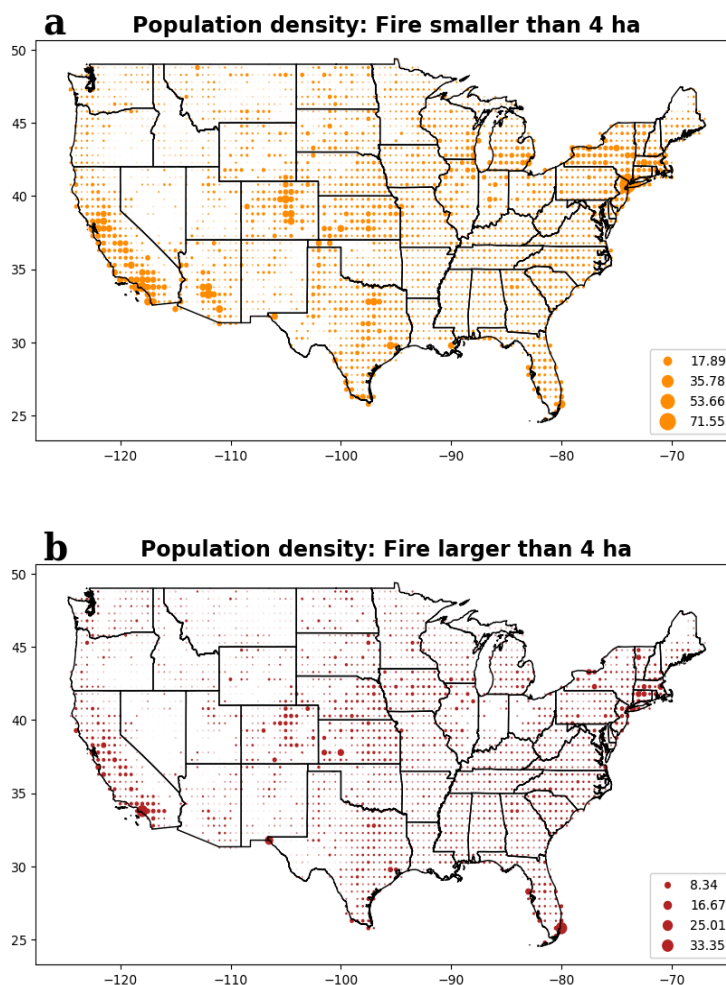

465 Figure 5. Number of fires (a) less than 4 ha (10 acres) and (b) greater than or equal to 4 ha
466 in 0.5-degree grid cells.

467

468 Small fires were associated with an average population density (2.35 people/ha; Figure
469 6a), an order of magnitude greater than that associated with large fires (0.24 people/ha;
470 Figure 6b). Fires in California, the Front Range of Colorado, and Florida were associated
471 with especially high population densities. In California, for example, small and large fires
472 were associated with population densities of 3.88 and 1.04 people/ha, respectively.
473 Furthermore, the population density associated with human-caused fires was more than
474 four times greater than that associated with natural fires (2.03 and 0.47 people/ha,
475 respectively).

476 Consistent with topography across CONUS, the average elevation of fires west of -102
477 degrees longitude was 2,146 m, compared to 1,194 m to the east. The average elevations
478 of the ignition points of natural fires were markedly higher (1,863 m) than those of
479 human-caused fires (571 m).

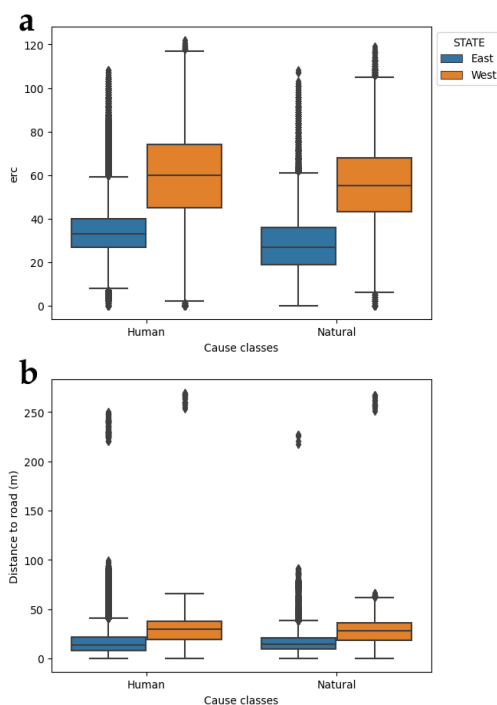

480

481 Figure 6. Average population density (people/ha) associated with fires that burned less
482 than 4 ha (a) and more than or equal to 4 ha (b) in each 0.5-degree grid cell.

483

484 Values of several attributes of fires varied along a longitudinal gradient across CONUS
485 (Figures 7-8). For example, ERC and minimum distance to the nearest road were markedly
486 greater in the western United States than in the eastern United States. Human-caused fires
487 were associated with greater ERC (60 in the western and 34 in the eastern United States)
488 than natural fires (56 in the western and 29 in the eastern United States). The minimum
489 distance to the nearest road was much lower in the eastern than western United States, which
490 is consistent with the East's higher road density and percentage of human-caused fires.
491 Minimum distance to road did not differ markedly between natural and human-caused fires
492 (Figure 7b), which likely reflects a reporting bias.

493

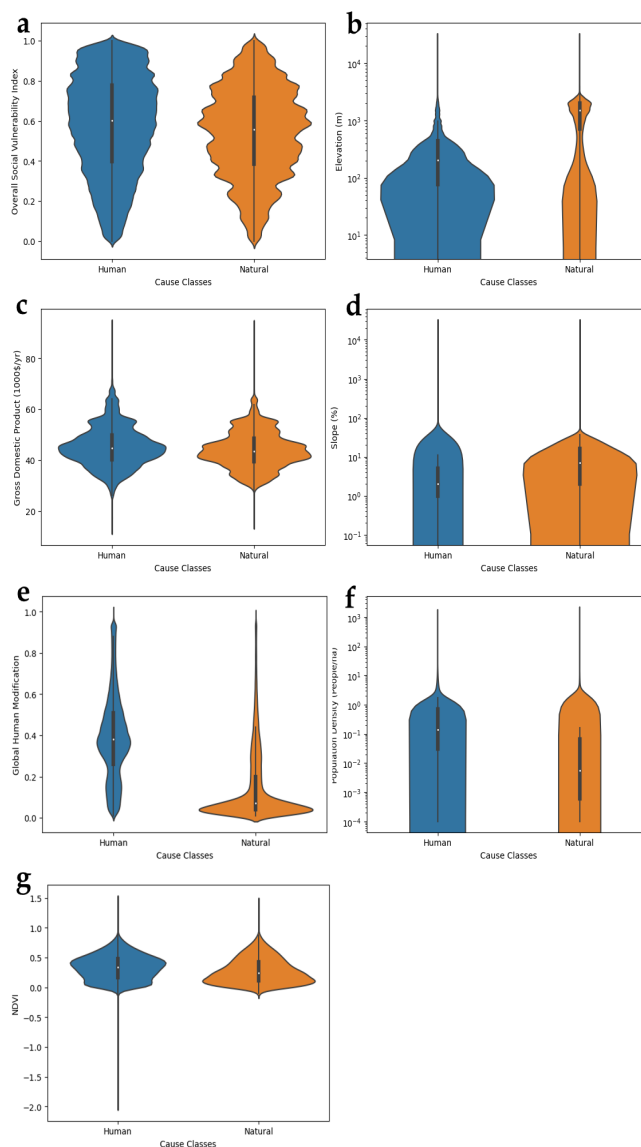

494 Figure 7. Boxplots of the Energy Release Component (ERC, fire danger index) (a) and
495 minimum distance to the nearest road (b) associated with human-caused and natural fires in
496 the eastern and western United States.

497

498 The elevation and slope associated with natural fires were higher than those of fires ignited
499 by human causes (Figures 8b,d). Natural fires also were associated with a lower population
500 density, normalized difference vegetation index, and global human modification index than

501 fires ignited by human causes (Figures 8e-f). Differences in the overall social vulnerability
502 and gross domestic product associated with the ignition locations of human-caused and
503 natural fires were less noticeable (Figures 8a,c), partly driven by the spatial resolution of the
504 source data (Table 1).

505

506 Figure 8. Distribution of overall social vulnerability index (a), elevation (b), gross domestic
507 product (c), slope (d), global human modification index (e), population density (f), and
508 normalized difference vegetation index (g; one day prior to ignition date) for fires ignited by
509 natural and human causes.

510

511 **4. Discussion**

512 Critical analysis of past fire occurrences and assessment of the success of prevention and
513 mitigation strategies are key for improving fire planning, response, adaptation, and
514 mitigation (Show and Kotok, 1923; Short, 2014). Improved understanding of the causes and
515 impacts of fires is needed to prioritize cost-effective mitigation and limit adverse fire impacts
516 (Barros et al., 2021; Houtman et al., 2013; Santos et al., 2023). Scientific advances in support
517 of fire management require comprehensive, easily accessible data that harmonize fire
518 occurrence data with potential covariates, causal factors, and associated impacts.
519 Importantly, by integrating variables that represent a range of biological, physical, and social
520 factors, the FPA FOD-Attributes dataset facilitates research that considers fire in the context
521 of social-ecological-technological systems (Iglesias et al., 2022; Shuman et al., 2022).

522 The FPA FOD-Attributes dataset includes 310 biological, physical, social, and administrative
523 attributes associated with more than 2.3 million fire records from 1992-2020 across the
524 United States. These attributes can be used for hypothesis testing and incorporation into
525 artificial intelligence and machine learning models that explain drivers of past fires or project
526 likelihoods or effects of future fires. The FPA FOD-Attributes dataset potentially could be
527 integrated with satellite detection of fire starts. Satellites have been increasingly used to
528 identify new fire starts, enabling rapid deployment of suppression resources (Weaver et al.,
529 2004; Chuvieco et al., 2020). Satellite detection could be compared with the FPA FOD-
530 Attributes dataset to identify ignitions with potential to become destructive, given the
531 surrounding conditions. This information could help prioritize the deployment of limited
532 suppression resources (Roberto Barbosa et al., 2010; Mazzeo et al., 2022). The FPA FOD-
533 Attributes dataset also could be used in collaborative planning of forest restoration or fuel
534 treatments. In cases where ideas about prioritization of resources and assets for fire
535 prevention efforts conflict (Butler et al., 2015), robust scientific data such as the FPA FOD-
536 Attribute dataset can help facilitate a consensus (Colavito, 2017).

537 A rigorous quality assurance and quality check process was applied to the original FPA FOD
538 dataset, but some uncertainties remain. For example, some smaller fires are overseen by local
539 jurisdictions that may not have reporting standards as strict as those of federal firefighting
540 agencies (Short, 2014). It is therefore possible that smaller fires may be underreported in the
541 FPA FOD. The quality assurance process checks for duplicate fire records, but it is possible
542 that some duplicates remain due to the potential for multiple responding agencies to record
543 different information on the same fire. There is also uncertainty associated with reported
544 ignition locations. As a prerequisite for inclusion in the FPA FOD, a fire record's geographic
545 location must be at least as precise as a Public Land Survey System section, which covers
546 one square mile. In addition, the locations of many smaller fires overseen by local
547 jurisdictions may reflect the reporting location rather than the ignition location. For a full
548 description of the fire selection process for the FPA FOD and potential uncertainty, see
549 (Short, 2014). The FPA FOD-Attributes dataset does not provide details about large fire

550 growth days that may have occurred days to weeks from the ignition date, and interested
551 readers are encouraged to pair this dataset with the “all-hazards dataset” of (St. Denis et al.,
552 2023) for studies that focus on fire growth rates and intense fire behavior. Furthermore, the
553 current version of FPA FOD-Attributes dataset does not directly support analysis of
554 secondary fire impacts such as wildfire emissions and smoke that impact downwind
555 communities (Fowler et al., 2019).

556 Human ignition processes and wildfire impacts are prime areas for extensive new research,
557 and the FPA FOD-Attributes dataset is an initial effort to facilitate such knowledge
558 development. The FPA FOD-Attributes dataset also merits refinements and additions that
559 would further enhance its utility. For example, some of the socioeconomic variables (GDP,
560 population) are based on coarse scale information gathered through international efforts, and
561 using finer scale data may enhance the accuracy of the fire attributes. Additional economic
562 data to include in future versions may cover personal income and the workforce, also
563 available at sub-state levels from the Department of Commerce. Refined and expanded data
564 could allow for more direct inferences that connect human-caused ignition processes to fire
565 activity (e.g., Prestemon and Butry, 2005; Aldersley et al., 2011; Abt et al., 2015).

566 Although the entire FPA FOD-Attributes dataset is available in CSV format, the file is large
567 (over 4 GB). Therefore, advanced computing resources are necessary to work with the data.
568 To obtain a data file that is a more manageable size, the dataset can be filtered by attributes,
569 time period, or locations from the web portal (<https://fpafod.boisestate.edu/>) prior to
570 downloading.

571

572 **Data availability**

573 The FPA FOD-Attributes dataset, for 1992-2020 and for individual years, is available
574 through <https://zenodo.org/record/8381129> (DOI: 10.5281/zenodo.8381129) (Pourmohamad
575 et al. 2023)

576 The FPA FOD-Attributes dataset can be visualized and downloaded through
577 <https://fpafod.boisestate.edu>

578 Source data used to develop FPA FOD-Attributes are listed in Table S1.

579

580 **Code availability**

581 All codes that compiled FPA FOD-Attributes were developed in python and are available
582 through the FPA FOD-Attributes Github repository:
583 <https://github.com/YavarPourmohamad/FPA-FOD.git>
