## Abstract:

Climate warming and anthropogenic disturbances result in permafrost degradation in cold regions, including in the Qilian Mountains. These changes lead to extensive hillslope thermokarst (HT) formation, such as retrogressive thaw slumps, active-layer detachment slides, and thermal erosion gullies. These in turn cause, e.g., degradation of local vegetation, economic losses, infrastructure damages, and threats to human safety. However, despite its importance, there is currently no thermokarst inventory for the Qilian Mountains. Through manual visual interpretation and field validation, we therefore produce the first quantification of HT features. We count a total of 1064 HT features, with 67% located in the upper reaches of the Heihe River Basin, which encompasses ~13% of the Qilian Mountains region. We further identified that 187 HT features (18%) existed before 2010, while the remaining 874 (82%) were initiated in the recent period. More specifically, 392 sites (37%) were initiated during 2010–2015, and 482 (45%) after 2015. Thermokarst terrain is observed primarily in areas with shallow active layer depths (average thickness: 2.98 m) on northern shaded slopes of 3–25°, with low solar radiation and moderate elevations ranging from 3200 to 4000 m. This first inventory of HT features is an important and missing piece in documenting changes on the Qinghai-Tibetan Plateau, and this new dataset also provides an important basis for further studies, such as automated extraction of HT features, susceptibility analysis of HT, and estimating losses caused by HT. The datasets are available from the National Tibetan Plateau/Third Pole Environment Data Center and can be downloaded from <https://doi.org/10.11888/Cryos.tpd.300805> (Peng and Yang, 2023).

## 43 **1 Introduction**

44 The Qilian Mountains are located in the northeastern part of the Qinghai-Tibetan  
45 Plateau, at the confluence of three major geographical regions that include the eastern  
46 monsoon zone, the northwestern arid zone, and the alpine zone of the Qinghai-Tibetan  
47 Plateau. The Qilian Mountains play an important role in maintaining the ecological  
48 balance of the Tibetan Plateau, stopping the southward progression of deserts, and  
49 maintaining the stability of the oases in the Hexi Corridor. Due to its unique  
50 geographical and environmental characteristics, permafrost is widespread and  
51 underlies about 50% of the area (Ran et al., 2021). Permafrost has an important role in  
52 storing frozen water, thereby contributing to water conservation (Wang et al., 2022).  
53 These roles can aid in inland river runoff recharge, which is crucial to regional  
54 ecology, production, and life. Due to climate warming and human activities,  
55 significant permafrost degradation results in the frequent occurrence of thermokarst,  
56 representing a serious threat to ecological security and adversely impacts the  
57 environment and human beings (Li et al., 2022a).

58 Despite the importance of thermokarst processes and their potential geohazards, the  
59 distribution of thermokarst landscapes is currently mostly undocumented. The  
60 available distribution of thermokarst in the Northern Hemisphere, including  
61 retrogressive thaw slumps (RTSs), thermokarst lakes, and other terrain features,  
62 represents mainly probabilistic estimates (Olefeldt et al., 2016; Yin et al., 2021;  
63 Huang et al., 2023; Yang et al., 2023). Muster et al. (2017) determined the distribution  
64 of circumpolar Arctic permafrost lakes and ponds from 2002–2013 at a resolution of 5  
65 m using optical remote sensing, satellite (Geo-Eye, QuickBird, WorldView-1 and -2,  
66 KOMPSAT-2), and radar imagery (TerraSAR-X), but temporal inconsistencies make  
67 comparisons in time and space difficult. At the regional scale, the techniques and  
68 spatial resolution of remote sensing imagery currently used at different study areas are  
69 inconsistent, e.g., estimating the distribution and development of RTSs on Banks  
70 Island, Canada, based on the interpretation of a Google Earth Engine Timelapse  
71 dataset (Lewkowicz and Way, 2019). Satellite imagery at 30-m resolution from  
72 Landsat has been used to analyze RTSs and thermokarst lakes in the region of Alaska  
73 within the circumpolar Arctic, eastern Canada, and Siberia (Nitze et al., 2018). Nicu et  
74 al. (2023) employed orthorectified imagery with a resolution of 5 meters to visually  
75 interpret and identify cryospheric hazards (such as thaw slumps and thermo-erosion  
76 gullies) in Nordenskiöld Land, covering an approximate area of 4000 square  
77 kilometers in the Svalbard Archipelago. The permafrost zone of the Qinghai-Tibetan  
78 Plateau (QTP) has been a site of thermokarst geomorphology research in recent years.  
79 For example, combining field surveys and SPOT-5 satellite data for August 2010, a  
80 total of 2,163 thermokarst lakes and ponds were recorded within 10 km on either side  
81 of the Chumar River to Fenghuo Mountain of the Qinghai-Tibet Railway, with a total  
82 surface area of  $1.09 \times 10^7 \text{ m}^2$  and ranging in size from  $100 \text{ m}^2$  to  $4.49 \times 10^5 \text{ m}^2$  (Luo  
83 et al., 2015; Niu et al., 2014). In the Beiluhe region of the central QTP, the number of  
84 RTSs increased from 124 to 438 between 2008 and 2017, with an approximate 9-fold  
85 increase in area (Huang et al., 2020; Luo et al., 2019). The latest results show that the  
86 number of RTSs on the QTP is 2669, but for the Qilian Mountains in the northeastern  
87 part of the region, only 6 (Luo et al., 2022) or as many as 15 are documented (Mu et  
88 al., 2020). A lack of a thermokarst inventory in this region is therefore evident,  
89 representing a crucial gap in the RTSs inventory on the QTP.

90 Frequent occurrence of hillslope thermokarst hazards due to permafrost degradation,

91 with significant ecological impacts on the Qilian Mountains. The ecological  
92 environment of the permafrost areas has a significant impact, and there is a direct  
93 correlation between human activities and major permafrost engineering problems,  
94 including uneven subsidence of infrastructure, slumps, and cracks. Meanwhile, there  
95 is little to no information regarding hillslope thermokarst (HT) features such as RTSs,  
96 active-layer detachment slides, and thermo-erosion gullies (Gooseff et al., 2009) in  
97 the Qilian Mountains. HT refers to a specific type of thermokarst formation that  
98 occurs in permafrost regions. While it is similar to regular thermokarst, what  
99 distinguishes hillslope thermokarst is its occurrence on sloped terrain or hillsides,  
100 where permafrost thaw leads to slope instability. This can result in various landforms  
101 like retrogressive thaw sumps, thermo-erosion gullies, or active layer detachments,  
102 affecting the stability and shape of hillslopes in permafrost regions. These features can  
103 significantly impact the landscape and have implications for infrastructure,  
104 ecosystems, and land use in areas affected by hillslope thermokarst processes (Kokelj  
105 and Jorgenson, 2013; Olefeldt et al., 2016; Gooseff et al., 2009). Thus, the urgent need  
106 to survey and quantify these undocumented HT features in the Qilian Mountains  
107 motivates and represents the goal of this study.

## 108 109 **2 Study Area**

110 The Qilian Mountains are located at the northern edge of the QTP, with an average  
111 elevation of 3855 m. The region is underlain by permafrost and seasonally frozen  
112 ground (36–40°N and 94–104°E, Figure 1a), with a permafrost area of 94,235 km<sup>2</sup>  
113 that accounts for 49% of the study domain. Characterized by both an alpine mountain  
114 climate and a temperate continental monsoon climate, the mean annual air  
115 temperature is 0.30°C (Jin et al., 2022) with high precipitation variability and higher  
116 amounts in the southeast during the thawing season of June to September (Chen et al.,  
117 2013; Li et al., 2022b). Due to human activities, climate change, and earthquakes,  
118 permafrost instability in Qilian Mountains has gradually increased, resulting in HT  
119 formation including RTSs, active-layer detachment slides, and thermal erosion gullies,  
120 which pose a direct threat to the local economy, ecology, and safety.

121

122 **Figure 1** The location of the study area and a) its HT distribution (Qilian Mountains  
 123 permafrost extent data is from Sheng et al., 2020), and b)–h) HT features obtained  
 124 from different watersheds during our field surveys with the exception of e) a Google  
 125 Earth image, as this site is too difficult to access, the positions corresponding to b)–h)  
 126 have been labeled in a).

127

### 128 3 Data Sources

129 We collected and collated validated satellite imagery available starting in 1999 for  
 130 temporal detection of the onset of the HT formation. These data include unmanned  
 131 aerial vehicle imagery (e.g., Figure 1b–h) and 30 m resolution digital elevation model  
 132 data from the Shuttle Radar Topography Mission (Farr et al., 2007). A combination of  
 133 Omap and Google Earth software was used to detect the location of HT occurrence,  
 134 and Wayback imagery provided by ESRI was used to access high-resolution (<1 m)  
 135 satellite imagery and Jilin-1 satellite imagery (0.75 m) provided free of charge by  
 136 China Commercial Satellite Corporation to aid in the identification (Table 1). In  
 137 addition, we used digital elevation model data to calculate variables such as slope and  
 138 topographic position index (TPI) of the HT. The TPI is calculated as follows (YU  
 139 Hong, 2001):

$$140 \quad TPI = \log_{10} \left( \frac{E}{Mean E} + 1 \right) \times \left( \frac{S}{Mean S} + 1 \right) \quad (1)$$

141 where  $E$  is the elevation (m),  $S$  is the slope ( $^{\circ}$ ), and  $Mean$  indicates that the mean  
 142 value for the entire Qilian Mountain region is used.

143 To further analyze the distribution of HT and the analogous environmental variables,  
 144 we obtain seismic data from the U.S. Geological Survey  
 145 (<https://earthquake.usgs.gov/earthquakes/search/>) describing earthquakes, including

146 their timing, epicenter location, and magnitude. To categorize vegetation types into  
 147 deciduous-coniferous forests (DCF), undergrowth (U), alpine scrub meadow (ASM),  
 148 alpine meadow (AM), alpine grassland (AG), alpine vegetation (AV), and  
 149 non-vegetated area (NA), based on data from the Resource and Environment Science  
 150 and Data Center (<https://www.resdc.cn/data.aspx?DATAID=122>). To assess the  
 151 relationship of air temperature and precipitation with HT, we download monthly mean  
 152 air temperature and precipitation at 2 m above ground level from the fifth generation  
 153 of the European Centre for Medium-Range Weather Forecasts (ECMWF) reanalysis  
 154 (ERA5;  
 155 <https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-land-monthly-means?tab=overview>).  
 156  
 157

158  
 159  
 160 **Figure 2** Frequency distribution of HT on the Qilian Mountains. The concentration of  
 161 HT features is shown per 100 km<sup>2</sup> grid cell.

162  
 163 **4 Methods**

164 *4.1 Manual Mapping*

165 We first quantified and mapped HT via remote sensing observations. Most  
 166 occurrences of HT in the permafrost region of the Qilian Mountains since 2000 were  
 167 compiled by visual interpretation in Google Earth Pro and Omap. They were also  
 168 aided by high resolution (<1 m) observations from Esri Wayback Imagery, which  
 169 archives all published versions of world imagery (Table 1). We used a fishnet with a  
 170 mesh size of 1×1 km to segment the latest satellite imagery for the entire Qilian  
 171 Mountains to quantify HT mesh by mesh. RTSs are often horseshoe shaped, tongue  
 172 shaped, elongated, branched, and circle chair-shaped (Lantuit and Pollard, 2008; Yin  
 173 et al., 2021), characterized by a steep backwall, low-angle bottom, and a tongue of  
 174 displaced saturated soil (Lantz and Kokelj, 2008; Nicu et al., 2021). These features are  
 175 tonally and morphologically different from their surroundings in color satellite images  
 176 during the thawing season. RTSs also produce folded textures due to soil

177 accumulation, which appear as laterally folded stripes on imagery. Active-layer  
 178 detachment slides are a common shallow landslide in permafrost areas. Their  
 179 morphological characteristics vary based on vegetation cover, slope, and permafrost  
 180 conditions, but common features include highly disturbed slopes, lateral shear zones,  
 181 and fracture zones formed after the sliding of the active layer (Lewkowicz, 2007). We  
 182 detected and sketched these features based on morphological, tonal, textural, shading,  
 183 and other characteristics on remote sensing images, and then digitized their  
 184 morphological features into polygonal data. Although the accuracy of this type of  
 185 visual interpretation is relatively high, some HT features can be missed via this  
 186 manual interpretation. To reduce such errors, satellite images of the similar period  
 187 from different sources were evaluated four times using the same methods to ensure  
 188 accurate results. The date of the satellite image when perturbations caused by HT can  
 189 be first observed was defined as the initiation year of a particular HT feature.  
 190 Depending on the initiation year, HT is categorized as occurring before 2010,  
 191 2010–2015, or after 2015. To observe the temporal evolution of HT features, we used  
 192 the initiation year and retraced historical images covering the Qilian Mountains, a  
 193 process that also helped us distinguish between HT features and one-time transient  
 194 landslides.

195

#### 196 *4.2 Field Verification*

197 Similar HT can have different morphological characteristics due to different triggers.  
 198 It is thus difficult to identify the type of HT simply through imagery. In addition, after  
 199 an initial trigger and HT formation, thermokarst can evolve into different types. For  
 200 example, active layer detachment slides may transition into RTS due to the exposure  
 201 of subsurface ice at the trailing edge and water erosion due to thawing, which can  
 202 cause the RTS to further progress into mudflows. Therefore, with visual interpretation  
 203 based on imagery only providing individual snapshots, it is essential to also conduct  
 204 field surveys as a validation exercise. We conducted a total of three field surveys in  
 205 winter 2022, and spring and summer of 2023. Field work covered the Shiyanghe basin,  
 206 Heihe basin, Datonghe basin, Qinghai Lake basin, and Shulehe basin. Due to the  
 207 harsh climatic conditions and accessibility issues in the Qilian Mountains, unmanned  
 208 aerial vehicles were used to survey and verify hard-to-reach areas.

209

210 **Table 1** List of the data used for manual interpretation and mapping of HT features.

Software Platform	Time Span	Resolution	Data Sources
Google Earth pro	1999–2022	0.6–15 m	Quickbird, IKONOS, etc.

UAV images	Feb., Apr., May 2023	~15 cm	Field Surveys

211

#### 212 *4.3 Morphological and Spatial Statistical Analysis*

213 A landscape shape index (LSI) can be quantified to characterize shape complexity by  
 214 calculating the degree of deviation of a given patch from a circle or square of the

215 same area. To quantify the shape characteristics of HT features, two LSIs are  
216 calculated as follows:

$$217 \quad LSI_{square} = \frac{0.25P}{\sqrt{A}} \quad (2)$$

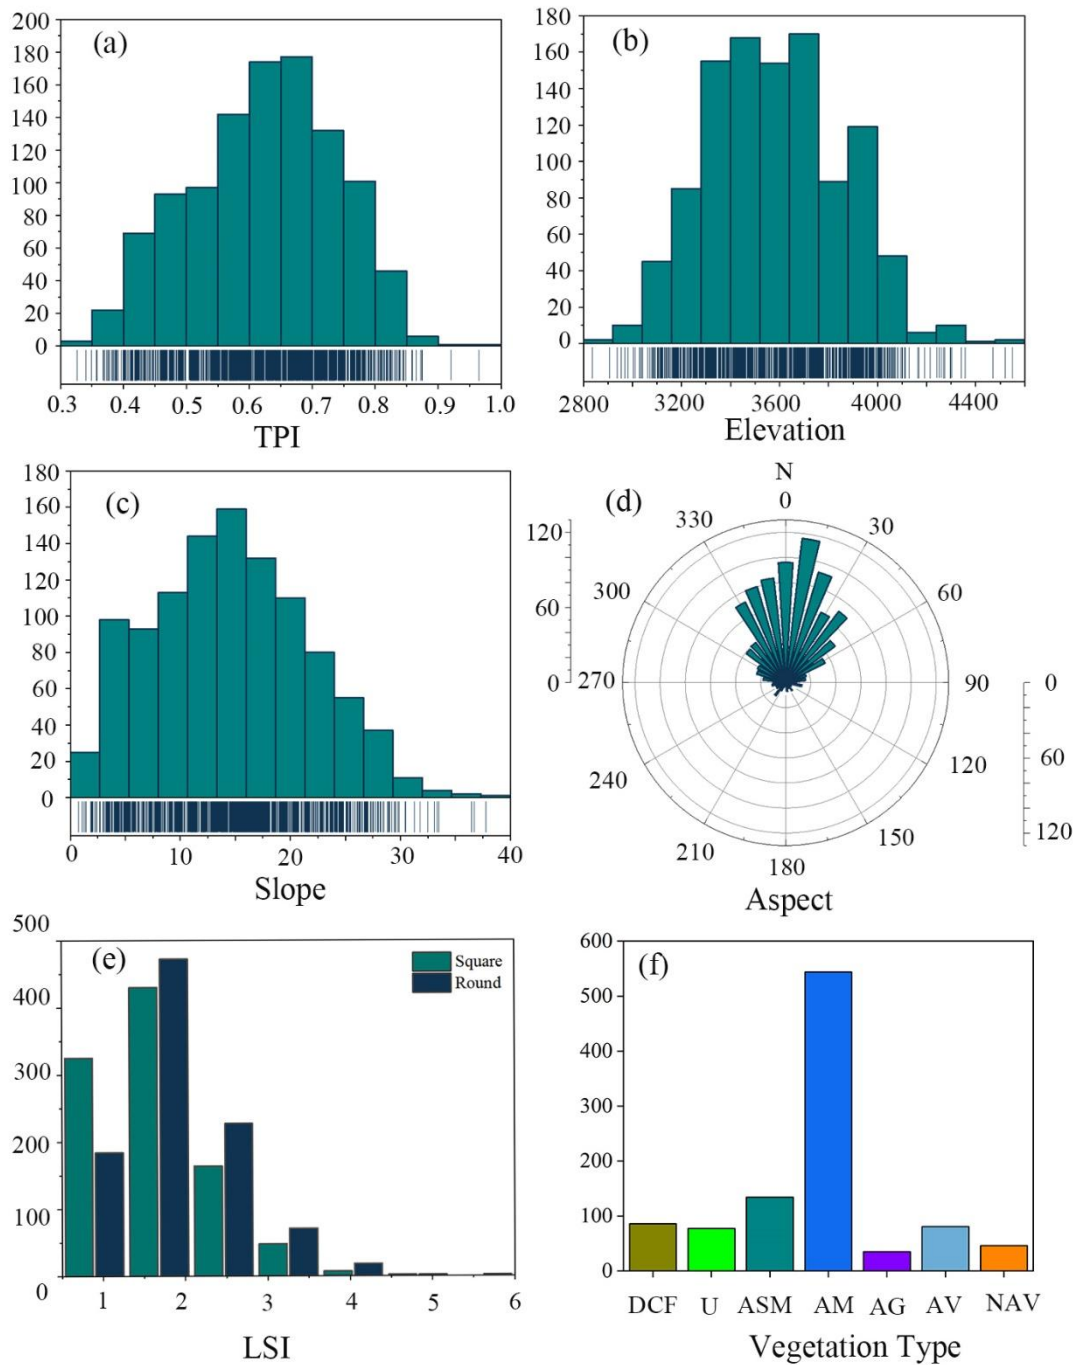

$$218 \quad LSI_{round} = \frac{P}{2\sqrt{\pi A}} \quad (3)$$

219 where  $P$  is the perimeter (m) and  $A$  is the area (m<sup>2</sup>). The closer the values of  $LSI_{square}$   
220 or  $LSI_{round}$  are to 1, the more square or round the shape of the HT feature is,  
221 respectively.

222 To further investigate the spatial distribution of HT, we computed a global Moran's  
223 index, z-score, and p-value to determine whether there is autocorrelation in the spatial  
224 distribution of HT, where p-values of z-scores are used to measure statistical  
225 significance. When p-value < 0.01 and z-score > 2.58, there is a 99% probability that  
226 HTs are clustered within the study area. The smaller the p-value and the larger the  
227 z-score, the greater the probability that such spatial patterns are clustered. Moran's  
228 index ranges from -1 to 1, with negative values corresponding to negative  
229 correlations, positive values to positive correlations, and 0 denotes that the spatial  
230 objects in the study area are independent of each other. Additionally, the closer the  
231 index is to 1, the more clustered the HT features are, and the closer of the index is to  
232 -1, the more dispersed the HT features are. To delineate the regions that may have  
233 spatial autocorrelation (Bivand and Wong, 2018), we further process local  
234 autocorrelation on this basis. The local autocorrelation regions are divided into four  
235 types based on the local Moran's index: High-High (HH) clustering, High-Low (HL)  
236 clustering, Low-High (LH) clustering, and Low-Low (LL) clustering. HH signifies a  
237 region with both a higher amount of HT and neighboring regions also having a higher  
238 amount of HT; HL indicates a region with a higher amount of HT surrounded by  
239 neighboring regions with a lower amount of HT; LH indicates a region with a lower  
240 amount of HT neighboring areas with a higher amount of HT; and LL represents a  
241 region with both a lower amount of HT and neighboring regions with a lower amount  
242 of HT. Although the methods described above can identify global and local spatial  
243 autocorrelation, respectively, they are unable to identify clusters of concentrated HT  
244 features. We therefore also apply hot spot analysis, which is another effective way of  
245 exploring the characteristics of local spatial distributions. All the above techniques are  
246 based on spatial statistical analysis functions in ArcGIS.

247 To explore the effects of climate on HT, we obtained the monthly mean air  
248 temperature and precipitation at 2 meters above ground level from ERA5 over the  
249 period 2000–2020 and calculate their annual spatial means and standard deviations  
250 (Figure 6).

251  
 252 **Figure 3** The number of HT terrain features (y-axes) of HT as categorized by (a)  
 253 topographic position index (TPI), (b) elevation, (c) slope, (d) aspect, (e) landscape  
 254 shape index (LSI), and (f) vegetation type including deciduous coniferous forests  
 255 (DCF), undergrowth (U), alpine scrub meadow (ASM), alpine meadow (AM), alpine  
 256 grassland (AG), alpine vegetation (AV), and non-vegetated area (NA); the blue  
 257 vertical lines at the bottom of panels a–c represent the number of HT features in each  
 258 x-axis bin.

259

260 **5 Results**

261 Our inventory of HT includes the Heihe Basin, Shulehe Basin, Datonghe Basin,  
262 Shiyanghe Basin, Qinghai Lake Basin, and Tsaidam Basin within the Qilian  
263 Mountains, with a total of 1064 HT features. In any 100 km<sup>2</sup> grid cell, the maximum  
264 density of HT is 63 (Figure 2). This density is lower than the 68 per 25 km<sup>2</sup> in the  
265 central Tibetan Plateau reported by (Luo et al., 2022) and 88 per 25 square km<sup>2</sup> on  
266 Banks Island, Canada from (Lewkowicz and Way, 2019). 67% of these HT features  
267 were identified in the Heihe River basin, followed by the Datonghe River Basin,  
268 accounting for 19%. The HT distribution in these river basins is irregular,  
269 corroborated by a positive statistically significant Moran's index value of 0.3, p-value  
270 of 0.00001, and z-score of 32.5. Of all the HT features, the largest is 58 ha, the  
271 smallest area is 0.01 ha, with most being smaller than 10 ha. The average area is 1.75  
272 ha, with a total area of 1708 ha.

273 The spatial distribution of RTS on the QTP is strongly controlled by terrain factors  
274 such as the elevation, slope, TPI, and aspect (Luo et al., 2022). The statistical results  
275 indicate that HT is observed at elevations ranging from 2,835 to 4,550 m. However,  
276 90% of HTs are more likely to occur at elevations ranging from 3,200 to 4,000 m in  
277 the middle/high elevation area of the Qilian Mountains. HT tends to occur on  
278 north-facing slopes (Figure 3b and 3d), with slopes ranging from 3° to 25° (Figure 3c).  
279 In addition, the TPI shows that ~85% of the HTs occur mainly between 0.5 and 0.8  
280 (Figure 3a), suggesting that they commonly occur in locations that are lower than  
281 their surroundings. Both LSI indices suggest that 75% of HT has values close to 1.0  
282 (Figure 3e), indicating that most HT is simple in shape and compact in morphology  
283 (Niu et al., 2016). Alpine meadow areas contain ~53% of HT, followed by alpine  
284 scrub meadows, which contain 13% (Figure 3f).

285 The initiation years of HT features are variable across the study area. 187 HT features  
286 (18%) were identified before 2010, and the remaining 82% in the last 10 years. 392  
287 sites (37%) were initiated in 2010–2015 and 482 (45%) after 2015. Much of the newly  
288 initiated HT occurred in the Heihe basin and the middle and upper reaches of the  
289 Datonghe basin (Figure 4), which is also a HT hotspot region. The recent increase in  
290 HT can be attributed to the anomalous weather conditions in the corresponding years.  
291 The association between newly observed HT and meteorological data indicates a  
292 sudden HT increase in years with unusually high temperatures during the thawing  
293 season (Figure 6).

294  
295 **Figure 4** The timing of HT initiation within 100 km<sup>2</sup> grid cells.

296  
 297 **Figure 5** (a) Spatial autocorrelation indicating high-high (HH), high-low (HL), and  
 298 low-high (LH) clustering, and (b) hotspot analysis where the different colors represent  
 299 the confidence levels.

300

## 301 **6 Discussion**

### 302 6.1 Drivers of HT in the Qilian Mountainous

#### 303 6.1.1 Permafrost Conditions

304 Formation of HT is facilitated by thick subsurface ice and various internal and  
 305 external environmental conditions (Stephani et al., 2023). Permafrost stability in  
 306 ~80% of the permafrost area of the Qilian Mountains is predominantly transitional,  
 307 and higher permafrost temperatures (Ran et al., 2021) will exacerbate the climate  
 308 sensitivity of this area (Lewkowicz and Way, 2019; Patton et al., 2021) leading to  
 309 melting of the subsurface ice and an increase in active layer thickness, thus decreasing  
 310 the stability of the slope (Behnia and Blais-Stevens, 2018). This is also supported by  
 311 our finding that ~90% of HT occurs in the transition zone between permafrost and

312 seasonally frozen soil where mean annual ground temperature is greater than  $-1^{\circ}\text{C}$ .

313

### 314 *6.1.2 Environmental Factors*

315 Topographic conditions facilitate the formation of subsurface ice and the continuous  
316 development of HT. At elevations below 5100 m on the QTP, aspect dominates the  
317 distribution of permafrost. More permafrost underlies regions of shaded, north-facing  
318 slopes than sunny south-facing slopes (Ran et al., 2021). Indeed, we find that ~95% of  
319 Qilian Mountain HT is found on north-facing slopes where it also enhances vegetation  
320 growth and soil moisture storage (Jin et al., 2009). Lower solar radiation, higher  
321 permafrost ice content, and shallow active layer thickness (Lacelle et al., 2015; Ward  
322 Jones et al., 2019) also enables HT formation (Luo et al., 2022; Niu et al., 2016; Xia  
323 et al., 2022). We find more than half of the HT occurs in alpine meadows, which  
324 require more water content than alpine steppes (Yin et al., 2017) and consequently  
325 also results in more ground ice development under this vegetation type. We  
326 determined that ~90% of HT in the Qilian Mountains occurs on  $3^{\circ}$  to  $25^{\circ}$  slopes. Low  
327 and gentle slopes are favorable for groundwater pooling (Luo et al., 2022), whereas  
328 slopes greater than  $16^{\circ}$  are relatively steep and therefore not conducive to  
329 groundwater enrichment for ice formation, but such slopes also provide dynamic  
330 conditions for active layer detachments and collapsing ground (Wang, 1990). We also  
331 observe more HT initiation at locations that are lower compared to their surroundings,  
332 as such depressions favor the accumulation of snow and rainwater (Stieglitz et al.,  
333 2003) and prevent heat loss from the soil. This encourages melting of subsurface ice  
334 (Zhang, 2005) at the base of the active layer and, after an unstable layer is formed  
335 between the permafrost and the active layer, the overlying soil can slide along the  
336 slope (Patton et al., 2021).

337 The Qilian Mountains were and are still formed by the ongoing collision of the Indian  
338 Ocean Plate and the Eurasian Plate, resulting in the Qilian Mountains-Hexi Corridor  
339 active fault system (Xiong et al., 2017) that has seen nearly 400 earthquakes of  
340 magnitude 2 or greater over the past two decades. In particular, the high seismic  
341 activity of the Heihe, Shiyanghe, and Datonghe Basins (Figure 7a) represents a  
342 potential threat to the safety and integrity of current and future infrastructure in the  
343 region. During our field investigations we found a nearly 3 km long and 2 m deep  
344 slope fracture caused by a 6.9-magnitude earthquake in 2022, resulting in a massive  
345 exposure of subsurface ice and the collapse of the Lanzhou-Xinjiang High Speed Rail  
346 Tunnel (Figure 7b and c). The occurrence of an earthquake can result in an  
347 instantaneous increase in pore water pressure and sliding forces that reduce slope  
348 stability and potentially leads to a massive exposure of subsurface ice (Niu et al., 2016;  
349 Xia et al., 2022), sediment liquefaction (Dadfar et al., 2017), and permafrost warming  
350 due to the seismic vibrations. These vibrations lead to cracking and deformation of the  
351 ice layers within the permafrost, releasing moisture and heat, consequently resulting  
352 in a temperature rise of the permafrost. Additionally, earthquakes can induce the flow  
353 of pore water within the permafrost, further influencing its temperature (Che et al.,  
354 2014), creating the ideal setting for active-layer detachment slides. The clustering of  
355 earthquake activity in the lower left corner of Figure 7a is not associated with HT  
356 features, because there is no permafrost in this region.

357

### 358 *6.1.3 Climate Factors*

359 Extreme summer temperatures and precipitation have been identified as triggers for  
360 the initiation of RTSs in many Arctic permafrost zones (Balsler et al., 2014; Kokelj et

361 al., 2015; Lewkowicz and Way, 2019; Segal et al., 2016). Given our finding that 82%  
362 of HT was initiated in approximately the last decade (Figure 4), mostly during  
363 2010-2015 and after 2015, we used ERA5 to determine the temperature and  
364 precipitation characteristics for the Qilian Mountains over the last 20 years (Li et al.,  
365 2022b) (Figure 6, the square symbols). The mean thawing season air temperatures in  
366 2010 and 2016 were higher than in other years (Figure 6a, red square symbols). A  
367 warming thaw season could lead to thaw consolidation at the base of the active layer  
368 or to higher porewater pressure in the transient thaw layer, reducing the effective  
369 shear strength, and causing slope failure (Lewkowicz and Way, 2019). The anomalous  
370 air temperatures during the thawing season could accelerate permafrost thaw and  
371 expose ice-rich permafrost, thus leading to new HT (Figure 6a, dark brown and dark  
372 red bars, respectively). Rainfall infiltration may transfer heat to the top layer of  
373 permafrost and induce melting of ground ice in ice-rich transient layers, which would  
374 increase the porewater pressure at the active layer-permafrost interface and thereby  
375 trigger formation of HT (Luo et al., 2022). However, precipitation variability during  
376 the thawing season does not match HT formation (Figure 6b). Despite high  
377 precipitation in both 2007 and 2018 (Figure 6b, blue squares), no initiation of HT was  
378 found to subsequently coincide with these peaks (blue squares), and precipitation also  
379 does not explain the significant initiation of HTs between 2010-2015, nor after 2015  
380 (Figure 6b, yellow and red bars, respectively). The same conclusion also applies to the  
381 other three sub-regions—Hoh Xil Mountain, Maqu county, and Honglianghe—and it  
382 could be speculated that the nature of the soils on the QTP may instead play a role  
383 (Luo et al., 2022).  
384

385  
 386 **Figure 6** The relationship between HT numbers (variable-width bars, the darker  
 387 colors represent years with extreme weather events) and (a) temperature and (b)  
 388 precipitation in the thawing season from 2000 to 2020 (square symbols, the red  
 389 squares and the blue squares represent the extreme weather events). The solid  
 390 horizontal line represents the mean air temperature and precipitation, respectively, and  
 391 the dashed lines represent  $\pm 1$  standard deviation.

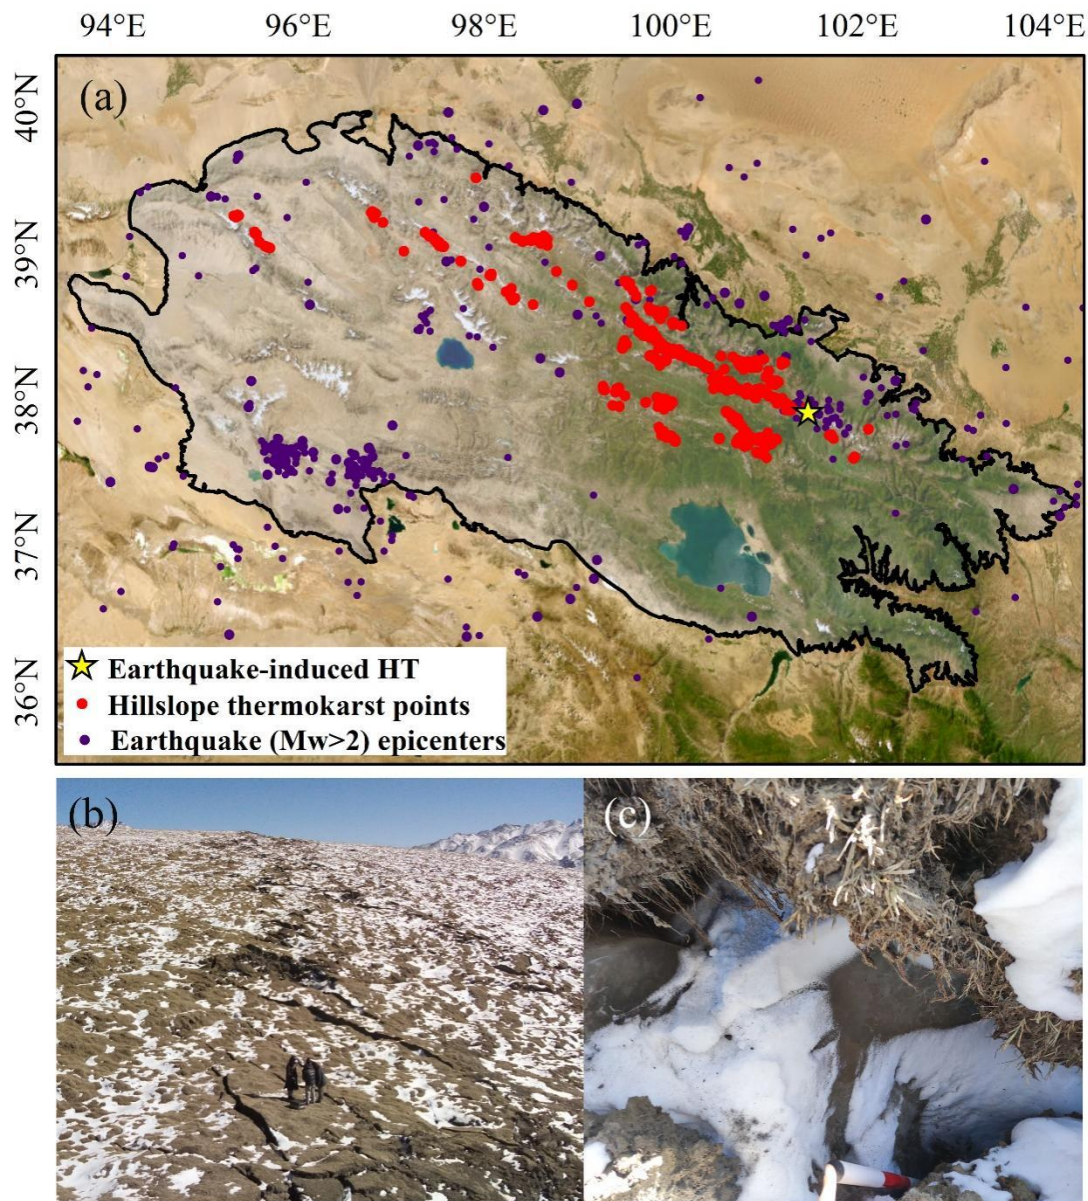

392

#### 393 6.1.4 Human Activities

394 Extensive and increasing human activities have been shown to significantly accelerate  
 395 permafrost degradation (Cheng & Jin, 2013; IPCC, 2019). The total population of the  
 396 Qilian Mountains is about 60,000, there are approximately 1,000 metal, energy, and  
 397 other types of mineral deposits (National Mineral Properties Database 2021 Edition,

398 <http://data.ngac.org.cn/mineralresource/index.html>), and there are ~8,000 km of  
399 railroads and highways. The core of this human activity is concentrated on the eastern  
400 side of the Qilian Mountains, which generally coincides with the spatial distribution  
401 of the HT hotspots we documented. This qualitatively suggests a role of human  
402 activities on HT from, e.g., engineering disturbances, vegetation degradation due to  
403 overgrazing, etc. (Sharkhuu et al., 2007). Establishing the impact of human activities  
404 on HT quantitatively is still a difficult challenge, but our identification of the location  
405 and timing of HT formation is a first, important step for further future studies,  
406 especially on the socioeconomic development in the region.  
407

408 **Figure 7** Qilian Mountains showing (a) the location of HT locations and earthquakes  
409 with magnitude >2 in the last 20 years, (b) slope fractures caused by earthquakes, and  
410 (c) exposed subsurface ice.  
411

412

## 413 **7 Data Availability**

414 DEM data can be accessed through NASA

415 (<https://www.earthdata.nasa.gov/sensors/srtm>). Landsat5-8 data are available from  
416 USGS (<https://www.usgs.gov/>) and Sentinel-2 from ESA (<https://www.esa.int/>), and  
417 can be downloaded through Google Earth Engine. Esri World Imagery can be  
418 accessed through Esri Wayback Imagery at: <https://livingatlas.arcgis.com/wayback>.  
419 Some GF-2 imagery is also available online through Omap software  
420 (<https://www.ovital.com/283-2/>), and high-resolution 3D satellite imagery of the  
421 Qilian Mountain region can be viewed in Google Earth software. High-resolution  
422 satellite images captured by the Jilin-1 satellite in China can be viewed by accessing  
423 <https://www.jl1mall.com/rskit/>. The HT inventory for the Qilian Mountains can be  
424 freely downloaded from the National Tibetan Plateau/Third Pole Environment Data  
425 Center (<https://doi.org/10.11888/Cryos.tpdc.300805>, Peng and Yang, 2023).

426

## 427 **8 Conclusion**

428 This study used visual interpretation and field investigations with repeated  
429 verification to investigate HT in the permafrost zone of the Qilian Mountains. We  
430 successfully produced the first HT inventory for this area, identifying a total of 1064  
431 HT features. The area of these features ranged from 0.01 to 58 ha, with an average of  
432 1.75 ha. Thermokarst is primarily concentrated at the junction between the upstream  
433 portion of the Heihe River Basin and the mid and upstream portion of the Datonghe  
434 Basin. Within a 10×10 km area, thermokarst has a maximum density of 63 features,  
435 affecting an area of ~20 km<sup>2</sup>. HT in the Qilian Mountains is more likely to occur on  
436 north-facing shaded slopes, at elevations between 3200–4000 m, slopes of 3–25°,  
437 0.5<TPI<0.8, and in alpine meadow vegetation. Based on long-term satellite imagery,  
438 874 new HT features were initiated after 2010, accounting for 82% of all HT features.  
439 Of these, 392 and 482 were initiated during the periods of 2010–2015 and after 2015,  
440 respectively. Recent higher air temperatures during the thawing season are likely  
441 important reasons for the intensification of HT formation in the Qilian Mountains,  
442 while precipitation does not seem to play a role. This first HT inventory for the Qilian  
443 Mountains will be fundamental for quantitative assessments that explore the exact  
444 causes and underlying thermokarst processes, providing observational data support for  
445 automated extraction of HT features, and ultimately enhance the identification and  
446 prediction of regions prone to thermokarst processes in the future. Furthermore, it will  
447 facilitate the evaluation of local risk levels, potential economic losses, population  
448 casualties, and other impacts, thereby furnishing governmental decision-makers and  
449 relevant stakeholders with essential reference materials for mitigating potential risks.

450

451 **Author contributions.** XP and GY designed the research and obtained funding. GY  
452 analyzed the data and prepared the data files. GY, WT, XL and XP conducted the field  
453 work. GY, XP, OWF, JL, CM, FN wrote the paper with input from the coauthors and  
454 coordinated the analysis and contributions from all coauthors. XP and GY contributed  
455 to the work equally and should be regarded as co-first authors.

456
