8

9 **Abstract:** Forest fires, while destructive and dangerous, are important to the functioning and renewal of ecosystems.  
10 Over the past two decades, large-scale, severe forest fires have become more frequent globally, and the risk is expected  
11 to increase as fire weather and drought conditions intensify. To improve quantification of the intensity and extent of  
12 forest fire damage, we have developed a 30-meter resolution Global Forest Burn Severity (GFBS) dataset of the degree  
13 of biomass consumed by fires from 2003 to 2016. To develop this dataset, we used the Global Fire Atlas product to  
14 determine when and where forest fires occurred during that period and then we overlaid the available Landsat surface  
15 reflectance products to obtain pre-fire and post-fire normalized burn ratios (NBRs) for each burned pixel, designating  
16 the difference between them as dNBR and the relative difference as RdNBR. We compared the GFBS dataset against  
17 the Canada Landsat Burned Severity (CanLaBS) product, showing better agreement than the existing MODIS-based  
18 global burn severity dataset (MOSEV) in representing the distribution of forest burn severity over Canada. Using the  
19 in situ burn severity category data available for the 2013 wildfires in southeastern Australia, we demonstrated that  
20 GFBS could provide burn severity estimation with clearer differentiation between the high-severity and moderate/low  
21 severity classes, while such differentiation among the in situ burn severity classes are not captured in the MOSEV  
22 product. Using the CONUS-wide Composite Burn Index (CBI) as a ground truth, we showed that dNBR from GFBS  
23 was more strongly correlated with CBI ( $r = 0.63$ ) than dNBR from MOSEV ( $r = 0.28$ ). RdNBR from GFBS also  
24 exhibited better agreement with CBI ( $r = 0.56$ ) than RdNBR from MOSEV ( $r = 0.20$ ). On a global scale, while the  
25 dNBR and RdNBR spatial patterns extracted by GFBS are similar to those of MOSEV, MOSEV tends to provide  
26 higher burn severity levels than GFBS. We attribute this difference to variations in reflectance values and the different  
27 spatial resolutions of the two satellites.

28

## 29 1. Introduction

30 In recent years, many regions around the world have experienced an increase in the frequency, intensity, and extent  
31 of wildfires (Doerr and Santín, 2016; Shukla et al., 2019; Dupuy et al., 2020). Wildfires are now among the most

32 popular research topics as a result of this rising global concern, which is further heightened by changes expected in  
33 fire regimes as a consequence of changes in climate and land use (Moreira et al., 2020). While most wildfires occur  
34 in grasslands and savannas (Scholes and Archer, 1997; Abreu et al., 2017), forest fires are more dangerous and  
35 destructive and perhaps of greater interest because of their importance to the functioning and renewal of ecosystems  
36 (Flannigan et al., 2000; Nasi et al., 2002; Flannigan et al., 2006). Changes brought by the warming climate, which has  
37 dried fuels and lengthened fire seasons across the globe (Jolly et al., 2015), are also particularly significant to forested  
38 ecosystems with abundant fuels (Kasischke and Turetsky, 2006; Aragão et al., 2018).

39 With the rapid development of remote sensing techniques, more frequent observations from satellites  
40 facilitate the monitoring of global fire activities. The valuable information they provide at fine spatial and temporal  
41 resolutions can be used to study the number and size distributions of individual fires (Archibald and Roy, 2009;  
42 Hantson et al., 2015; Oom et al., 2016), fire shapes (Nogueira et al., 2016; Laurent et al., 2018), and locations of  
43 ignition points (Benali et al., 2016; Fusco et al., 2016). Among the most widely accepted techniques are those based  
44 on the Moderate Resolution Imaging Spectrometer (MODIS) (Chuvieco et al., 2016), which retrieves information on  
45 the entire Earth in 36 spectral bands every one to two days. The MODIS-derived burn area (BA) products are essential  
46 for ascertaining the patterns of fire occurrence, extent, propagation (Rodrigues and Febrer, 2018), and frequency  
47 (Andela et al., 2019). Based on these products, an essential indicator called “burn severity” has been derived for  
48 determining the degree of biomass consumption and the overall impact of fire on ecosystems (Keeley, 2009).

49 Traditionally, burn severity could be quantified from satellite sensors through spectrum information. The  
50 changes caused by fire to near-infrared (NIR) and shortwave infrared (SWIR) reflectance are highly sensitive to,  
51 respectively, canopy density and moisture content (Chuvieco, 2010). Several burn severity datasets have been  
52 generated and released based on this method. Regionally, the Monitoring Trends in Burn Severity (MTBS) dataset,  
53 which includes burn severity assessments for the contiguous United States (CONUS) and provides information on fire  
54 perimeters and severity classes, uses satellite data—specifically, Landsat imagery (Eidenshink et al., 2007). Similarly,  
55 the Canadian Landsat Burn Severity (CanLaBS) product uses Landsat imagery to assess, and map burn severity at a  
56 national scale (Guindon et al., 2021). Globally, MODIS burn SEverity (MOSEV) has provided monthly burn severity  
57 data with global coverage at 500m spatial resolution, based on MODIS Terra and Aqua satellites (Alonso-González  
58 and Fernández-García, 2021). However, a dataset for assessing and mapping global forest burn severity based on  
59 Landsat at high spatial resolution (30m resolution) is not yet available. Such a product would support advances in fire  
60 management strategies and ecosystem conservation efforts, leading to more resilient and sustainable landscapes.

61 In this paper we describe a new global dataset comprising information on burn severity derived at high spatial  
62 resolution (30 meter) from Landsat imagery from the period 2003–2016. This dataset represents a step forward in  
63 quantifying and analyzing wildfire impact on forest ecosystems worldwide. We begin with a section detailing the  
64 input data and the algorithm used to process the dataset, as well as the analytical techniques employed. Section 3  
65 presents the characteristics of the dataset and its performance in representing the distribution of forest fires. In the  
66 results section, we analyze the advantages and disadvantages of the dataset and set forth its main contributions to

67 forest fire management strategies worldwide. The last section summarizes the primary findings and suggests possible  
68 implications of the dataset.

## 69 **2. Data and Method**

70 Below we delineate the specifics of data input and pre-processing and the analytical techniques we employed to create  
71 the dataset. The Global Fire Atlas was the main source of global fire records, which was overlaid with annual land  
72 cover types from MCD12Q1 to determine when and where forest fires occurred. We then utilized the reflectance  
73 information from Landsat's satellite archives to calculate burn severity indices for the burned forest areas. Finally, we  
74 compared GFBS with the CanLaBS dataset available over Canada, and used the field assessed burn severity category  
75 data in southeastern Australia and the CONUS-wide Composite Burn Index (CBI) as the ground truth to evaluate the  
76 performances of GFBS relative to that of the existing MODIS-based global burn severity dataset (MOSEV).

### 77 **2.1. Input data**

78 The input data we used to build the GFBS dataset comprised the fire records available in the Global Fire Atlas for the  
79 years 2003–2016 and all Landsat images for the same period.

80 The Global Fire Atlas tracks the daily dynamics of individual fires globally to determine the time and location  
81 of ignition, area burned, and duration, as well as daily expansion, fireline length, velocity, and direction of spread. A  
82 detailed description of its underlying methodology is provided by Andela et al. (2019).

83 The Terra and Aqua combined Moderate Resolution Imaging Spectroradiometer (MODIS) Land Cover Type  
84 (MCD12Q1) Version 6.1 data product provides global land cover types at yearly intervals (Friedl and Sulla-Menashe,  
85 2022). With its global coverage and the insights, it offers into the planet's diversity of land cover types, the MCD12Q1  
86 dataset is pivotal to various ecological and environmental studies.

87 *Landsat 5,7,8* scene is a 16-day composite image with 7, 8, 11 surface reflectance bands. With its 30 meter  
88 resolution and global coverage, it provides a high-quality, atmospherically corrected snapshot of the Earth's surface.  
89 Use of the best available observations gathered over the 16-day period ensures the image is as clear and accurate as  
90 possible, minimizing issues, such as cloud cover, that can obscure the satellite's view.  
91 (<https://developers.google.com/earth-engine/datasets/catalog/landsat> ).

### 92 **2.2. Pre-processing**

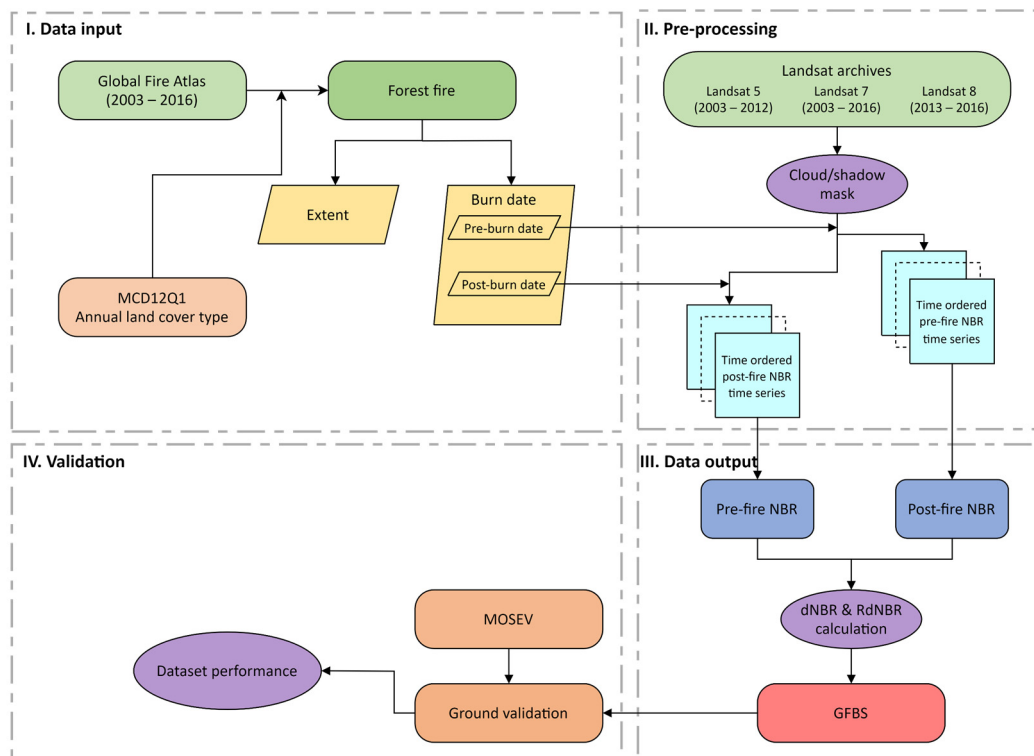

93 To pre-process the data, we first imported individual fire polygons from the Global Fire Atlas into the Google Earth  
94 Engine (GEE) and then collected the most recent Landsat images based on the tags demarcating the start and end times  
95 of each individual fire. We applied a cloud- and snow-masking algorithm to remove any snow, clouds, and their  
96 shadows from all imagery based on each sensor's pixel quality assessment band. By mosaicing the masked images,  
97 we created a composite with the smallest possible cloud and shadow extent ([https://developers.google.com/earth-  
98 engine/guides/landsat](https://developers.google.com/earth-engine/guides/landsat) ).

99 **2.3. Algorithm overview**

100 In the first step, we determined the forest fire polygons using the Global Fire Atlas data associated with the  
 101 MCD12Q1 land cover data and then utilized reflectance information from Landsat’s satellite archives to obtain the  
 102 forest fire NBRs from the Landsat composites. Healthy plants absorb most of the visible light (for photosynthesis)  
 103 while reflecting a large portion of the near-infrared (NIR) light. In contrast, areas that have been burned exhibit low  
 104 NIR reflectance and high shortwave-infrared (SWIR) reflectance [Key and Benson, 2003; Montero et al., 2023]. This  
 105 change in spectral properties is due to the loss of vegetation and the exposure of the underlying soil and charred  
 106 material, which have different reflective characteristics. By computing this ratio for images taken before and after a  
 107 fire, it's possible to determine the extent and severity of the burn [Cocke et al., 2005; Alcaras et al., 2022].

108 In the second step, we used the pre- and post-fire dates by the Global Fire Atlas data to obtain the  
 109 corresponding pre- and post-fire NBRs, which allowed us to create the burn severity indices—that is, dNBR and  
 110 RdNBR—based on the respective differences between them.

111 We took additional steps to validate the performance of the dataset by comparing the burn severity category  
 112 data over southeastern Australia and CBIs over CONUS with those based on the MOSEV dataset. These steps are  
 113 detailed in Sections 2.3.1, 2.3.2, and 2.3.3.

**Figure 1. Methodology for building the GFBS database (2003–2016) and validation and comparison with the MOSEV benchmark.**

### 114 2.3.1. Identification of global forest fires

115 To identify global forest fires, we first overlaid the fire polygons from the Global Fire Atlas with MCD12Q1 data  
116 from the corresponding year. Based on annual International Geosphere-Biosphere Programme (IGBP) classifications  
117 of land cover, we identified a forest fire polygon within each area where we found forest to be the dominant land cover  
118 type within the fire extent—that is, wherever the proportion of burned pixels representing forest, including evergreen  
119 needleleaf forests, evergreen broadleaf forests, deciduous needleleaf forests, deciduous broadleaf forests, and mixed  
120 forests, was largest relative to the proportion of burned pixels for other land cover types, such as shrublands and  
121 grasslands.

### 122 2.3.2. Estimation of the normalized burn ratio (NBR)

123 We calculated the normalized burn ratio (NBR) spectral index for each Landsat composite. according to the formula  
124 in Equation 1 (<https://www.usgs.gov/landsat-missions/landsat-normalized-burn-ratio>):

$$125 \text{NBR} = (\text{NIR} - \text{SWIR}) / (\text{NIR} + \text{SWIR}) \quad (1)$$

126 In Landsat series 4 through 7, we collected NIR information from Band 4 and SWIR information from Band  
127 7. In Landsat 8, we collected NIR information from Band 5 and SWIR information from Band 7.

### 128 2.3.3. Estimation of dNBR and RdNBR

129 Having obtained burn area locations and burn dates from the Fire Atlas product, we selected from the Landsat 16-day  
130 time series valid pre-fire and post-fire NBR pixels that were, respectively, from the date most closely preceding the  
131 start date and the date most closely following the end date of each burned polygon within a three-month time window.

132 The dNBR index, calculated according to Key and Benson (2006) as shown in equation (2), is the reference  
133 burn severity spectral index used by the European Forest Fire Information System ([https://effis.jrc.ec.europa.eu/about-](https://effis.jrc.ec.europa.eu/about-effis)  
134 [effis](https://effis.jrc.ec.europa.eu/about-effis)) and by the United States' Monitoring Trends in Burn Severity program (<https://www.mtbs.gov>). Larger dNBR  
135 values indicate higher burn severity:

$$136 \text{dNBR} = \text{preNBR} - \text{postNBR} \quad (2)$$

137 RdNBR is another burn severity spectral index that is widely used, including by the United States' Monitoring  
138 Trends in Burn Severity program (<https://www.mtbs.gov/>, last access:1 May 2021). The RdNBR normalizes the  
139 dNBR to the square root of pre-fire NBR value, which helps in reducing the variability caused by pre-fire vegetation  
140 conditions and enhances the accuracy in assessing burn severity [Miller et al., 2009]. As formulated in equation (3)  
141 (Miller and Thode, 2007), higher RdNBR values indicate higher burn severity:

$$142 \text{RdNBR} = \text{dNBR} / \sqrt{|\text{preNBR}|} \quad (3)$$

143 **2.4. Validation**

144 To validate the GFBS database, we used the 112 ground-verified burn severity category data following the Fire Extent  
145 and Severity Mapping (FESM) scheme for the 2013 wildfires over southeastern Australia. The FESM severity classes  
146 include unburnt, low severity (burnt understory, unburnt canopy), moderate severity (partial canopy scorch), high  
147 severity (complete canopy scorch, partial canopy consumption), and extreme severity (full canopy consumption).  
148 Besides FESM, we used the ground-measured CONUS-wide Composite Burn Index (CBI) from 2003 to 2016. CBI  
149 was developed by Key and Benson (2006) to assess the aboveground effects of fire on vegetation and soil land use  
150 types (i.e., burn severity). It is determined through direct field observations after a fire when assessors visited various  
151 sites within the burned area to evaluate the effects of the fire on different components of the ecosystem, such as the  
152 degree of charring, percentage of foliage consumed, changes in ground cover, and mortality of plants. The CBI score  
153 for each site was calculated by averaging the scores of the different components. This overall score represents the burn  
154 severity at a specific site. The index ranges continuously from 0 (unburned) to 3 (high severity). These values have  
155 been related to satellite-derived burn severity values through regression equations  
156 (<https://burnseverity.cr.usgs.gov/products/cbi>). In this study, we used all available CBI values over CONUS to  
157 establish relationships between CBI and the dNBR and RdNBR values of the GFBS and MOSEV datasets. We used  
158 the Pearson correlation coefficient and bias as metrics to evaluate the performance of the two datasets. Figure 2 (a)  
159 shows the locations of the 112 ground-verified burn severity sites for the 2013 wildfires over southeastern Australia.  
160 Figure 2 (b) shows the locations of CBI observations over CONUS for the period from 2003 to 2016. Of the 1,315  
161 ground-surveyed CBI reports for forest fires during that time, most came from western states, such as Arizona,  
162 Colorado, and Oregon, where forest fires are more frequent and severe. Fewer CBI records are available in eastern  
163 states, such as Florida and Georgia.

164

**Figure 2. Locations of (a) ground verification burn severity sites over southeastern Australia and (b) forest fire CBIs over CONUS.**

165

166 In addition to validation against in-situ data., we also compared the fire severity magnitudes of GFBS with  
 167 the CanLaBS dataset available over Canada. CanLaBS provides burn severity information for burned areas identified  
 168 from the Canada Landsat Disturbance product at the level of individual 30m resolution pixels. The dataset was derived  
 169 from Landsat imagery and uses values of pre-fire to post-fire differences in dNBRs for nearly 60 million hectares of  
 170 burned areas across Canada's forests from 1985 to 2015. [Guindon et al., 2017; Guindon et al., 2018].

171 **3. Results**

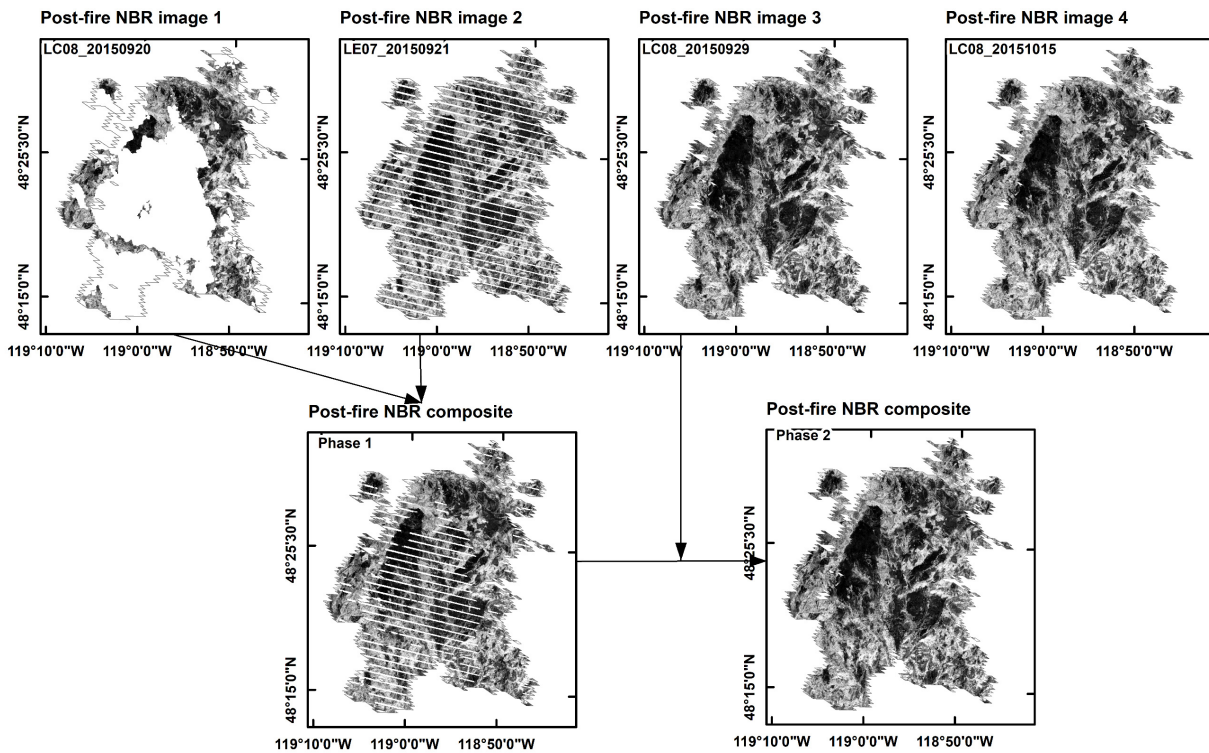

172 **3.1. Forest fire coverage of Landsat composites.**

173 Figure 3 (a) shows the number of forest fire polygons globally between 2003 and 2016, representing individual fire  
 174 events, from the Global Fire Atlas dataset. Approximately 80,000 forest fire events occur in the world each year on  
 175 average, where more than 90,000 happened in 2004 and more than 100,000 in 2003 and 2015, respectively. Figure 3  
 176 (a) displays the availability of Landsat imagery covering the burn area where individual forest fires happened  
 177 worldwide. From 2003 to 2012, Landsat 5 could provide images covering between 35% and 68% of the recorded  
 178 forest fire events in the Global Fire Atlas, while Landsat 7 images covered 83% to 93% of the Global Fire Atlas events.  
 179 From 2013 to 2016, Landsat 7 images covered between 90% and 98% of the fire events, while Landsat 8 images  
 180 covered more than 97%. The Landsat composites combining all available Landsat 5 and Landsat 7 images from 2003  
 181 to 2012 and Landsat 7 and Landsat 8 images from 2013 to 2016 significantly increased the number of forest fires  
 182 shown by Landsat images, with coverage of the fire events ranging from 88% to 99%. Figure 3 (b) shows the  
 183 distribution of the spatial coverage of cloud-free Landsat composites for individual fires from the Fire Atlas. We used  
 184 a cloud and shadow removal algorithm to eliminate invalid poor-quality pixels from recorded forest fires, resulting in  
 185 a line chart showing the distribution of the percentages of valid pixels to the total burn pixels in each year. Overall,  
 186 the spatial coverage was above 72%, and the coverage has been above 85% since 2013, when Landsat 8 was launched.

**Figure 3. (a) Numbers of individual fires from the Fire Atlas and available Landsat imagery; (b) Spatial coverage of cloud-free Landsat composites for individual fires reported in the Fire Atlas.**

188 Figure 4 shows the data process for a single post-NBR Landsat composite for the fire event that ended on 17  
 189 September 2015 in north Washington. The first prior image for NBR calculation was on 20 September 2015 from  
 190 Landsat 8 (as image 1). The cloud and shadows are removed in image 1 after applying the cloud/shadow mask. The  
 191 next available image on 21 September 2015 from Landsat 7 (as image 2) was then used to fill those gaps in image 1  
 192 and obtain a new Landsat composite (phase 1). The third available image on 29 September 2015 from Landsat 8 (as  
 193 image 3), image on 15 October 2015 if needed, was adopted sequentially to fill the un-scanned gap pixels in phase 1  
 194 and generate the final post NBR image for this event. The process for pre-NBR image calculation is the same but in a  
 195 reversed time-order from the start time of the fire event.

**Figure 4. NBR image process for Landsat composite, for the fire event ended on 17 September 2015 in north Washington.**

196

197 The scatterplot in Figure 5 (a) shows the NBR values of the overlapping pixels in image 1 and image 2, with  
 198 the associated distributions of NBR for the fire event. It is noted that NBR values in images 1 and 2 show high  
 199 correlation ( $r = 0.96$ ), relatively low bias ( $-23.81\%$ ) and similar probability densities, even though they are derived  
 200 from two different Landsat images (Landsat 8 and Landsat 7). The scatterplot in Figure 5 (b) shows the NBR values  
 201 of overlapping pixels in image 1 and image 3, with the associated distribution of NBR for the fire event. Similarly,  
 202 NBR values in image 1 and image 3 have high correlation ( $r = 0.96$ ) and low bias ( $12.30\%$ ) and similar probability  
 203 densities, even though they are derived from different times (9 days apart). The results indicate that the cloud-free

204 NBR composite mosaicking of all available Landsat images has reasonable accuracy with high spatial and temporal  
 205 consistency.

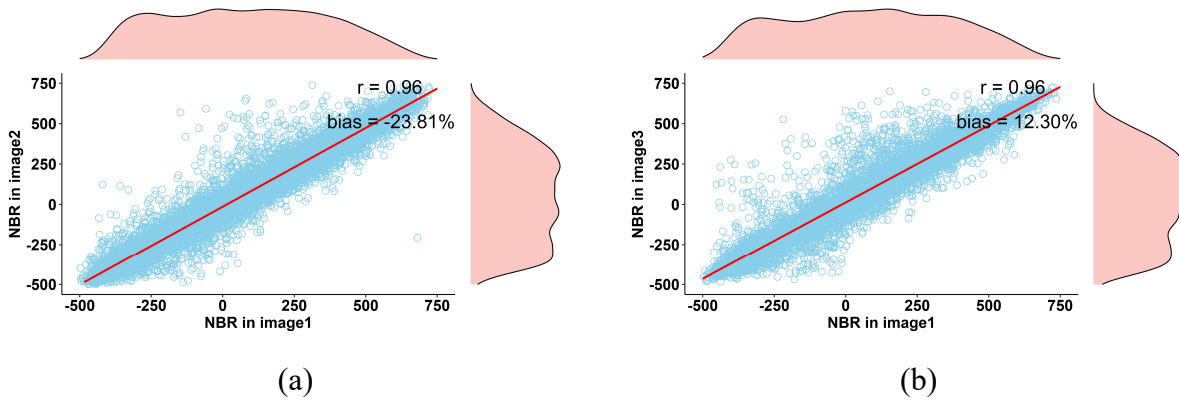

Figure 5. Scatterplots of overlapped pixel values in (a) image 1 and image 2; (b) image 1 and image 3.

206

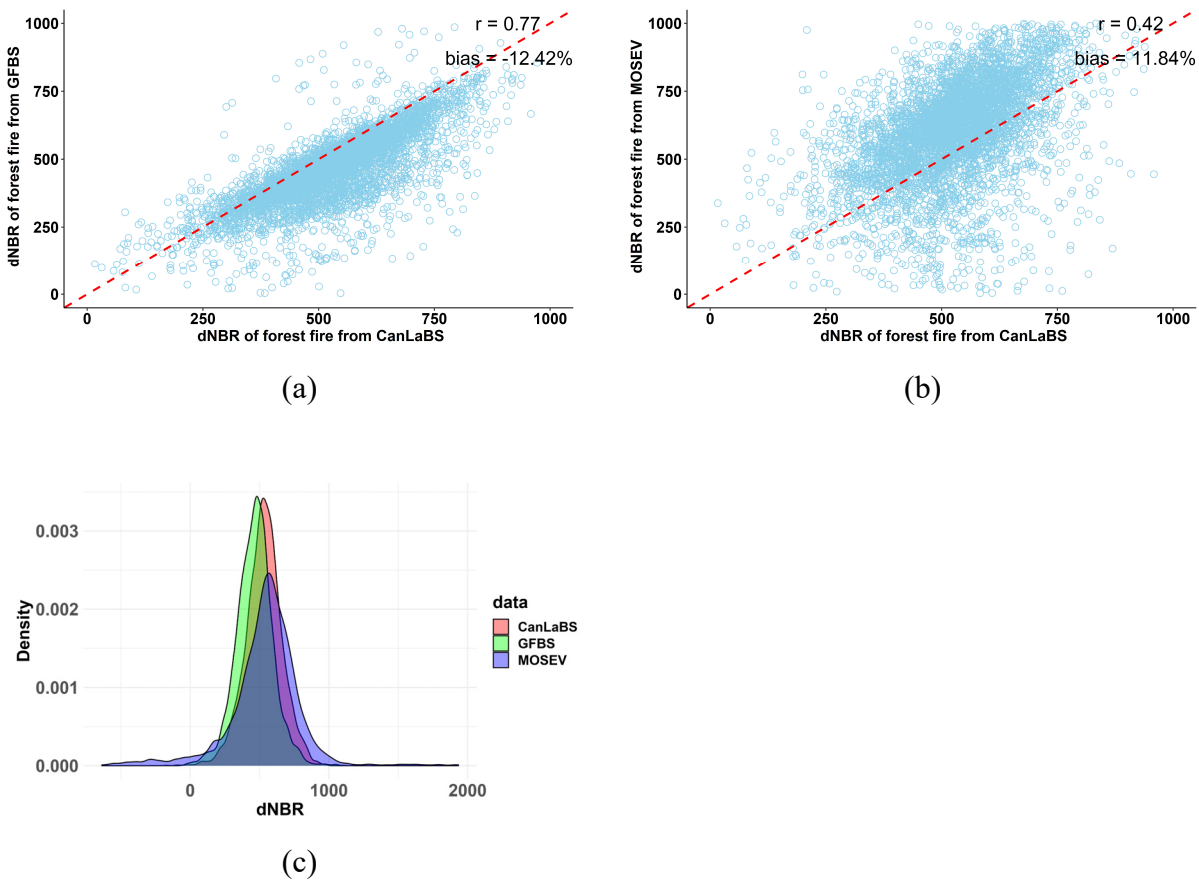

207 3.2 Comparison between GFBS and CanLaBS over Canada

208 In this section we describe the comparison of the fire severity maps of GFBS and MOSEV datasets to the ones from  
 209 the CanLaBS dataset over Canada for an overlapped period from 2003 to 2015. Figure 6 shows the number and the  
 210 trend of forest fires over Canada from 2003 to 2015, by CanLaBS data and GFBS products, while the vertical bar  
 211 represents the number of forest fires recorded by both CanLaBS and GFBS each year. Due to the different sources  
 212 and algorithms to map the burn area, the number of forest fires depicted by CanLaBS is larger than those by GFBS  
 213 each year. Nevertheless, it is noted that GFBS agrees with CanLaBS in terms of the variations of forest fire activities,  
 214 such as the intense forest fires in 2004 and 2015 and the relatively low number of forest fires in 2007 and 2008.

**Figure 6. Number of forest fires by CanLaBS and GFBS dataset. Vertical bars show the number of overlapping forest fires.**

215 Figure 7 illustrate the scatterplots of dNBR of forest fires from CanLaBS against those from GFBS (panel a)  
 216 and MOSEV (panel b), for the period 2003 to 2015. Consistent to the results shown in Figure 6, dNBR from GFBS  
 217 shows strong correlation with the dNBR from CanLaBS with  $r$  being 0.77 and a slightly underestimation of the overall  
 218 dNBR for forest fires (bias = -12.42%). On the other hand, dNBR from MOSEV exhibited low correlation with the  
 219 dNBR from CanLaBS ( $r = 0.42$ ) and slight overestimation (bias = 11.84 %). Figure 7 (c) displays the probability  
 220 density function (PDF) plots of CanLaBS dNBR, GFBS dNBR and MOSEV dNBR. It is noted the close PDFs of  
 221 GFBS dNBR and CanLaBS dNBR, though the mode of GFBS distribution is at slightly lower dNBR value relative to  
 222 the CanLaBS distribution. On the other hand, the distribution of MOSEV dNBR significantly deviates from CanLaBS  
 223 dNBR, having a lower peak and larger tails.

**Figure 7. Scatterplots of dNBR from CanLaBS against those from (a) GFBS and (b) MOSEV; (c) density plot of dNBR from CanLaBS, GFBS and MOSEV, for forest fires from 2003 to 2015 over Canada.**

224

225 Figure 8 presents the boxplots of distributions of dNBR from CanLaBS, GFBS and MOSEV separate by  
 226 year. Consistent to the previous results, GFBS compares well with CanLaBS in terms of the dNBR distribution of  
 227 annual forest fires and as well as the variations of dNBR over time, even though it provides slightly lower dNBR

228 values compared to CanLaBS. On the other hand, MOSEV compared poorly with CanLaBS annual dNBR  
229 distributions, exhibiting overall larger dNBR values and larger anomalies over time.

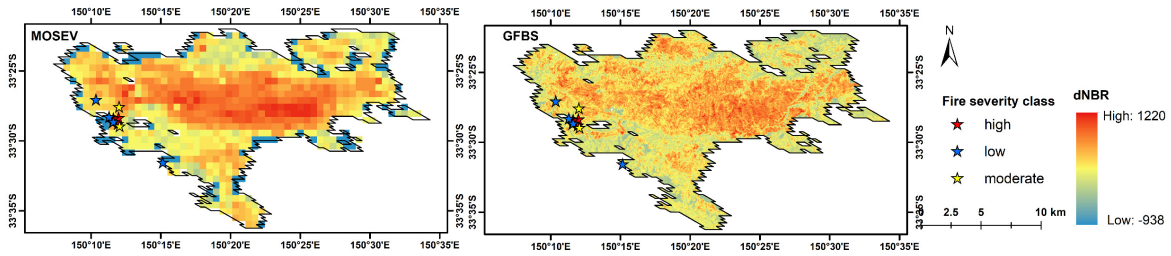

Figure 8. Boxplots of annual distributions of dNBR values from CanLaBS, GFBS and MOSEV for forest fires over Canada from 2003 to 2015.

### 230 3.3. Validation against in situ fire severity category over southeastern Australia

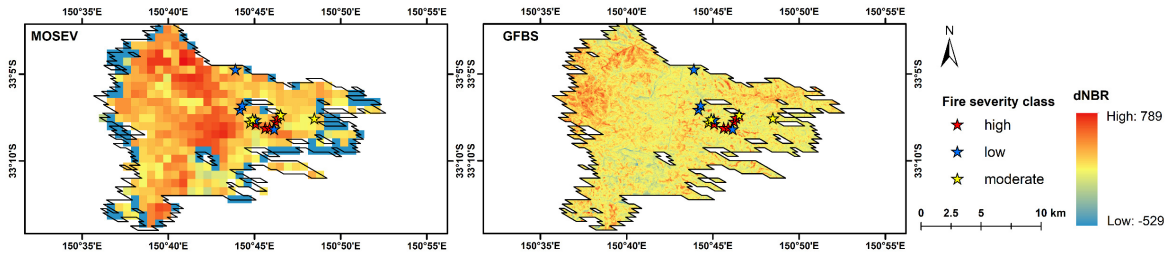

231 Using as the ground truth the in-situ burn severity categorizations from the 2013 wildfires over southeastern Australia,  
232 we evaluate the performance of GFBS and MOSEV datasets. Figure 9 (a), (b) and (c) display the spatial patterns of  
233 GFBS dNBR and MOSEV dNBR for wildfires that happened on October 15 2023, October 17 2023 and October 21  
234 2023, respectively, in southeastern Australia, where relatively dense in situ burn severity categorization data are  
235 available. It is noted that GFBS dNBR shows similar spatial patterns to the MOSEV dNBR in the events on October  
236 15 2023 and October 17 2023, both showing significant fire centers where high dNBR are found. For the October 21  
237 2023 event, however, the dNBR map from MOSEV shows a larger high burn severity area than GFBS.

(a)

(b)

(c)

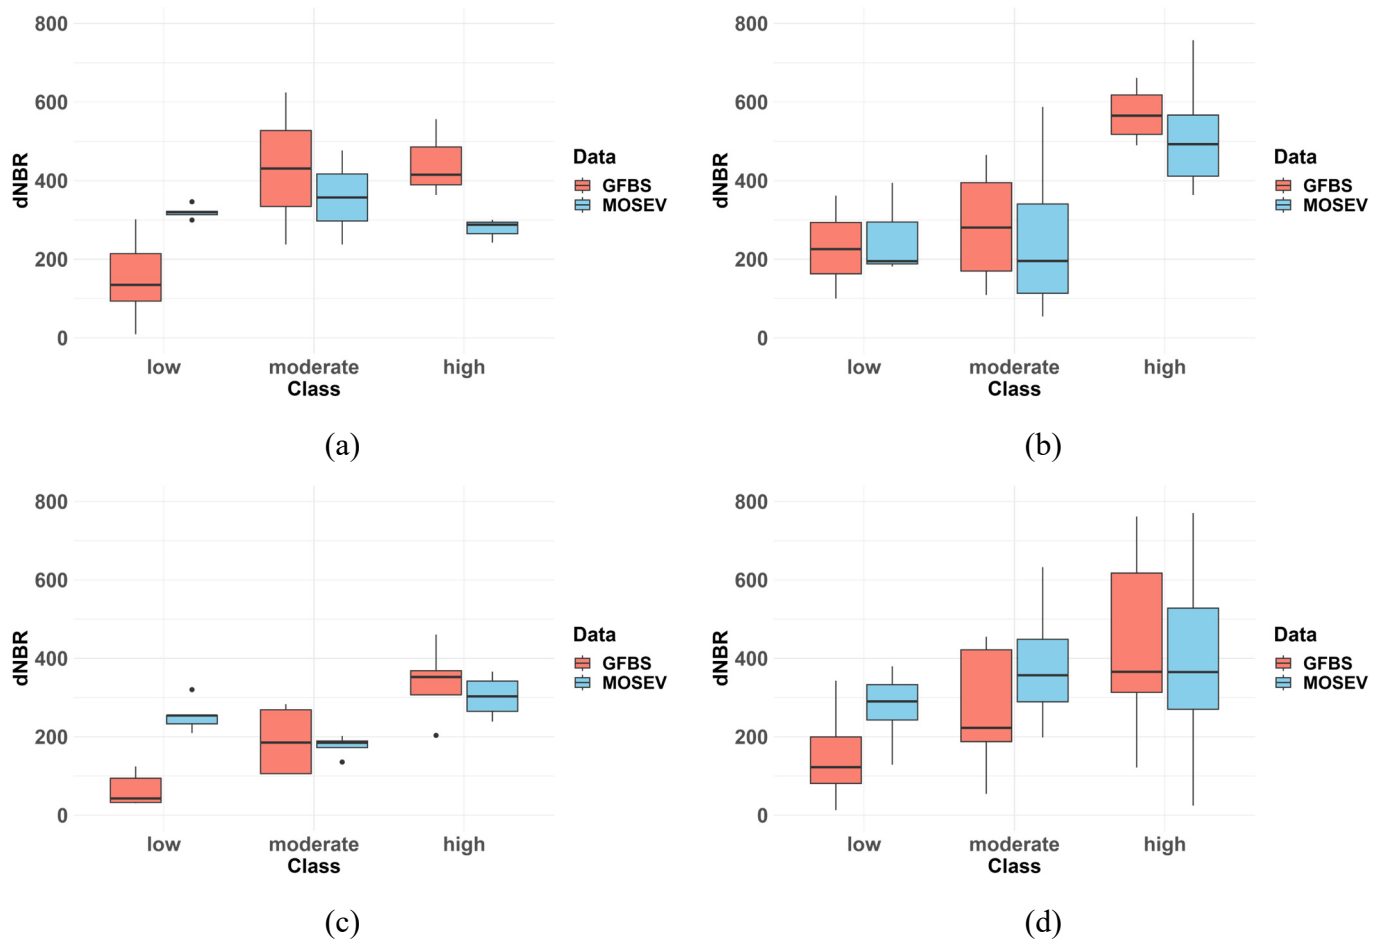

**Figure 9. Spatial patterns of dNBR for wildfires on (a) October 15 2023, (b) October 17 2023 and (c) October 21 2023, in southeastern Australia, derived from the GFBS and MOSEV datasets.**

238

239 The boxplots in Figure 10 (a), (b) and (c) display the corresponding distributions of dNBR from GFBS and  
 240 MOSEV at different observed severity classes in the events on October 15 2023, October 17 2023 and October 21  
 241 2023, respectively. The severity classes, e.g. low, moderate and high, are categorized from the field assessed sites in  
 242 the corresponding fire events. For the event on October 15 2023, dNBR from GFBS shows significant difference  
 243 between the moderate/high and low severity class, and no difference between high and moderate severity class. The  
 244 dNBR from MOSEV, however, presents lower dNBR at high severity class than those at moderate and low severity  
 245 class. For the event on October 17 2023, both GFBS and MOSEV show significant discrepancies on dNBR between  
 246 high and moderate/low severity class. For the event on October 21 2023, GFBS could clearly differentiate among  
 247 high, moderate and low severity classes in terms of dNBR values, while MOSEV presents the lowest dNBR values at  
 248 the moderate severity class, while exhibits small differences in dNBR values between the low and high severity  
 249 classes. Figure 10 (d) shows the overall performances of dNBR from GFBS and MOSEV for the different severity

250 classes, combining all 112 ground verification sites. More significant differences are shown in the GFBS dNBR  
 251 boxplots between high, moderate and low severity classes than those from MOSEV, indicating a better skill of GFBS  
 252 to distinguish between forest fires of different severity levels.

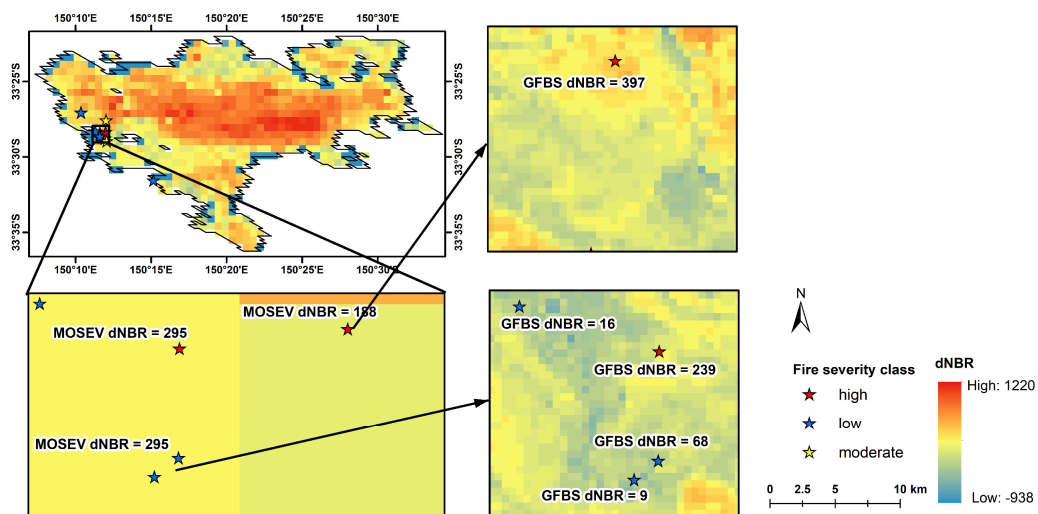

**Figure 10. Boxplots of distributions of dNBR at different burn severity classes from the in situ data for (a) event on October 15 2023; (b) event on October 17 2023; (c) event on October 21 2023; and (d) combining all events with in situ data.**

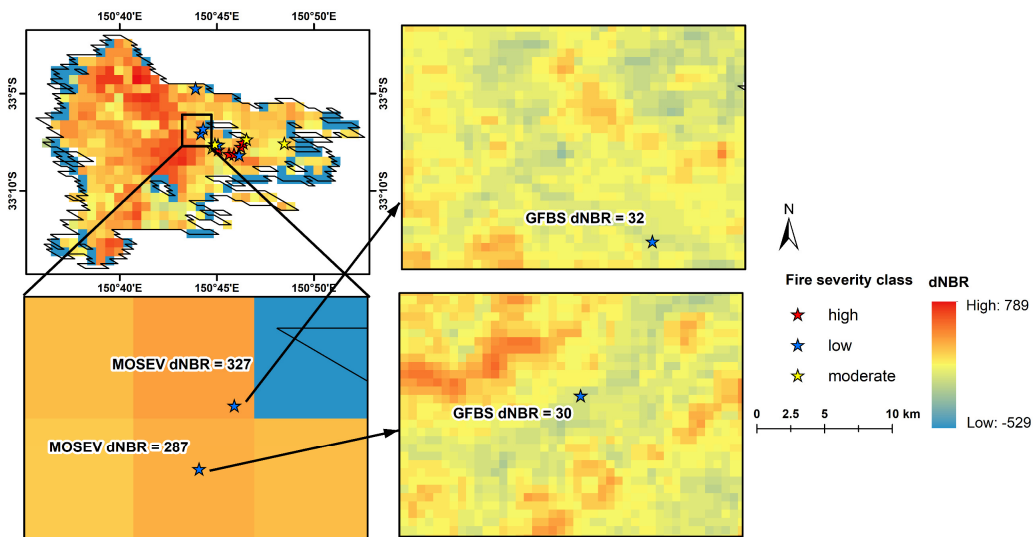

253

254 As mentioned above, MOSEV gave relatively small dNBR values in the event on October 15 2023, where  
 255 burn severity is classified from in situ measurement as high. Figure 11 (a) displays the location of the ground  
 256 verification sites with the corresponding burn severity class and associated dNBR values from MOSEV and GFBS. It  
 257 is noted that within one MOSEV grid cell (500 meter) four ground verification sites are located. The dNBR value  
 258 from MOSEV is 295 for all four sites, while three of the sites are classified as low and only one site is classified as  
 259 high severity. On the other hand, at GFBS resolution (30 meter), we can note significant spatial variation in dNBR,  
 260 with GFBS dNBR being 239 for the site classified as high and 9, 16 and 68 for the sites classified as low severity. In  
 261 a surrounding MOSEV pixel we note a site classified as high severity, but dNBR from MOSEV is 188 while dNBR  
 262 from GFBS is 397. In the event on October 21 2023, we found that MOSEV gave relatively high dNBR values at  
 263 ground verification sites that are classified as low severity. Figure 11 (b) shows the locations of ground verification

264 sites with corresponding classified burn severity and associated dNBR values from MOSEV and GFBS. In the two  
 265 adjacent MOSEV grids, the dNBR values from MOSEV are 287 and 327 respectively where both sites are classified  
 266 as low severity. At GFBS resolution more significant changes between high and low dNBR are found within the same  
 267 MOSEV grid, resulting in dNBR values of 30 and 32 for the ground verification sites classified as low severity. The  
 268 results demonstrate the significance of GFBS high resolution data in representing the small-scale variations of dNBR  
 269 and providing more granular and reliable dNBR estimations.

(a)

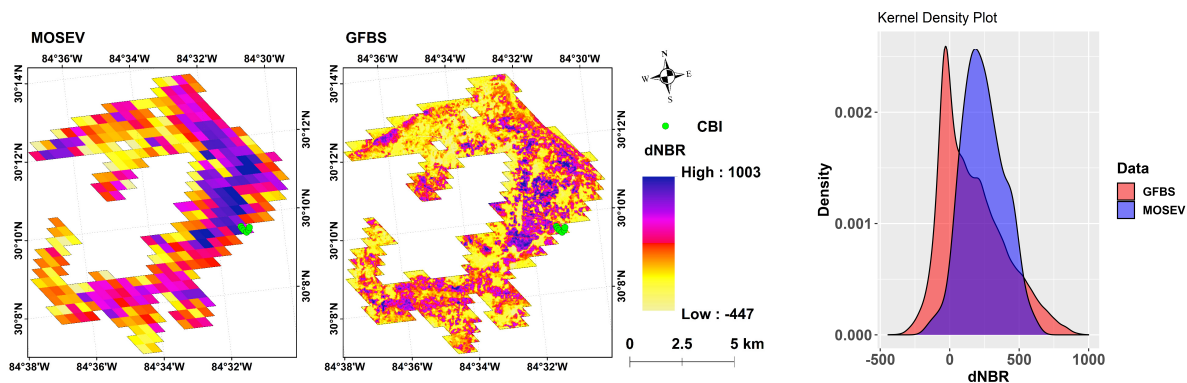

(b)

270 **3.4. Validation against CBI over CONUS**

271 Figure 12 (a), (b), (c) and (d) shows the spatial patterns of dNBR derived from GFBS and MOSEV over CONUS for  
 272 the forest fires with the largest burn areas (referred to as annual maximum forest fire hereafter) in 2004, 2006, 2007,  
 273 and 2013 respectively for which CBI records are available. The figures present the PDFs of dNBR values from GFBS  
 274 and MOSEV, along with spatial distribution maps of dNBR. The similarity in spatial patterns between GFBS burn  
 275 severity and MOSEV burn severity is noted in these plots. Significant differences occur, however, between dNBR  
 276 from GFBS and MOSEV. Specifically, MOSEV tends to provide overall larger dNBR values, but where dNBR from  
 277 GFBS is relatively high MOSEV dNBR values are relatively lower. This difference could also be inferred from the  
 278 PDFs of dNBR from GFBS and MOSEV where dNBR from MOSEV distributed more on the mean dNBR of around  
 279 300, while dNBR from GFBS is bimodal with peaks on both low and high values. For the annual maximum forest fire  
 280 in 2007, especially, MOSEV showed more extensive areas with high dNBR values compared to GFBS, a difference  
 281 that was also revealed in the large deviation of mean dNBR values in the PDFs of dNBR from the GFBS (mean dNBR  
 282 around 100) and MOSEV (mean dNBR around 500) datasets.

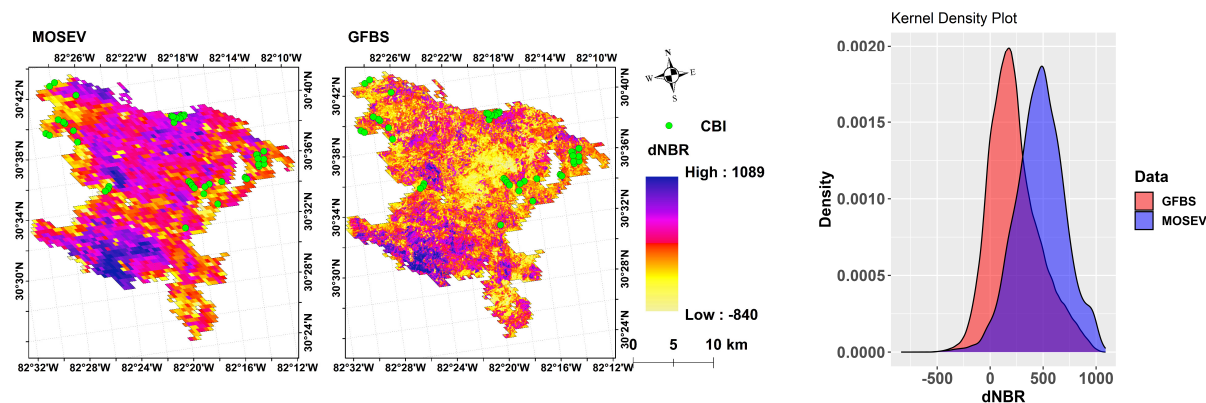

283 The density plot of dNBR in Figure 12 also shows the bi-modal distribution for dNBR from GFBS, at around  
 284 100 (associated with low severity) and 700 (associated with high severity), for the annual maximum forest fire in  
 285 2006. dNBR from MOSEV on the other hand shows a single peak distribution at around 500, indicating that dNBR  
 286 from MOSEV underestimated the high severity occurrences, and overestimated the low severity ones, depicted in the  
 287 GFBS dataset. For the annual maximum forest fire in 2013, though the density plot presents two different peaks in the  
 288 distributions of GFBS and MOSEV, indicating a significant difference in the burn severity depicted in the two datasets.

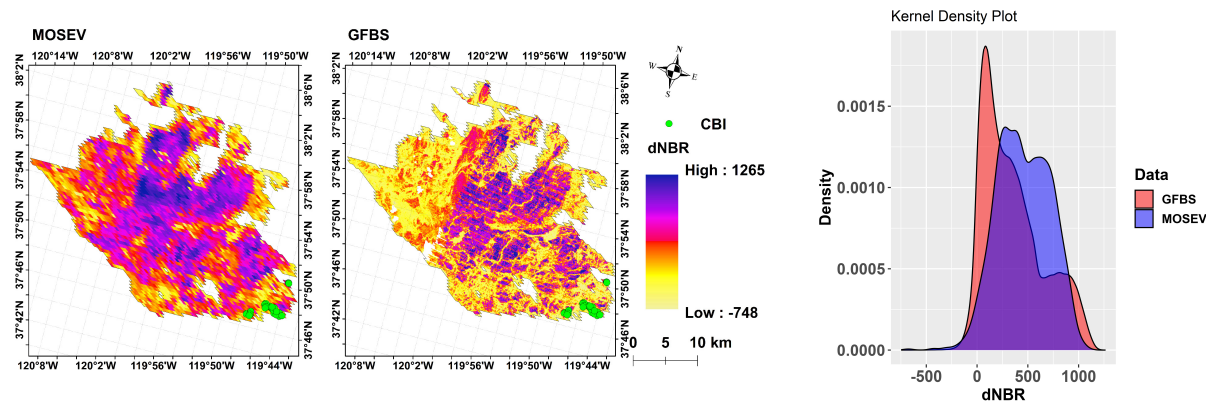

(a)

(b)

(c)

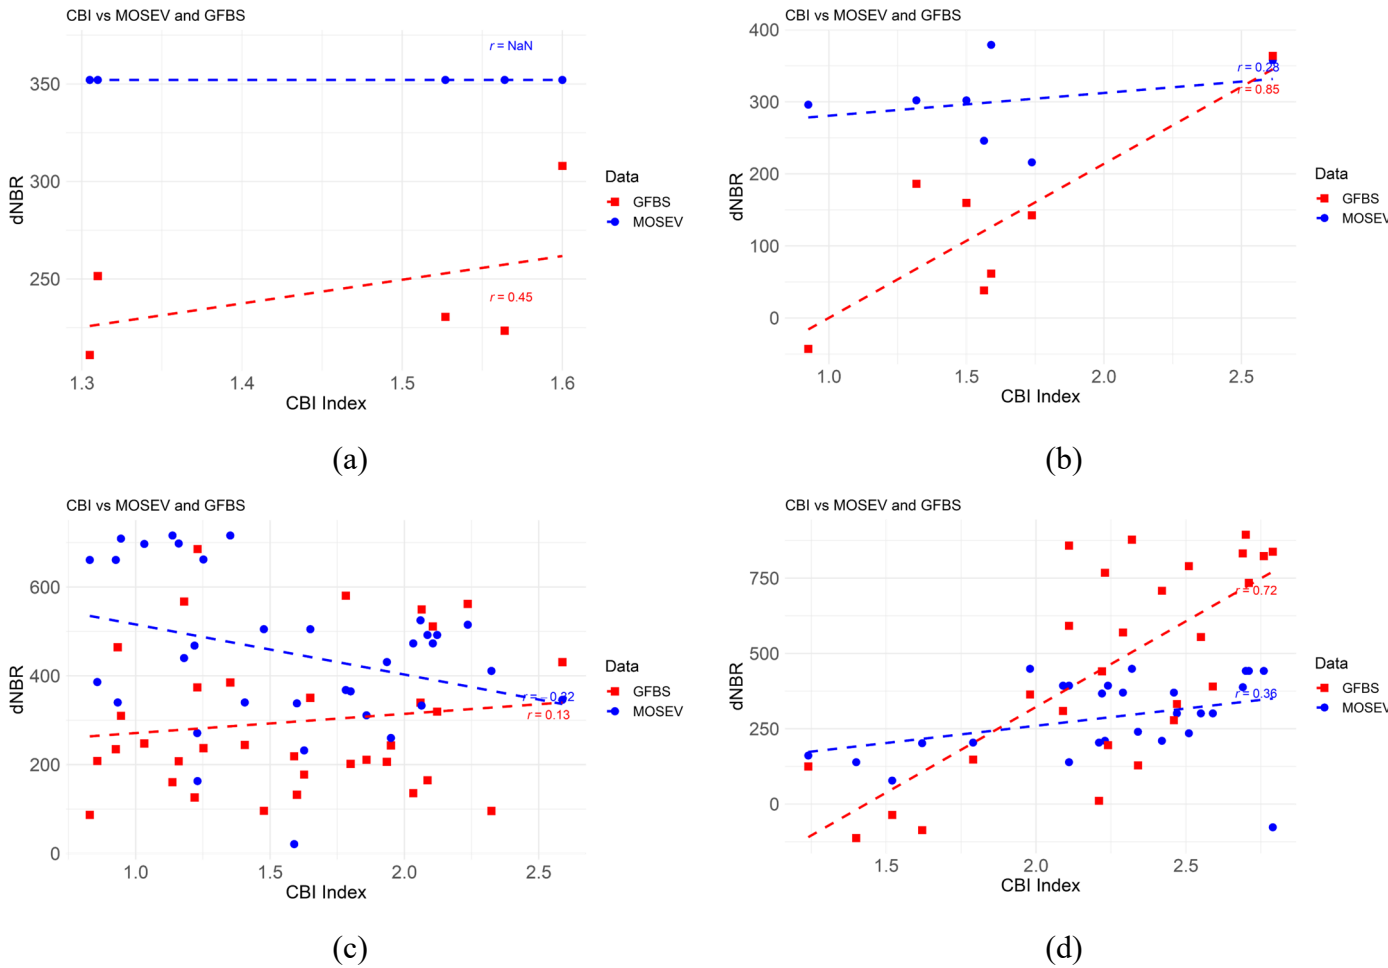

(d)

**Figure 12. Spatial patterns of dNBRs for annual maximum fires over CONUS with distribution of probability density functions in (a) 2004, (b) 2006, (c) 2007, and (d) 2013, derived from the GFBS and MOSEV datasets.**

289 Figure 13, panels (a), (b), (c), and (d), present the scatterplots of CBI against dNBR from GFBS and dNBR  
 290 from MOSEV for the annual maximum forest fires in 2004, 2006, 2007, and 2013, respectively. For the annual  
 291 maximum forest fire in 2004, Figure 13 (a) shows a positive correlation between CBI ( $r = 0.45$ ) and dNBR from

292 GFBS, while we found no correlation between CBI and dNBR from MOSEV. For the annual maximum forest fire in  
 293 2006, we found good agreement between the CBI and dNBR from GFBS, with a  $r$  value of 0.85, while the  $r$  value was  
 294 only 0.28 for dNBR from MOSEV. Though correlations between CBI and dNBR from GFBS and MOSEV were poor,  
 295 dNBR from GFBS showed a positive trend to CBI, while the relationship between CBI and dNBR from MOSEV was  
 296 negative, for the annual maximum forest fire in 2007. For the annual maximum forest fire in 2013, dNBR from GFBS  
 297 ( $r = 0.72$ ) was more strongly correlated with CBI than dNBR from MOSEV ( $r = 0.36$ ).

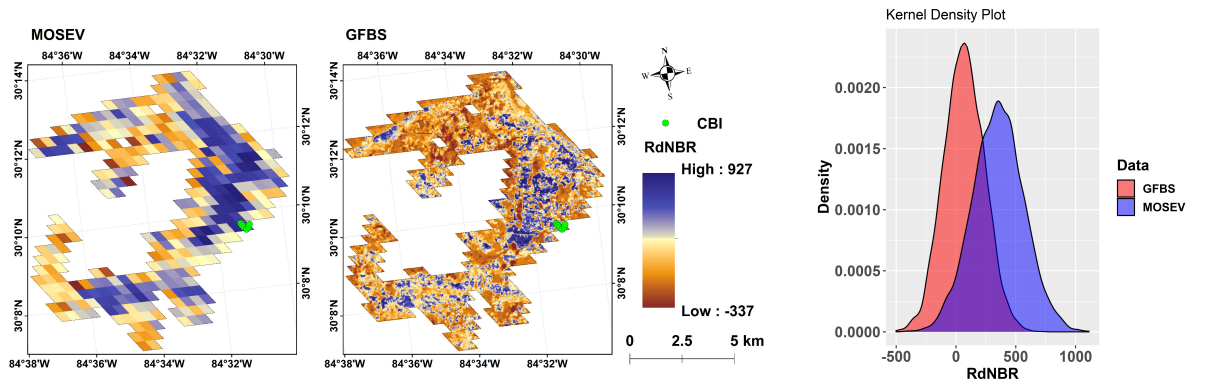

298 **Figure 13. Scatterplots of CBI against dNBR from GFBS and MOSEV for annual maximum fires in (a) 2004,**  
 299 **(b) 2006, (c) 2007, and (d) 2013.**

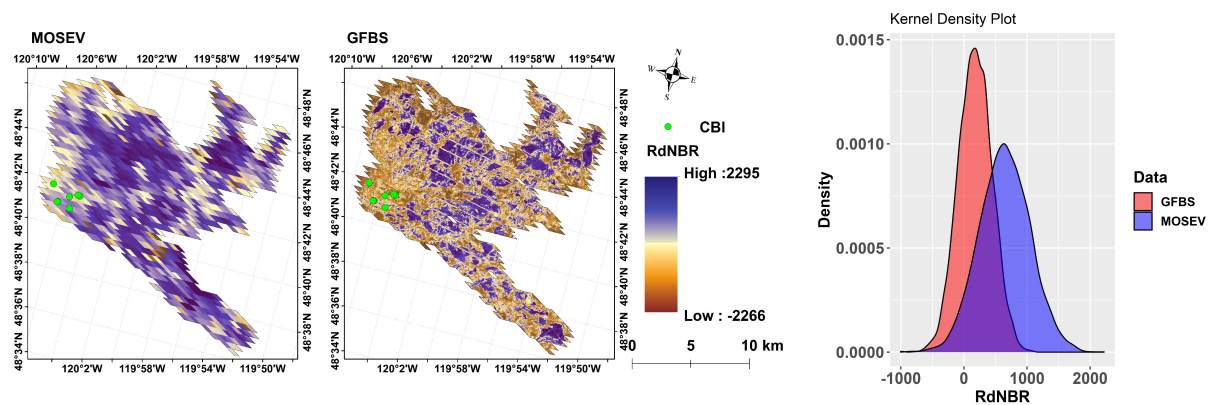

300 Figure 14 (a), (b), (c) and (d) shows the spatial patterns of RdNBR from GFBS and MOSEV along with the  
 301 associated PDFs of RdNBR, for the forest fires over CONUS with the largest burn areas (referred to as annual  
 302 maximum forest fire hereafter) in 2004, 2006, 2007, and 2013 respectively. RdNBR from GFBS and MOSEV exhibit  
 303 similar spatial patterns yet provide different ranges of RdNBR values over burn area. RdNBR from MOSEV tended  
 304 to be higher than RdNBR from GFBS, which is consistent to the density plots of RdNBR from GFBS. The mean value  
 305 in the distribution of RdNBRs from MOSEV is larger than the mean value in the distribution of RdNBRs from GFBS,  
 306 for the annual maximum forest fires in 2003, 2006 and 2007. The density plots of RdNBR from GFBS and MOSEV

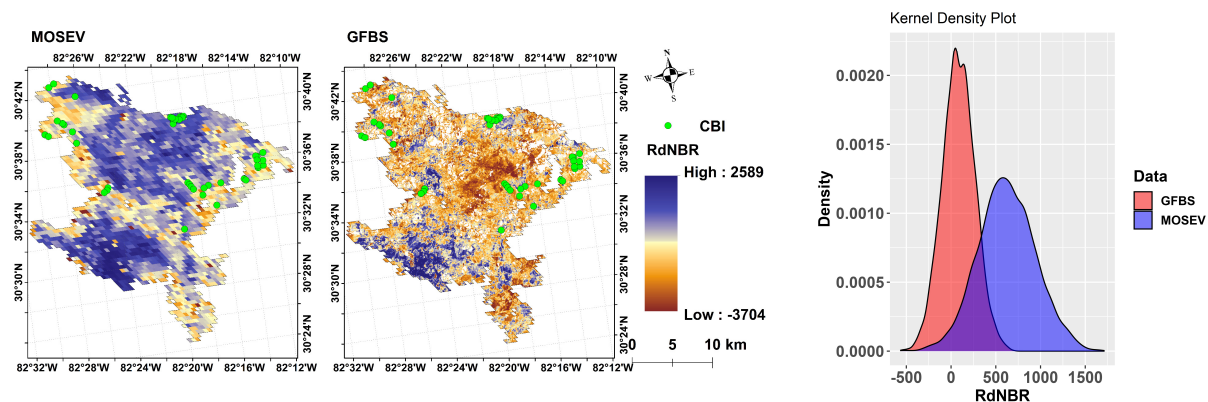

307 are largely overlapped for the annual maximum forest fire in 2013, but RdNBR from MOSEV distributed more on the  
 308 mean values around 800 than RdNBR from GFBS, while RdNBR from GFBS distributed more on the extreme low  
 309 values above 0 and high values above 1500. These findings demonstrate that RdNBR from MOSEV represents overall  
 310 larger burn severity estimations than RdNBR from GFBS.

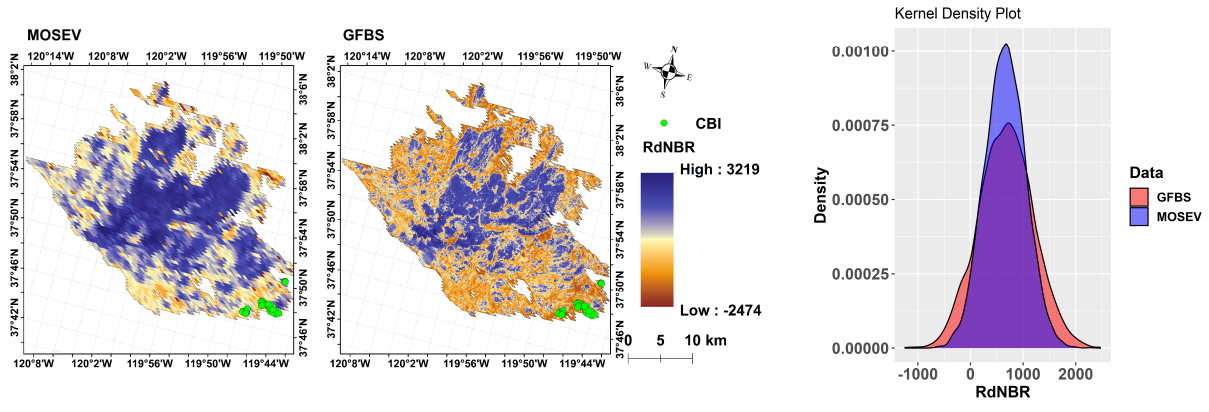

(a)

(b)

(c)

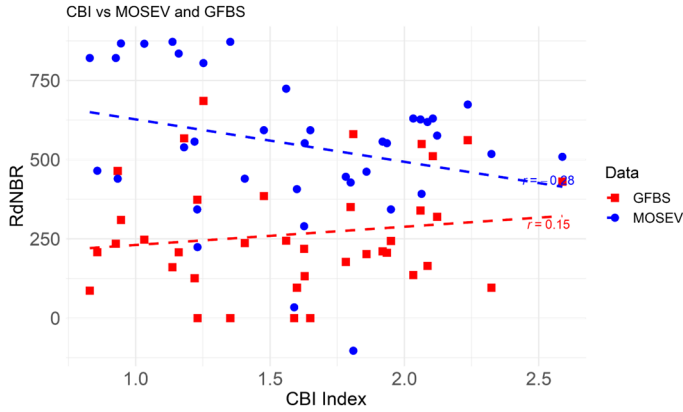

(d)

**Figure 14. Spatial patterns of RdNBRs for annual maximum fires over CONUS with distribution of probability density functions in (a) 2004, (b) 2006, (c) 2007, and (d) 2013, derived from the GFBS and MOSEV datasets.**

311 Figure 15, panels (a), (b), (c), and (d), present the scatterplots of CBI against RdNBR from GFBS and  
 312 MOSEV, for the annual maximum forest fires in 2004, 2006, 2007, and 2013, respectively. For the annual maximum  
 313 forest fire in 2004, RdNBR from GFBS shows a positive correlation with CBI ( $r = 0.57$ ), while no correlation was  
 314 found between CBI and RdNBR from MOSEV. For the annual maximum forest fire in 2006, RdNBR from GFBS  
 315 correlated well with the CBI for showing a  $r$  value of 0.85, while the  $r$  value was only 0.18 between CBI and RdNBR  
 316 from MOSEV. The correlations between CBI and RdNBR from GFBS and MOSEV are bad for the annual maximum  
 317 forest fire in 2007, the RdNBR from GFBS showed a positive trend to CBI with  $r = 0.15$ , while the RdNBR from  
 318 MOSEV showed a negative trend to CBI with  $r = -0.28$ . For the annual maximum forest fire in 2013, RdNBR from  
 319 GFBS ( $r = 0.74$ ) was more strongly correlated with CBI than RdNBR from MOSEV ( $r = 0.40$ ).

320

(c)

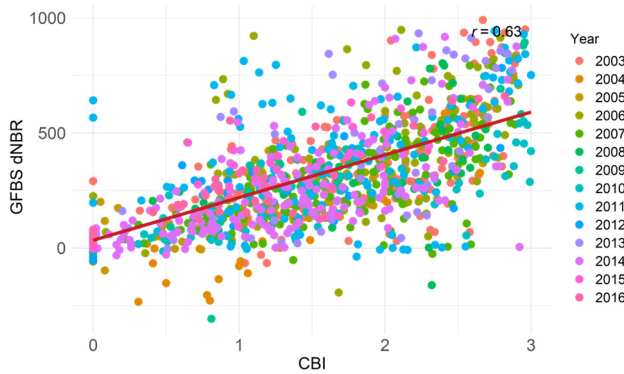

(d)

321 **Figure 15. Scatterplots of CBI against RdNBR from GFBS and MOSEV for annual maximum fires in (a) 2004,**  
 322 **(b) 2006, (c) 2007, and (d) 2013.**

323 Figure 16 (a) and (b) shows the scatterplots of CBI against dNBR from GFBS and MOSEV, respectively, for  
 324 all forest fires from 2003 to 2016 over CONUS. Involving all ground validations, we found GFBS dNBR shows a  
 325 stronger correlation with CBI ( $r = 0.63$ ) than MOSEV dNBR ( $r = 0.28$ ). Using RdNBR as the burn severity, Figure  
 326 16 (c) and (d) show that GFBS RdNBR ( $r=0.56$ ) outperformed MOSEV RdNBR ( $r=0.20$ ).

### 328 3.5. Comparison of GFBS and MOSEV globally

329 Figure 17 (a) displays the global spatial distributions of the overlapping area between the density plots of dNBR from  
 330 GFBS and MOSEV, which is defined as the area intersected by two probability density functions presented in Figure  
 331 12 and Figure 14. The overlapping areas in density plots typically represent the percentage of common values between  
 332 the distributions of two datasets, which ranges from 0 to 1 with the larger value indicating the two distributions are  
 333 more likely come from the same distribution. As Figure 17 (a) shows, we found the overlapping area over most of the  
 334 world to be above 0.4, indicating a similarity of 40% between the burn severity information provided by GFBS and  
 335 MOSEV in these regions. For some regions, like South America, Western Europe, and southeast Australia, the overlap  
 336 was above 0.6.

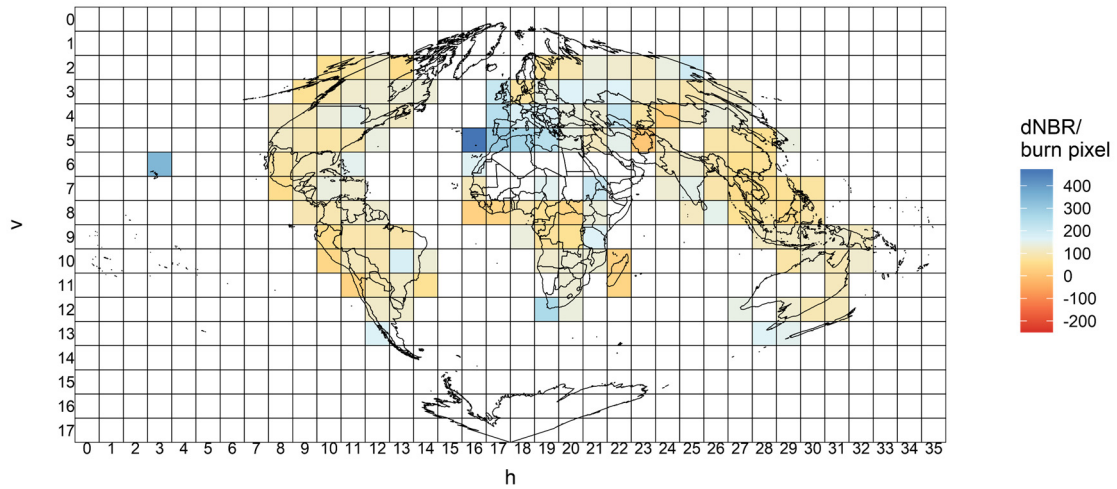

337 From Figure 17 (b), which shows the global distribution of the mean dNBR for each burn pixel derived from  
 338 GFBS, we found the global spatial heterogeneity of burn severity to be small, with dNBR values from GFBS around  
 339 100 and 200. The exception was in Western Europe, where dNBR was above 300. The global distribution of the mean  
 340 dNBR for each burn pixel derived from MOSEV, as shown in Figure 17 (c), however, indicated a large spatial  
 341 variability in burn severity globally. The MOSEV dataset, for example, indicated that the forest fires in north CONUS  
 342 and Canada should have an average dNBR above 300, while in the GFBS dataset the average dNBR value was around  
 343 100 to 200. The MOSEV dataset also indicated the average dNBR values for forest fires in South Africa and China  
 344 should be close to or below 0, while in the GFBS dataset they were around 100 to 200, respectively.

345 Figure 17 (d) presents a more detailed comparison between the dNBR from GFBS and MOSEV globally,  
 346 showing the difference in the mean dNBR for each burn pixel, as calculated by dNBR from MOSEV minus dNBR  
 347 from GFBS. Globally, MOSEV data indicated higher forest burn severity than GFBS over Canada and CONUS, also  
 348 found in the results presented in section 3.2 and 3.4, as well as southeast Australia (also found in the results presented  
 349 in section 3.3). MOSEV data presented lower forest burn severity over Mexico, South Africa, Europe, China, and

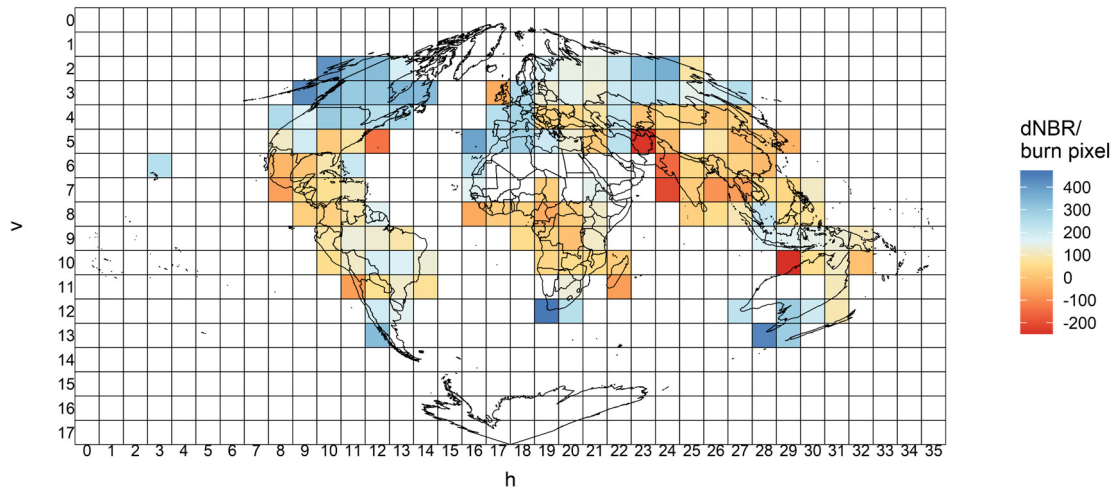

350 Southeast Asia. These findings revealed that the forest burn severity information provided by GFBS might be more  
351 reliable and reasonable than that provided by MOSEV for some fire-prone areas, such as CONUS, as validated in this  
352 study. This improved accuracy over MOSEV data would support advances in decision making in fire management  
353 strategies and ecosystem conservation efforts.

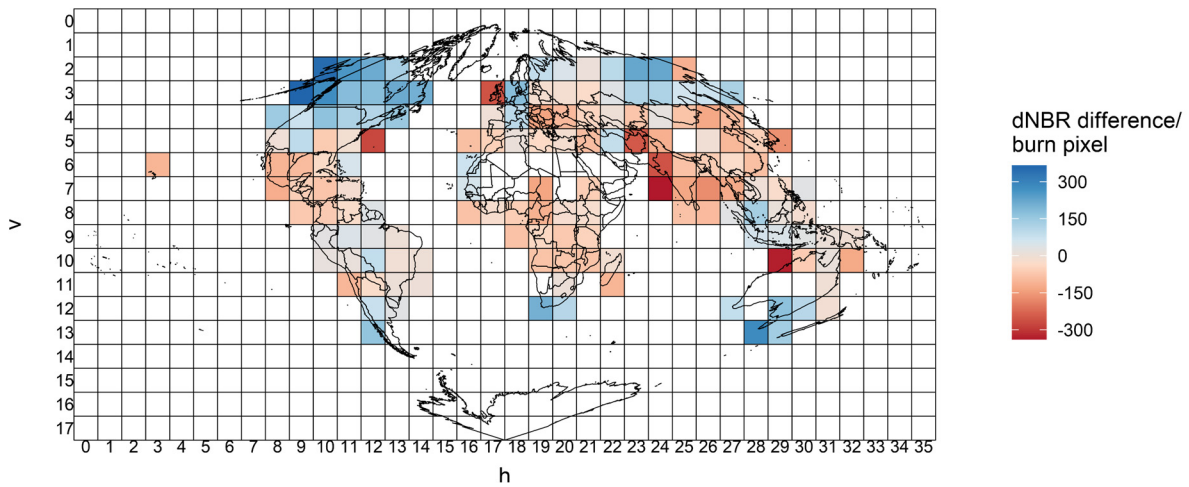

(a)

(b)

(c)

(d)

**Figure 17. Global spatial distributions of (a) overlapping areas between the density plots of dNBR from GFBS and MOSEV, (b) the mean dNBR per burn pixel from GFBS, (c) the mean dNBR per burn pixel from MOSEV, and (d) the differences in the mean dNBR per burn pixel between MOSEV and GFBS (MOSEV – GFBS).**

354 **4. Discussion**

355 The GFBS dataset presented in this paper is the first to provide fine spatial resolution (30m) burn severity information  
 356 for global forest fires from 2003 to 2016. Compared with the existing Landsat based CanLaBS dataset, GFBS shows  
 357 closer agreement to CanLaBS in describing the distribution of annual forest fire burn severity than the MODIS based  
 358 MOSEV data. As suggested by the validation against the ground reference, GFBS can better represent the spatial  
 359 variability and provide higher performance than the MOSEV dataset. In addition, GFBS is shown to have more reliable  
 360 burn severity estimations than MOSEV for some fire-prone areas, like CONUS, Canada, and Australia, which could  
 361 support advances in decision making in fire management strategies and ecosystem conservation efforts.

362 The difference in the performance of GFBS and MOSEV with respect to burn severity can be attributed to  
363 two sources. The first is spatial resolution. GFBS, based on Landsat (5, 7, and 8) images, is at a resolution of 30  
364 meters, while MOSEV is based on MODIS Terra MOD09A1 and Aqua MYD09A1 images with a resolution of 500  
365 meters. As shown in Figure 11 (a), stemming from the coarse spatial resolution, MOSEV provides dNBR value of  
366 295 for the site classified as high severity as well as for those classified as low severity, leading to an overestimation  
367 for low severity sites. With the improved spatial resolution, GFBS is able to capture more detailed localized variability  
368 of dNBR, providing more reasonable dNBR estimation for low severity sites (dNBR equal to 9, 16, 68). Similarly, in  
369 the event shown in Figure 11 (b), MOSEV provides dNBR estimations of 287 and 327 for the low severity sites, which  
370 is relatively too large. In GFBS, the relative lower dNBR of 30 and 32 is provided at the corresponding low severity  
371 sites. The coarse resolution of MOSEV could also make it more difficult to capture the extreme values, as we found  
372 to be the case for the annual maximum forest fires in 2006 over CONUS. dNBR from GFBS clearly showed two peaks  
373 in the density plot of dNBR at around 100 and 700, representing the low and high severity, respectively. dNBR from  
374 MOSEV, however, showed only a single peak at around 500, indicating that the extreme low/high values in the 30m  
375 grid were averaged in the 500m grid. These findings reveal that burn severity from MOSEV has higher uncertainty  
376 for wildfires with larger spatial variabilities.

377 Another reason leading to the difference in the performances of the two data sets was related to sensors  
378 onboard Landsat and MODIS. MODIS has a wider spectral range and more spectral bands (36) than Landsat 7/8 (7  
379 spectral bands/ 11 spectral bands, respectively), which resulted in different sensitivity to surface reflectance. For  
380 example, the NBR is commonly calculated using near-infrared (NIR) and shortwave infrared (SWIR) bands. In  
381 MOSEV, the bands used to calculate NBR are NIR: Band 2 (Range: 0.841–0.876  $\mu\text{m}$ ) and SWIR: Band 7 (Range:  
382 2.105–2.155  $\mu\text{m}$ ). In GFBS, they are Landsat 5 Band 4 (Range: 0.76–0.90  $\mu\text{m}$ ) and SWIR: Band 7 (Range: 2.08–2.35  
383  $\mu\text{m}$ ); Landsat 7 Band 4 (Range: 0.77–0.90  $\mu\text{m}$ ) and SWIR: Band 7 (Range: 2.09–2.35  $\mu\text{m}$ ); and Landsat 8 Band 5  
384 (Range: 0.85–0.88  $\mu\text{m}$ ) and SWIR: Band 7 (Range: 2.11–2.29  $\mu\text{m}$ ). While MODIS and Landsat 8 are close in NIR  
385 and SWIR band information, Landsat 5 and 7 both have wider spectrums in NIR and SWIR than MODIS.

386 This study has shown that combining all available Landsat images, including those from Landsat 5, 7, and 8,  
387 could significantly improve the probability of obtaining dense cloud-free NBR time series. The NBR composite shows  
388 high spatial and temporal consistency with the NBR images closest to the start and end time of the fire event, despite  
389 different band settings used from Landsat 5, 7 and 8. Studies by Koutsias and Pleniou (2015) and Chen et al. (2020)  
390 also have shown that differences are small when using reflectance values from sensors aboard the Landsat 5, 7, and 8  
391 satellites to calculate burn severity over burned area. While studies (Mallinis et al., 2018; Howe et al. 2022) have  
392 demonstrated that Sentinel-2 generally performed as well as Landsat 8 in burn severity mapping, the further extension  
393 of this study will also incorporate images from Sentinel-2 to obtain dNBR composite, especially on extending the  
394 GFBS data set to the present. With the finer spatial resolution (10 meter) and more frequent revisit period (5 days),  
395 GFBS could provide improved burn severity information when incorporating Sentinel-2 images. The National  
396 Aeronautics and Space Administration (NASA) has launched the Harmonized Landsat and Sentinel-2 (HLS) project  
397 aiming to produce a seamless surface reflectance record from the Operational Land Imager (OLI) and Multi-Spectral

398 Instrument (MSI) aboard Landsat-8/9 and Sentinel-2A/B remote sensing satellites, respectively, which is an  
399 alternative source for extending the GFBS dataset (<https://hls.gsfc.nasa.gov/>)

400 With the development of radar-based techniques, Synthetic Aperture Radar (SAR) polarimetric images have  
401 been proven to be effective in burn severity mapping, owing to the strong correlation between SAR backscatter and  
402 burn severity [Czuchlewski and Weissel, 2005; Tanase et al., 2010; Tanase et al., 2011; Addison and Oommen, 2018].  
403 With the unique properties of L-band SAR, it is suitable for assessing and monitoring post-fire effects and burn  
404 severity [Tanase et al., 2010; Peacock et al., 2023]. For example, the frequency of L-band (1.26 GHz) allows it to  
405 penetrate through smoke, ash, and, to some extent, vegetation canopy. This capability makes L-band SAR particularly  
406 useful for assessing areas immediately after a fire, even in the presence of smoke or cloud cover that would obstruct  
407 optical sensors. The incorporation of L-band Synthetic Aperture Radar (SAR) data, such as the ALOS-2 PALSAR-2  
408 ScanSAR Level 2.2 data ([https://www.eorc.jaxa.jp/ALOS/en/alos-2/a2\\_about\\_e.htm](https://www.eorc.jaxa.jp/ALOS/en/alos-2/a2_about_e.htm)) and the incoming NASA-  
409 ISRO Synthetic Aperture Radar (NISAR, <https://nisar.jpl.nasa.gov/>), can also facilitate the retrieval of burn severity.

410 By comparing GFBS with CanLaBS, we found that the number of forest fires in CanLaBS dataset is larger  
411 than those in GFBS. This is because CanLaBS is based on the burn area map from Canada Landsat Disturbance  
412 product at 30 meter resolution, while GFBS is based on the burn area map from Global Fire Atlas which is derived  
413 from MODIS burn area product at 500 meter resolution. This difference in the spatial resolution of the burn area  
414 causes some small forest fires to be ignored in the GFBS dataset. Therefore, finer spatial resolution burn area product  
415 (10/30 meter) is promoted regionally and globally to better reveal the forest fire behavior, e.g. fire number, size and  
416 severity (Roy et al., 2019; Bar et al., 2020). Despite the differences in number of forest fires, GFBS agreed well to  
417 CanLaBS in terms of the annual forest burn severity. While the method to generate GFBS remains consistent, with  
418 the small difference to be ignored in banding settings from Landsat 5, 7 and 8, GFBS provides comprehensive temporal  
419 coverage spanning from 2003 to 2016 for forest burn severity, indicating the potential application of GFBS in long  
420 term analysis of burn severity for forest fires beyond Canada, i.e. regions over the globe, e.g. CONUS, Australia,  
421 where GFBS has been demonstrated to perform well against ground truth. Moreover, integrating the 30 meter GFBS  
422 into the regional forest planning can enhance fire resilience in vulnerable areas, shaping policies that prioritize the  
423 forest environment [Bradley et al., 2016]. As climate change exacerbates the frequency, intensity, and unpredictability  
424 of wildfires globally, the analysis on GFBS data can help to assess the impact of these fires on carbon emissions [Xu  
425 et al., 2020], forest recovery [Meng et al., 2018], and biodiversity [Huerta et al., 2022], which would in turn inform  
426 predictive models that project future fire behavior under various climate scenarios.

## 427 **5. Conclusion**

428 We have introduced a newly developed dataset, named GFBS, which provides forest burn severity information with  
429 global coverage for the period 2003–2016. We identified global forest fires by overlaying the Global Fire Atlas data  
430 with the annual land cover data, MCD12Q1, and proposed an automated algorithm for calculating the severity of these  
431 fires. The algorithm used the band information from Landsat 5, 7, and 8 surface reflectance imagery to compute the  
432 most used burn severity spectral indices (dNBR and RdNBR) with a 30m spatial resolution and provide the output  
433 depicted in the GFBS dataset. Comparison between CanLaBS and GFBS showed good agreement in representing the

434 distribution of forest burn severity over Canada. The validation against field assessed burn severity category data in  
435 southeastern Australia showed that GFBS could provide burn severity estimation with clear differentiation between  
436 the high-severity class and moderate/low severity class of the in situ data, while such differences among burn severity  
437 class were not obvious in the MOSEV dataset. The validation results over CONUS showed dNBR values from GFBS  
438 to be more strongly correlated with CBI ( $r = 0.63$ ) than dNBR from MOSEV ( $r = 0.28$ ). RdNBR from GFBS also  
439 showed better agreement with CBI ( $r = 0.56$ ) than RdNBR from MOSEV ( $r = 0.20$ ). Thus, this database could be more  
440 reliable than prior sources of information for future studies of forest burn severity at global scale, as well as for studies  
441 to which forest burn severity could be relevant, such as in forest management and CO<sub>2</sub> emissions research.

442 A future direction for this study would be to extend the GFBS dataset to the present based on updated Global  
443 Fire Atlas data or other datasets providing global burn area and burn date information. Another direction is to involve  
444 more ground validations from the fire prone areas like south Africa and south Mexico to further evaluate and improve  
445 the performances of GFBS data globally.

446 **Competing interests:** The authors declare they have no conflict of interest.

447 **Data availability:** The GFBS data are freely accessible at <https://doi.org/10.5281/zenodo.10037629> (He et al., 2023)

448 **Author contributions:** KH and EA designed and organized the manuscript. KH and XS prepared the related materials  
449 and ran the models for generating GFBS and the related assessments. XS and EA made contributions to the scientific  
450 framework of this study and discussed the interpretation of the results. All authors discussed the results and  
451 commented on the manuscript.

452 **Acknowledgments:** This research was supported by a National Science Foundation HDR award entitled  
453 “Collaborative Research: Near Term Forecast of Global Plant Distribution Community Structure and Ecosystem  
454 Function.” Kang He received the support of the China Scholarship Council for four years’ Ph.D. study at the University  
455 of Connecticut (under grant agreement no. 201906320068). Thanks for Rachael Gallagher and Eli Bendall from  
456 Western Sydney University for sharing the field assessed fire severity category data over southeastern Australia.
