#### 36 **Abstract**

37 International efforts to assess the status of marine ecosystems have been hampered by insufficient  
38 observations of food web interactions across many species, their various life stages, and geographic  
39 ranges. Hence, we collated data from multiple databases of fish stomach contents from samples taken  
40 across the North Atlantic and Arctic Oceans containing 944,129 stomach samples from larvae to  
41 adults, with 14,196 unique interactions between 227 predator species and 2158 prey taxa. We use  
42 these data to develop a data-driven, reproducible approach to classifying broad functional feeding  
43 guilds and then apply these to fish survey data from the Northeast Atlantic shelf seas to reveal spatial  
44 and temporal changes in ecosystem structure and functioning. In doing so, we construct predator-  
45 prey body size scaling models to predict the biomass of prey functional groups, e.g., zooplankton,  
46 benthos, and fish, for different predator species. These predictions provide empirical estimates of  
47 species- and size-specific feeding traits of fish, such as predator-prey mass ratios, individual prey mass,  
48 and the biomass contribution of different prey to predator diets. The functional groupings and feeding  
49 traits provided here help to further resolve our understanding of interactions within marine food webs  
50 and support the use of trait-based indicators in biodiversity assessments. The data used and  
51 predictions generated in this study are published on the Cefas Data Hub at:  
52 <https://doi.org/10.14466/CefasDataHub.149> (Thompson et al., 2024).

53

54 Keywords: feeding guilds; species traits; marine ecosystem structure and functioning; food web  
55 indicator; biodiversity; trophic interactions; stomach contents data.

56

## 57 1 Introduction

58

59 Human pressures are affecting global patterns in marine ecosystem structure and functioning, from  
60 species distributions and their body sizes, to how and where energy fluxes through food webs  
61 (Daufresne et al., 2009; du Pontavice et al., 2020; Kortsch et al., 2015). Grouping organisms into broad  
62 functional feeding guilds and assessing change in their populations has been widely advocated to  
63 assess marine ecosystem status, gauge sustainable levels of human pressure, and inform management  
64 interventions (ICES, 2018; Rombouts et al., 2013; Tam et al., 2017). Yet, international efforts to  
65 develop indicators of marine ecosystem status have been hampered by the large number of  
66 observations needed to understand food web processes involving many species, their various life  
67 stages, and geographic ranges.

68 Despite the complexity of natural food webs, their structure and dynamics are largely determined by  
69 the size of the interacting organisms because predators are systematically larger than their prey,  
70 especially in aquatic ecosystems (Brose et al., 2006; Petchey et al., 2008; Woodward et al., 2005). The  
71 behaviour of organisms relating to their evolutionary history, including adaptations for specific  
72 foraging strategies and habitats, also affects predator-prey interactions (Brose et al., 2019; Link, 2004;  
73 Pecuchet et al., 2020; Pomeranz et al., 2019). Fish fulfil many different roles in an ecosystem (Katara  
74 et al., 2021), often starting life as planktivores which feed lower in the food web, with some species  
75 developing into intermediate (e.g., benthivores) and higher predator feeding guilds (e.g., piscivores)  
76 which consume larger prey as they grow. Fish feeding guild biomasses are also responsive to human  
77 pressures including fishing and climate change (Garrison & Link, 2000a, 2000b; Thompson et al., 2020).  
78 Analysing change in fish feeding guild biomass can, therefore, provide simultaneous information on  
79 ecosystem structure and functioning, by revealing temporal change in the spatial distribution of, e.g.,

80 planktivore biomass (structure) which is also indicative of change in energy flux between plankton and  
81 fish (functioning). Change in feeding guild species richness provides a measure of functional  
82 redundancy where, for instance, relatively low and decreasing values highlight areas where a function  
83 is supported by only a few species and is at risk.

84 Internationally coordinated surveys with observations on fish species distributions, body sizes and  
85 biomass provide extensive data to assess change in fish feeding guilds (Lynam & Ribeiro, 2022).  
86 Complementing these, many fish stomach content data that contain information on food web  
87 interactions have been collected across the North Atlantic and Arctic Oceans (Arroyo et al., 2017;  
88 Cachera et al., 2017; ICES, 1997; Pinnegar, 2019; Smith & Link, 2010; Torres et al., 2013). However,  
89 idiosyncrasies in how feeding information has been quantified and reported across different stomach  
90 content databases have hampered efforts to depict general feeding traits. Specifically, four feeding  
91 guilds relevant to fish are used in OSPAR (The Convention for the Protection of the Marine  
92 Environment of the North-East Atlantic) and EU's MSFD (Marine Strategy Framework Directive)  
93 reporting processes, but without an agreed, data-driven method to categorise predators into them  
94 (i.e., planktivores, sub-apex demersal, sub-apex pelagic and apex predators; Boschetti et al., 2021;  
95 Walmsley et al., 2016; see also [https://oap.ospar.org/en/resource-catalogue/enumeration-  
96 tables/cemp-enumeration-tables/](https://oap.ospar.org/en/resource-catalogue/enumeration-tables/cemp-enumeration-tables/)). Any macroecological assessment of feeding guilds may therefore  
97 be confounded because changes could have a methodological basis. This has constrained the  
98 contribution of food web indicators to marine ecosystem status assessment.

99 The body size scaling relationship between predators and their prey offers a means to depict general  
100 feeding traits across many species, their various life stages, and geographic ranges that have so far  
101 been lacking. Predator-prey body size scaling is also important to measure empirically because it can  
102 affect the pathway and quantity of energy flux through a food web (Barnes et al., 2010; Brose et al.,  
103 2019; Nakazawa et al., 2011; Schneider et al., 2012). Predators feeding on relatively small prey with  
104 high predator-prey mass ratios (PPMR) can dampen strong oscillatory dynamics and thus help to  
105 maintain stability in food webs (Otto et al., 2007; Rooney et al., 2006) and ecosystem functioning

106 (Nakazawa et al., 2011; Schneider et al., 2012; Wang & Brose, 2018). Moreover, both predator and  
107 prey taxonomy and their traits can be used to predict interactions with typically high PPMRs that may  
108 be particularly important (Brose et al., 2019; Reum et al., 2019). For instance, we anticipate that  
109 planktivorous and benthivorous fish will have some of the highest PPMRs, especially those that remain  
110 in the same feeding guild through ontogeny, while fish species which develop into piscivores could  
111 see the largest change (a decrease) in their PPMR across their body size range.

112 Here we make use of predator-prey body size scaling relationships to draw on multiple stomach  
113 content databases and derive comparable fish feeding trait information for the North Atlantic and  
114 Arctic Oceans. This new data collation contains observations from 944,129 fish stomachs collected  
115 between 1836 - 2020. We use these feeding traits to categorise fish into feeding guilds in a way that  
116 is conducive to their application internationally, across ecosystems. Feeding guilds are then applied to  
117 survey data collected from across the northeast Atlantic shelf seas to demonstrate macroecological  
118 patterns in ecosystem structure and functioning relevant to status assessment advocated by OSPAR.  
119 We test the following hypotheses: i) intra and interspecific body size scaling for predator species is  
120 dependent on prey group (e.g., plankton, benthos, and fish prey); ii) multiple distinct feeding guilds  
121 are evident based on feeding trait data; iii) feeding guilds capture significant spatio-temporal trends  
122 in survey data. Our aim was twofold: to generate empirical estimates of fish feeding traits that could  
123 help improve understanding of changes in marine ecosystem structure and functioning; and to achieve  
124 international consensus on the best approach to assessing feeding guilds across ecosystems within  
125 the OSPAR Maritime Area and in a way that can be readily extended to other areas (e.g., Northeast  
126 US continental shelf) and organisms (e.g., invertebrates and mammals).

127

## 128 2 Methods

129

### 130 2.1 Stomach contents data

131

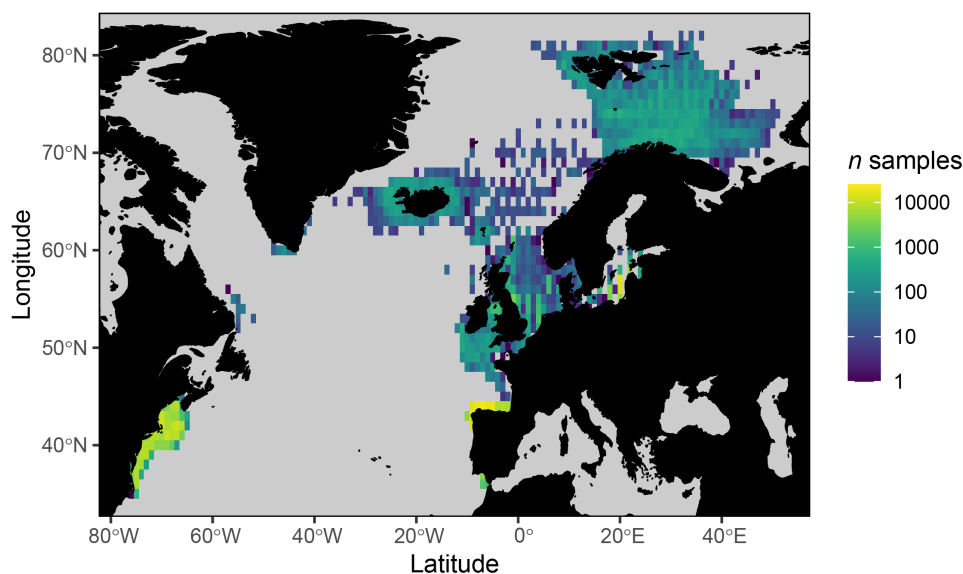

132 We draw together stomach contents data primarily collected from the North Atlantic shelf seas, with  
133 important contributions from the Baltic, Barents and Norwegian Seas (Fig. 1, S1). These data were

134 sourced from a combination of previously published and unpublished data including DAPSTOM  
135 (Pinnegar, 2019), ICES Year of the Stomach (Daan, 1981; ICES, 1997), the Northeast US continental  
136 shelf (Smith & Link, 2010), Northern Spanish shelf (Arroyo et al., 2017), Gulf of Cadiz (Torres et al.,  
137 2013), Swedish-, Icelandic-, Norwegian-, French- (Cachera et al., 2017; Timmerman et al., 2020;  
138 Travers-Trolet, 2017; Verin, 2018) and German-led surveys (e.g., FishNet, [https://www.nationalpark-  
139 wattenmeer.de/wissensbeitrag/fishnet/](https://www.nationalpark-wattenmeer.de/wissensbeitrag/fishnet/)). We have included stomach contents data from outside the  
140 OSPAR Area (i.e., Northeast US continental shelf and Baltic Sea) to demonstrate the wider applicability  
141 of our approach to defining feeding guilds and because those data have been used to classify feeding  
142 guilds previously (Garrison & Link, 2000a). The full data collation contains observations from larvae  
143 (<1 g) to adults (up to 351 kg), representing 14,196 unique interactions between 227 predator species  
144 and 2158 prey taxa (<https://doi.org/10.14466/CefasDataHub.149>; Thompson et al., 2024). We provide  
145 a summary of data sources, spatial and temporal ranges, and sample distributions in Table 1. All data  
146 processing and subsequent analyses were conducted in R version 4.02 (R Core Team, 2020). Predator  
147 and prey taxonomy were processed using the “taxize” package (Chamberlain et al., 2020) and assigned  
148 to ‘zooplankton’, ‘benthos’, ‘fish’, ‘nekton’ and ‘other’ functional groups after Webb & Vanhoorne  
149 (2020) using the “worrms” package (Chamberlain, 2019).

157

158 2.2 Quantifying intra- and interspecific body size scaling relationships between predators and  
 159 different prey functional groups

160

161 Prey count and biomass observations (wet weight in grams) are needed to estimate predator-prey

162 mass ratios (PPMR), but these were available for only 56% of the stomach contents data. Therefore,

163 to make use of all the data (Fig. 1; Table 1) when assigning fish to feeding guilds, a linear mixed effect

164 model of predator-prey body size scaling was constructed to estimate prey counts or biomass where

165 either were unavailable; using only data where taxonomy for both predator and prey was resolved  
166 (i.e., to species and functional group, respectively), and predator body size, prey body size and prey  
167 counts were all available. Major axis regression following Brose *et al.* (2019) was not suitable because  
168 we needed to make predictions of prey body size and minimise the squared residuals in the response  
169 (Legendre, 1998).  $\log_{10}$  transformed individual prey mass (wet weight in g) was fit as the response,  
170 with an interaction term between  $\log_{10}$  transformed predator body mass (wet weight in g). Random  
171 intercepts and slopes were fit for both predator taxa or prey functional group to test if either  
172 interacted with predator body mass. Random intercepts were fit for datasets to test for systematic  
173 differences in how data were generated: grouped into those from Spain, USA, and ICES, which each  
174 follow their own protocols for measuring prey biomass, and all others which represent a mixture of  
175 methods from across studies. Random intercepts were also fit for years, sites (a 3 by 3 grid across the  
176 study area based on splitting the gradients of longitude and latitude into 3 equal lengths; Fig S1) and  
177 the number of stomachs sampled with two levels, 1 = from multiple stomachs and 2 = were stomach  
178 samples were pooled (some stomach samples contained in DAPSTOM and ICES Year of the Stomach  
179 were pooled at the point of collection for size classes of predator species). We use a Student's t-  
180 distribution to account for heavy tails in the distribution of the response. The Akaike Information  
181 Criterion (AIC) was used on nested models to assess the importance of all predictors. The full model  
182 had the lowest AIC by >2 units meaning all predictors were retained (Table S1). Model diagnostic plots  
183 were performed using the R package *DHARMA* (Hartig, 2022).

184 The 'full' model was used to predict the mean individual body mass of prey functional groups for  
185 predator species of a given size. This enabled us to make use of many observations in DAPSTOM, for  
186 instance, which have recorded prey counts but no prey biomass. In such cases, we estimated the  
187 biomass of each prey taxa by multiplying the predicted mean individual body mass for their functional  
188 group by the observed prey count. Where prey counts were missing, e.g., much of the data from Smith  
189 & Link (2010; USA data in Fig. S1), we estimate these by dividing the observed biomass of each prey  
190 taxa by the predicted mean individual prey mass for their functional group. We provide R script and

191 the data underlying our model, with an example showing how to predict individual prey size based on  
192 a list of predator taxa, predator sizes and prey functional groups  
193 (<https://github.com/MurraySAThompson/fish-feeding-traits-glm>). Our full model has temporal and  
194 spatial information as random effects because we were interested in developing general feeding traits  
195 for the study area, irrespective of spatial and temporal gradients. However, the significance of spatial  
196 and temporal random effects (Table S1) suggests future work exploring environmental change drivers  
197 of predator-prey scaling could be fruitful. All linear mixed effects models were fit using the *glmmTMB*  
198 R package (Brooks et al., 2017).

199

### 200 2.3 Classifying predator feeding guilds based on feeding trait data

201

202 Predators were categorised by species and size. We use 20 equal size bins to categorise predator mass  
203 along a  $\log_{10}$  transformed gradient from 0.1 micrograms to 190 tonnes, capable of capturing organisms  
204 from plankton to blue whales (Table S2). Data for each species size class was then estimated across all  
205 available stomach samples (Fig. 1; Table 1), with means calculated for % prey functional group  
206 biomass, biomass weighted PPMR (after Reum et al., 2019) and mean individual prey mass (Table S3).  
207 We used directly observed data where available and predictions from our predator-prey body size  
208 scaling models where data were missing. Feeding guilds were assigned based on cluster analysis using  
209 the 'ward D2' agglomeration method on Bray-Curtis dissimilarities between predator diets available  
210 in the R *stats* package (R Core Team, 2020).

211 We compared different methods to classifying feeding guilds where the dissimilarity matrix used in  
212 the cluster analysis was generated using either: 1) the biomass of prey taxa (Garrison & Link, 2000a);  
213 2) prey taxa occurrence (Thompson et al., 2020) or; 3) via a novel method where dissimilarities are  
214 based on broad feeding traits (henceforth, the biomass, occurrence and trait methods). Feeding traits  
215 were  $\log_{10}$  transformed mean individual prey mass (g),  $\log_{10}$  transformed mean biomass weighted  
216 PPMR, and the mean % biomass contribution to the stomach contents of zooplankton (including fish  
217 <0.5g), benthos, nekton (other than fish) and fish (all fish prey  $\geq$  0.5g); with all variables rescaled to

218 values of or between 0 and 1. We tested for differences between these methods to classifying feeding  
219 guilds by comparing them after re-sampling ( $n = 1000$ ) subsets of the data ( $n = 30$  unique stomach  
220 samples per predator). Predators with fewer than 30 samples were not classified into feeding guilds.  
221 Compositional change in predators between successively reclassified feeding guilds was used to  
222 determine the ability of each method to consistently classify similar predators in the same guild.  
223 Compositional change was measured using the distance to centroid following analysis of multivariate  
224 homogeneity of groups dispersions (Anderson, 2006). The method with the lowest mean distance to  
225 centroid was determined to have the most robust feeding guild classifications as determined using  
226 analysis of variance tests. First, we tested whether compositional change across feeding guilds was  
227 non-random for each method: distance to centroid (i.e., compositional change) was the response,  
228 with 'Guild', and 'Data' (i.e., a factor identifying each unique re-sampling event) as predictors. We then  
229 tested for significant differences between methods: distance to centroid (i.e., compositional change)  
230 was the response, with 'Method', 'Guild', and 'Data' as predictors. Significant predictors were  
231 determined using the *F*-test on nested models. Targeted tests for differences between the mean  
232 distance to centroid across methods were carried out using Tukey's all-pairwise comparisons that  
233 corrects for multiple comparisons in the "multcomp" package (Hothorn et al., 2016).  
234 The ability to classify common feeding guilds across ecosystems (e.g., sub-apex and apex predators)  
235 rather than area-specific guilds (e.g., a feeding guild unique to the North Sea) is another important  
236 quality for a feeding guild indicator to exhibit. We assessed how important spatial gradients were in  
237 our three different approaches to classifying feeding guilds. First, we generated latitudinal and  
238 longitudinal coordinate centroids for each predator by taking a mean across their stomach samples.  
239 We then took a mean across these predator centroids to generate a centroid for all the data, and also  
240 means across these predator centroids but grouped by feeding guild and method to generate method-  
241 specific guild centroids. Next, we measured the distance between the overall data centroid to the  
242 method-specific guild centroids using the *geosphere* package (Hijmans et al., 2021) and summed  
243 distances for each method. A large sum of distances for a method to the overall data centroid would

244 indicate that feeding guilds were area-specific, largely made up of predators found close together, and  
245 thus spatial gradients would be important determinants of feeding guild structure. The method with  
246 the lowest sum of distances to the overall data centroid was deemed to be least affected by spatial  
247 gradients and thus preferred.

248 Four feeding guilds have been called for in OSPAR and MSFD guidance, i.e., planktivores, sub-apex  
249 demersal, sub-apex pelagic and apex predators (Boschetti et al., 2021; Walmsley et al., 2016; see also  
250 <https://oap.ospar.org/en/resource-catalogue/enumeration-tables/cemp-enumeration-tables/>),

251 without consensus on how to categorise predators into these guilds. We use four feeding guilds here  
252 to help bridge this gap and so that we can elegantly capture a broad set of ecosystem components  
253 while exploring guild responses in biomass and species richness in the survey data. Changing the  
254 number of feeding guilds could be justified, depending on the question, and is straightforward to  
255 implement by taking a higher or lower split in the classification tree. We see this as a strength of our  
256 approach because feeding guilds are hierarchically structured much like how taxonomic or other trait  
257 information has been organised. We provide a table which details the branches for up to five feeding  
258 guilds so future assessments can choose which level of complexity suits their need. We also present  
259 axis scores from a non-metric multidimensional scaling analysis of the dissimilarities used in our  
260 cluster analysis which provide a more nuanced understanding (i.e., bounded data as opposed to  
261 categorical) of different predator feeding traits in relation to others. Moreover, because it is a data-  
262 driven, reproducible approach, new information can be systematically integrated to 1) further resolve  
263 differences in feeding traits, 2) feeding guild composition and 3) test if changes in predator feeding  
264 traits provides evidence for spatially or temporally flexible classifications.

265

#### 266 2.4 Using feeding guilds to capture spatiotemporal trends in survey data

267

268 The new feeding guild classifications have been applied to processed otter trawl survey data for the  
269 Northeast Atlantic shelf seas collected between 1997–2020 (Lynam & Ribeiro, 2022) to reveal spatial  
270 and temporal patterns in feeding guild responses. These survey data have been processed specifically

271 to support state indicators, with observations for the biomass of species size classes standardised to  
272 the area swept for each haul. Survey data corresponding with all our stomach content data, from north  
273 of Norway, Icelandic waters, the Baltic Sea and eastern shelf seas of the USA, have not yet been  
274 standardised and processed in the same way, hence why we haven't included them here. Extending  
275 this work to assess change in ecosystem structure and function across the study region covered by the  
276 stomach contents data (Fig. 1) represents a key area for future development.

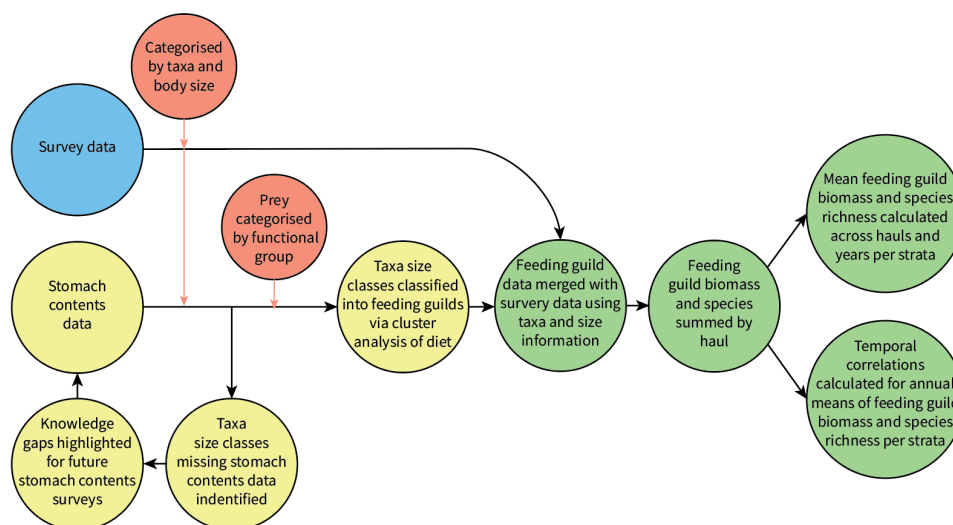

277 Compared with quarter 2 and 3 (April – September), data from quarters 1 and 4 (January-March and  
278 October – December, respectively) typically have longer time-series available over much of the study  
279 region and so were preferentially selected. Where data from quarters 1 or 4 were not available, otter  
280 trawl data from other quarters were used. Table S4 provides information on the surveys used and  
281 their spatial and temporal ranges. The temporal assessment covers 1997-2020 because the majority  
282 of the surveys considered have at least a near complete time-series covering that period. Longer time-  
283 series do exist for some surveys but including these data would mean we are looking at long-term  
284 change for some areas, but shorter-term change for others which could confound interpretation.

285 Spatial and temporal change in feeding guild responses were determined for the Greater North Sea,  
286 Celtic Seas, Bay of Biscay and Iberian Coast, and the wider Atlantic. The assessment strata used here  
287 replicate those used for the OSPAR food web indicators: mean-maximum length and size-composition  
288 in fish communities (Lynam et al., 2022; Lynam & Piet, 2022).

289 Kendall's  $\tau$  trend analysis was used to identify areas of significant temporal change in feeding guild  
290 responses based on the relationship between mean haul-level values of feeding biomass and species  
291 richness for each assessment strata and year. Kendall's  $\tau$  scores of  $-1$  to  $+1$  represent a 100%  
292 probability of a decreasing or increasing trend, respectively. By using Kendall's  $\tau$ , which is rank-based  
293 and non-parametric, we can detect correlations which may be non-linear. Stomach contents data,  
294 prey size predictions, haul-level estimates of feeding guild biomass and their species richness along  
295 with Kendall's  $\tau$  correlation coefficients and  $p$  have all been made available  
296 (<https://doi.org/10.14466/CefasDataHub.149>; Thompson et al., 2024).

### 3 Results

305

306

#### 3.1 Unique intra- and interspecific body size scaling relationships between predators and prey functional groups

307

308

309

There were significant differences in the  $\log_{10}$  transformed scaling relationship between predator and prey body mass captured by the interactions between predator body mass and predator species and

310

prey functional group combinations (Fig. 3). These results support our first hypothesis that predator

311

species can have unique intra- and interspecific body size scaling relationships with different prey

312

functional groups. Fish prey tended to be the biggest, meaning fish-fish interactions tended to have

313

higher intercepts and slopes (Fig. 3a, c, d, h) and thus the lowest mean PPMR, with predator species

314

of the same size consuming relatively small benthic and zooplankton prey (Fig. 3b, e, f, g, i, j, k, l).

315

These models enabled us to estimate prey biomass, counts and predator-prey mass ratios across the

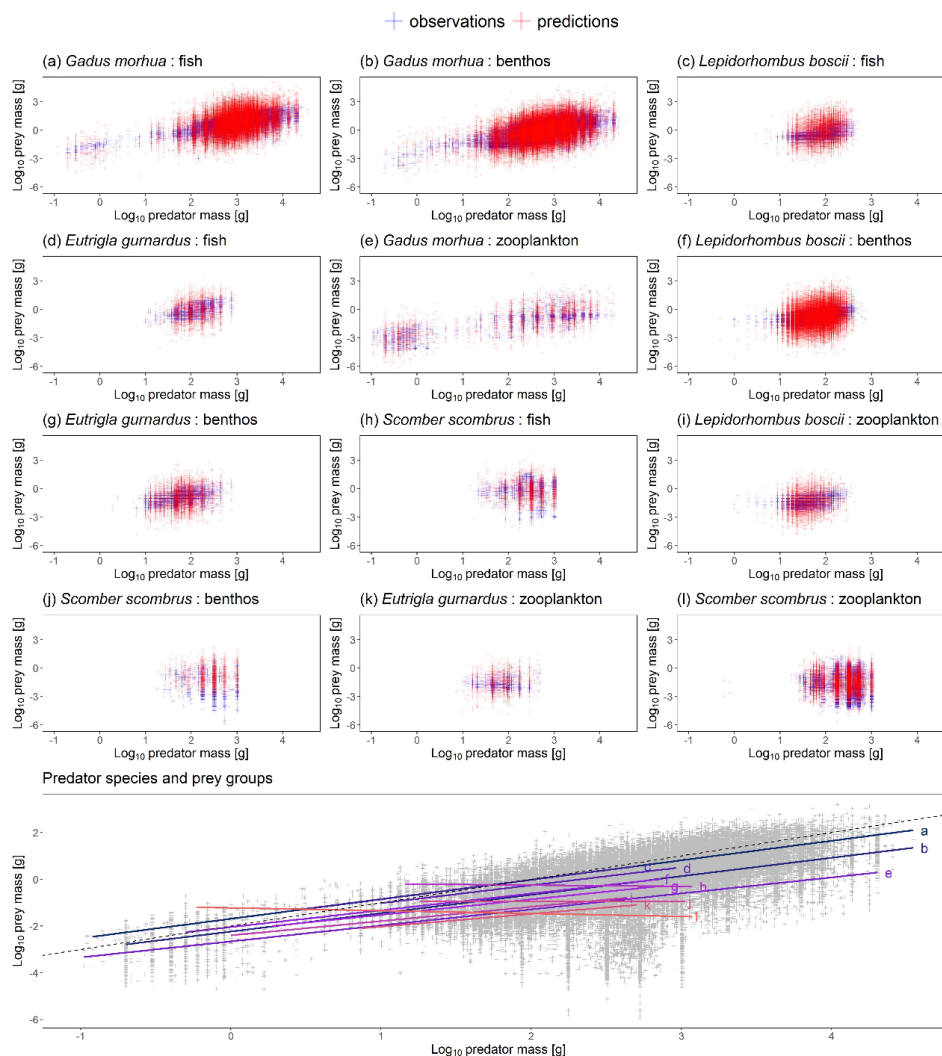

316

different stomach contents datasets, species and size classes useful for feeding guild classifications

317

(Table S3).

318

319  
 320 Figure 3: A subset of the 498 unique combinations of predator species and prey functional group body  
 321 mass scaling relationships on  $\log_{10}$  transformed axes. Blue points = observed values for specific  
 322 relationships, red points = model predictions for specific relationships, grey points = all observed  
 323 values. The final plot 'Predator species and prey groups' shows the different scaling relationships  
 324 across the preceding plots, ordered by prey size at maximum predator size with a dashed 1:1 line to  
 325 show scaling relationships were generally sublinear (i.e., prey increased less than their predators per  
 326 unit increase in body size).  
 327

328 3.2 Feeding trait data reveal multiple distinct feeding guilds

329

330 Feeding guilds captured significant variation in the composition of predators for each cluster-based

331 method (Table 2), confirming our second hypothesis that multiple feeding guilds can be delineated

332 from the analysis of feeding traits. The occurrence method had the most robust feeding guilds with  
333 the lowest compositional change in predators following re-sampling (mean distance to centroid =  
334 0.13), followed by the trait (mean distance to centroid = 0.22) and then the biomass methods (mean  
335 distance to centroid = 0.34; randomly generated feeding guild mean distance to centroid ranged  
336 between 0.6 – 0.61; Fig. S2; Table S5). The trait method had the lowest sum of distances to the data  
337 centroid (2,655 km) followed by the biomass (7,034 km) and occurrence methods (8757 km; Fig. S3).  
338 The trait method was therefore preferred because it could identify multiple distinct feeding guilds  
339 even where we consider small subsets of predator stomach contents ( $n = 30$  stomach samples) while  
340 being the least affected by spatial gradients in prey taxa.

341 The four feeding guilds identified using the trait method have been named based on the % biomass of  
342 prey functional groups as follows: planktivores, benthivores, benthopiscivores and piscivores (Fig. 4).  
343 Differences between feeding guilds were related to predator size, which correlated positively with  
344 piscivory and negatively with planktivory (Fig. S4). Small size classes of species often occur in the  
345 planktivore guild, moving to another guild as they increase in size, with multiple medium- to larger  
346 size-classes of a species often in the same guild (Table S3). Typically, the biggest fish within and across  
347 feeding guilds had the highest PPMR (hence the sublinear relationship in Fig. 3, where prey increased  
348 less than their predators per unit increase in body size), yet piscivores were typically the biggest and  
349 had the lowest PPMR on average. This apparent contradiction is largely because small piscivores had  
350 some of the lowest PPMR values, whereas big planktivores and benthivores had some of the highest  
351 values (Fig. 4; Table S3).

352

353

354

355

356

357

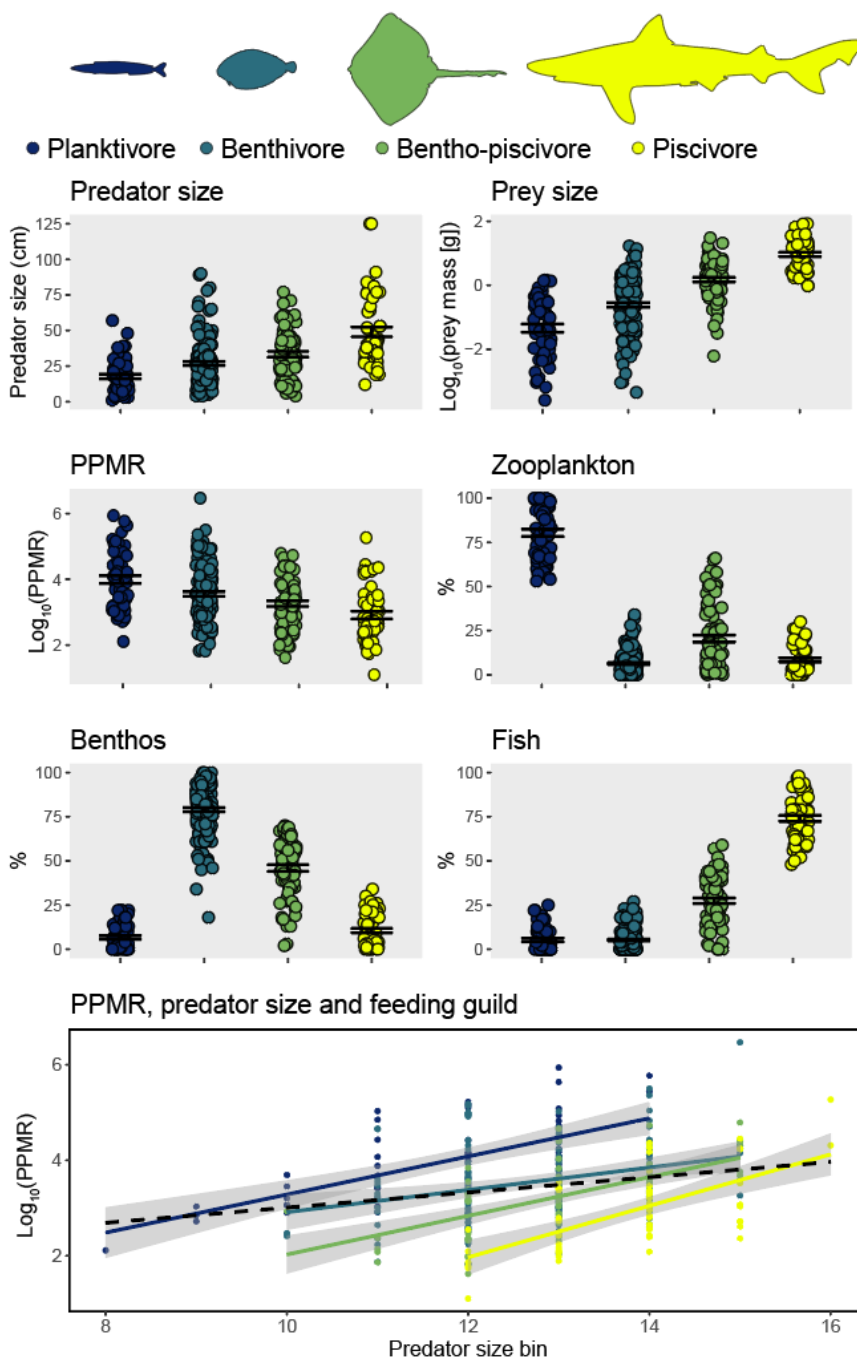

358 Table 2. Analysis of variance results across nested models for each cluster-based method and across  
 359 methods. Data for biomass, occurrence and trait methods were used to test whether guild (i.e.,  
 360 cluster-based groups) and data (i.e., a factor identifying each unique re-sampling event) captured  
 361 significant variation in the composition of predators. Data for all was used to test for differences  
 362 between the different methods (see also Table S5; Fig. S2). The term dropped column indicates which  
 363 term was dropped from each model (blanks indicate no predictors were dropped), AIC reveals change  
 364 in model fit, and *p*-values from *F*-tests highlight significant change in model fit.

366  
 367 Figure 4: Differences between feeding guilds in predator size, individual prey size, predator-prey mass  
 368 ratio (PPMR) and the % biomass contribution of different prey functional groups to stomach contents.  
 369 Points represent means for species size classes (Table S3), error bars represent standard error. Bottom  
 370 panel: PPMR increases with predator body size within (solid, coloured) and across (black, dashed line)  
 371 feeding guilds.

372 3.3 Feeding guilds capture significant spatiotemporal trends in survey data

373

374 When assigning feeding guilds in the survey data, we were able to classify 92% of the biomass which

375 included 122 species size classes. Many rare predators observed in the survey data ( $n = 366$ ,

376 representing 8% of the surveyed biomass) remain unclassified due to insufficient stomach contents

377 data (Table S6). The perspective of change in the survey data is therefore weighted towards predators

378 contributing most to community biomass and ecosystem functioning. We found clear spatial structure

379 and regions of contrasting temporal change in feeding guild biomasses and their species richness (Figs.

380 5-6), confirming our third hypothesis. For instance, significant and spatially extensive temporal

381 decreases in planktivore feeding guild biomass lower in the food web were evident in the Celtic Seas

382 and Bay of Biscay where the biomass of the bentho-piscivore and piscivore feeding guilds higher in

383 the food web has increased (Fig. 5). Benthivore biomass has increased in the southern North Sea,

384 where there has been little change in other feeding guilds. Planktivore, bentho-piscivore and piscivore

385 biomass have all decreased in at least one assessment strata in the northern North Sea. Regions of

386 temporal change in species richness were also different across feeding guilds (Fig. 6). For instance,

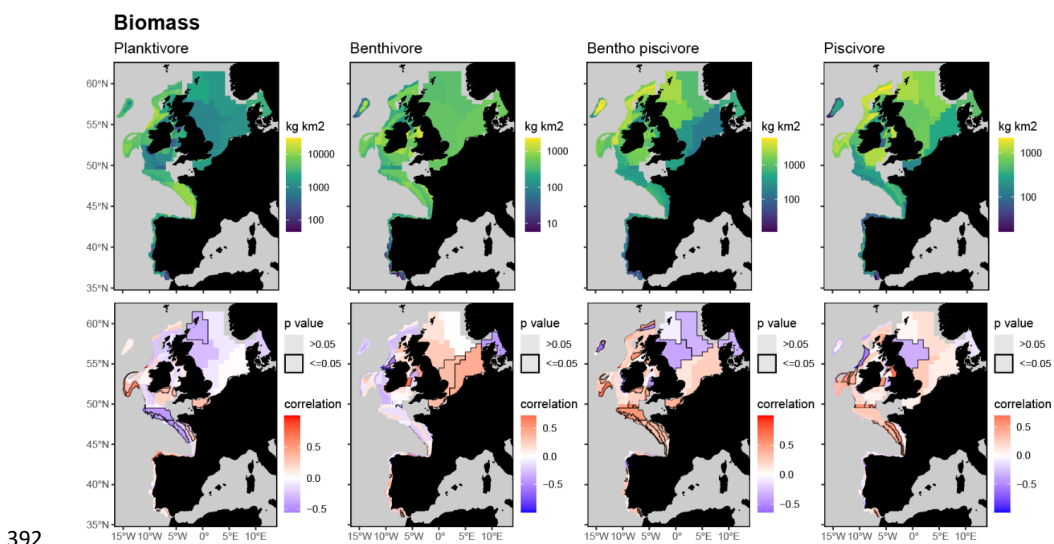

387 over large areas in the Celtic Seas, Bay of Biscay and northern North Sea where there was relatively

388 limited change in planktivore species richness, the species richness of benthivores, benthopiscivores

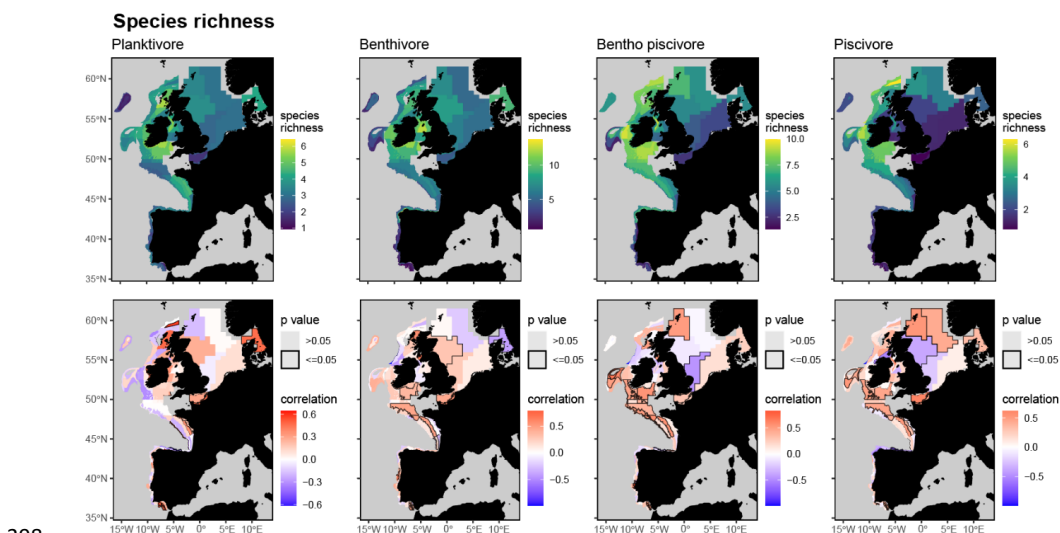

389 and piscivores all increased (see Fig. S5 for changes in unclassified biomass).

390

391

393 Figure 5: Mean spatial distribution (top row) and temporal change (bottom row) in feeding guild  
 394 biomass by assessment strata based on otter trawl data. Significant temporal trends are highlighted  
 395 with a black border and coloured blue or red to depict a decreasing or increasing trend, respectively  
 396 (Kendall's  $\tau$  scores of  $-1$  to  $+1$  represent a 100% probability of a decreasing or increasing trend).  
 397

399 Figure 6: Mean spatial distribution (top row) and temporal change (bottom row) in feeding guild  
 400 species richness by assessment strata based on otter trawl data. Significant temporal trends are  
 401 highlighted with a black border and coloured blue or red to depict a decreasing or increasing  
 402 trend, respectively (Kendall's  $\tau$  scores of  $-1$  to  $+1$  represent a 100% probability of a decreasing or increasing  
 403 trend).  
 404

#### 405 4 Discussion

406

407 Our predator-prey body size scaling models enabled predictions of mean individual prey mass for  
408 different predator species and prey functional groups across the Atlantic and Arctic Oceans. With  
409 these predictions we could estimate key fish feeding traits across species and sizes, such as predator-  
410 prey mass ratios and the relative biomass contribution of zooplankton, benthos and fish prey to  
411 predator diets. Our feeding trait-based approach to categorising feeding guilds was also less  
412 susceptible to large spatial gradients in the composition of prey than previously used methods  
413 (Garrison & Link, 2000a; Thompson et al., 2020). By using feeding guilds to assess routinely collected  
414 survey data, we revealed contrasting patterns of change in the biomass and species richness of fish  
415 feeding at different levels within the food web across the Northeast Atlantic shelf seas. For example,  
416 extensive decreases in the biomass of consumers lower in the food web (planktivores) were evident  
417 in the Celtic Seas and Bay of Biscay and this contrasted with biomass increases higher up (bentho-  
418 piscivores and piscivores; Fig 5). These contrasting patterns of change in how biomass and species are  
419 distributed across the food web indicate regions of temporal change in marine ecosystem structure  
420 and functioning as the relative importance of different energy pathways changes across the fish  
421 assemblage. This is because changes in species richness and the distribution of biomass across the  
422 food web can influence nutrient uptake and the efficiency of communities in converting nutritional  
423 resources into biomass (Cardinale et al., 2012; Wang & Brose, 2018; Worm et al., 2006).

424 A wide range of prey sizes could be consumed by a given predator species and size and this variability  
425 was generally captured well by our models (Fig. 3). Omnivory was also ubiquitous with all prey groups  
426 occurring in the diet of all feeding guilds, albeit to markedly different levels (Fig. 4; Table S3). This,  
427 along with the variability in our re-sampled feeding guild classifications (Fig. S2), highlights the  
428 plasticity of fish feeding behaviour with some individuals of, e.g., a typically planktivorous species  
429 having consumed mostly fish prey. Feeding guilds provide a necessary simplification of this complexity  
430 as a means to indicate change in marine food webs across ecosystems by taking the typical behaviour  
431 of a species size class. We have also provided more nuanced information, including empirical

432 estimates of predator-prey mass ratios, relative contributions of different prey groups, and from  
433 multivariate analysis on the dissimilarity of species size class feeding traits (Table S3; Fig. S4) which  
434 could help further unpick what such change means. This information is also widely applicable for  
435 quantifying and predicting the effects of different fishing and climate regimes where changes in the  
436 distribution of species and body sizes are anticipated (Kleisner et al., 2016; Lotze et al., 2019; Spence  
437 et al., 2021; Thompson et al., 2023).

438 Previous studies which identified feeding guilds used differing approaches, relied on a subset of the  
439 stomach contents data we use here and assessed different survey data to one-another (Garrison &  
440 Link, 2000a, 2000b; Thompson et al., 2020). It was therefore not clear which method would be optimal  
441 as an indicator across ecosystems. Moreover, differences in how feeding trait information has been  
442 quantified and reported has hampered the synthesis of stomach contents data. Here, we brought  
443 those different stomach contents data together by developing models to predict prey biomass and  
444 counts where information was missing. We were then able to compare different approaches to  
445 classifying feeding guilds across the datasets and apply the optimal approach to the same survey data.  
446 This approach has helped achieve international consensus on how to assess feeding guilds across  
447 ecosystems within the OSPAR Area (Thompson, Lynam, et al., 2023). The work we present here  
448 represents a development of that pilot indicator, with improvements in how we estimated prey  
449 weights (i.e., improved modelling framework that made use of more stomach contents data) which  
450 affected feeding guild classifications; and the use of Kendall's  $\tau$  trend analysis on the classified survey  
451 data (as opposed to Pearson's correlation coefficients) in order to detect correlations which may be  
452 non-linear. Many of the temporal patterns we present here are similar to those in the pilot indicator.  
453 The most notable differences appear for feeding guild species richness where values were relatively  
454 low (i.e., where relatively little change could have a large influence) in the central and northern North  
455 Sea.

456 We use a trend-based assessment rather than one based on reference limits. Setting thresholds for  
457 feeding guilds was outside the remit of this study and will require reference limits for Good

458 Environmental Status to be established. This could be done through synthesising empirical evidence  
459 on feeding guild response to environmental change and human pressure (e.g., following Garrison &  
460 Link, 2000b; Thompson et al., 2020) with dynamical modelling capable of predicting ecosystem state  
461 under varying levels of human pressure (Link et al., 2010; Rossberg et al., 2017; Samhouri et al., 2010),  
462 for instance. Such work would benefit from data products capable of integrating information from  
463 different surveys, e.g., acoustic and various trawl gears, that catch a broad range of species and sizes  
464 including smaller pelagic species which are likely under-sampled by demersal trawls (Kotwicki et al.,  
465 2018; Nnanatu et al., 2020). Developing understanding of the drivers in spatial and temporal change  
466 in fish feeding behaviour (Table S1) could also be fruitful, potentially leading to the quantification of  
467 energy fluxes from different habitats (e.g., benthos and pelagic), regions, species, and seasons, for  
468 instance. Such work could help develop understanding of the connections between the wider suite of  
469 indicators which draw on different assemblages and often rely on data collected at different times and  
470 at different spatial scales (e.g., Preciado et al., 2023). The inventory of feeding interactions could also  
471 continue to develop, e.g., via surveys targeting areas and predators with limited information (e.g., Fig.  
472 S5; Table S6), via DNA metabarcoding of stomach contents (Jakubavičiute et al., 2017), inference from  
473 similar predators (Gray et al., 2015; Hicks et al., 2019), biotracers (Pethybridge et al., 2018) and  
474 predictive modelling (Hervann et al., 2022; Link, 2004; Petchey et al., 2008). Variability in digestion  
475 rates driven by environmental gradients such as temperature and differences in prey sizes and tissue  
476 composition could also be modelled to help improve estimates of biomass flux across the food web  
477 (Temming & Herrmann, 2003).

478 Using change in functionally distinct feeding guilds to assess environmental status has been widely  
479 advocated to fulfil OSPAR and the Marine Strategy Framework Directive requirements (Boschetti et  
480 al., 2021; ICES, 2018; Rombouts et al., 2013; Tam et al., 2017; Walmsley et al., 2016), but international  
481 consensus on how to do this has been lacking. We drew together data and expertise from across the  
482 North Atlantic and Arctic Oceans to help achieve this. In doing so, we have made empirical estimates  
483 of a range of key fish feeding traits that are widely applicable in marine ecosystem science, identified

484 robust feeding guilds, and revealed how and where ecosystem structure and function was changing  
485 across the OSPAR Area. Such information will be critical to help better quantify and predict the effect  
486 of human pressures, such as fishing and climate change, on global patterns in marine ecosystem  
487 structure and functioning.

488

## 489 5 Conclusions

490

491 We make use of multiple stomach contents databases to predict species- and size-specific feeding  
492 traits for fish across the North Atlantic and Arctic Oceans. We then developed a repeatable, data-  
493 driven workflow that categorises fish based on these feeding traits and show how they can be applied  
494 to robustly define the feeding guilds required in OSPAR and the Marine Strategy Framework Directive  
495 guidance. This has provided an indicator capable of revealing change in ecosystem structure and  
496 function across the OSPAR Area based on routinely collected survey data. For instance, we reveal  
497 significant and spatially extensive temporal changes across the food web, with decreases in the  
498 biomass of smaller planktivorous fish which contrasted with increases in the biomass of larger more  
499 piscivorous fish. The information we have generated can be tailored to fulfil other specific evidence  
500 needs, such as improving the parametrisation of ecosystem models and quantifying sustainable levels  
501 of human pressure. Our study provides evidence supporting a candidate food web indicator for the  
502 OSPAR Area that can be readily extended to other areas and organisms.

### 523 **8 Authors' contribution statement**

524  
525 MSAT, CL, IP, AB conceived the project; MSAT, IP, VB, AB, MC, PC, EE, GH-M, IJ, FM, SR, SS, US, BES,  
526 MAT and CL were involved in designing the methodology and collating the data; MSAT analysed the  
527 data and led the writing of the manuscript. All authors contributed critically to the drafts and gave  
528 final approval for publication.  
529

### 530 **9 Data availability**

531  
532 The data we make use of are largely publicly available, cited, and displayed alongside URLs, where  
533 applicable. We also provide all observed fish stomach contents data used in our modelling, predictions  
534 of fish feeding traits from our linear mixed effects models, haul-level estimates of feeding guild species  
535 richness, numbers of fish and their biomass based on scientific trawl surveys from the Northeast  
536 Atlantic and the temporal trend values useful for indicator reporting processes  
537 (<https://doi.org/10.14466/CefasDataHub.149>; Thompson et al., 2024).
