21 **Abstract:**

22 Under a warming climate, occurrences of wildfires have been increasingly more
23 frequent in boreal and arctic forests during the last few decades. Wildfires can cause
24 radical changes in the forest ecosystems and permafrost environment, such as
25 irreversible degradation of permafrost, succession of boreal forests, rapid and massive

26 losses of soil carbon stock, and increased periglacial geohazards. Since 2016, we have
27 gradually and more systematically established a network for studying soil nutrients and
28 monitoring the hydrothermal state of the active layer and near-surface permafrost in the
29 northern Da Xing'anling (Hinggan) Mountains in Northeast China. The datasets of soil
30 moisture content (0-9.4 m in depth), soil organic carbon (0-3.6 m), total nitrogen (0-3.6
31 m), and total phosphorus and potassium (0-3.6 m) were obtained by field sampling and
32 ensuing laboratory tests in 2016. The datasets of ground temperatures (0-20 m) and
33 active layer thickness (2017-2022) were obtained by thermistor cables permanently
34 installed in boreholes or interpolated with these temperatures. The present data can be
35 used to simulate changes in permafrost features under a changing climate and wildfire
36 disturbances and to explore the changing interactive mechanisms of the fire-permafrost-
37 carbon system in the hemiboreal forest. Furthermore, they can provide baseline data for
38 studies and action plans to support the carbon neutralization initiative and assessment
39 of ecological safety and management of the permafrost environment. These datasets
40 can be easily accessed from the National Tibetan Plateau/Third Pole Environment Data
41 Center (<https://doi.org/10.11888/Cryos.tpdc.300933>, Li and Jin, 2024).

42 **1 Introduction**

43 As a key component of the Northern Hemisphere, permafrost and its changes can
44 have substantial consequences for natural and man-made systems (Smith et al., 2022).
45 Moreover, due to its high sensitivity to climate warming, surface disturbances, and
46 human activities, permafrost has undergone extensive degradation during the last six
47 decades (e.g., Biskaborn et al., 2019; Chang et al., 2024; Jin et al., 2000, 2007, 2021,
48 2022, 2023; Li et al., 2022a; Petrov et al., 2022). As one of the most common natural
49 agents and disturbance factors in boreal forests, wildfires can initiate ecosystem
50 renewal at different spatiotemporal scales (Johnstone et al., 2004; Li et al., 2019).
51 Wildfires impact the permafrost environment first by modifying or altering the ground
52 hydrothermal regimes (Jorgenson et al., 2013; Li et al., 2022b; Yoshikawa et al., 2003),
53 and subsequently by inducing modifications or radical/irreversible changes in

54 biogeochemical processes (e.g., Fultz et al., 2016; Li et al., 2023; Ping et al., 2010; Xu
55 et al., 2024). In boreal forests, wildfires have become increasingly more frequent in
56 recent decades under a warming climate and increasing human activities (Boyd et al.,
57 2023; Chen et al., 2023; Knorr et al., 2016; Westerling et al., 2006). Moreover, the
58 region immediately south of the Arctic circle (50°N-67°N) experienced a greater
59 number of vegetation fires compared to the Arctic (north of 67°N) in 2001-2020 (Chen
60 et al., 2023). Although the total burned area on Earth may be declining, the fire behavior
61 was worsening in several regions in 2003–2023, particularly the boreal and temperate
62 conifer biome (Cunningham et al., 2024).

63 In boreal regions, vegetation and soil organic layer are essential buffering and
64 protective layers of the underlying permafrost. The combustion of all vegetation cover
65 and partial or complete removal of the insulating organic layer have direct hydrothermal
66 impacts on permafrost. It reduces the land surface albedo, increases ground surface and
67 cryosol/ice exposure to direct solar radiation, and weakens the cooling effects of
68 vegetative shading and evapotranspiration (Johnstone et al., 2010; Nossov et al., 2013;
69 Shur and Jorgenson, 2007; Yoshikawa et al., 2003). All of these contribute to higher
70 ground surface temperature and more heat transferred into the ground, resulting in a
71 rapid ground warming and sharp deepening of the active layer (Li et al., 2022b;
72 Michaelides et al., 2019; Nossov et al., 2013; Smith et al., 2015). In Interior Alaska,
73 organic layer thickness decreased from 21 to 4 cm after fire, resulting in thaw depth
74 increasing from 72 to 152 cm, mean annual surface temperature rising from -0.6 to
75 $+2.1^{\circ}\text{C}$ and mean annual deep temperature going up from -1.7 to $+0.4^{\circ}\text{C}$ (Nossov et
76 al., 2013). In the boreal zone, 6-11 years after fire, mean annual ground temperature
77 (MAGT) increased by 1.5 - 2.3°C (Li et al., 2021; Munkhjargal et al., 2020; Nossov et
78 al., 2013; Smith et al., 2015), even mean annual ground surface temperatures in burned
79 areas were still 2 - 3°C higher than those in unburned areas 80 years after fire (Brown et
80 al., 2015). Meanwhile, 25 years after fire, the active layer thickness (ALT) could
81 increase by 2.75 m, from the initial value of 45 cm, and ALT could not recover to the
82 pre-fire level even 36 years after fire (Viereck et al., 2008). In Central Siberia, it

83 generally takes 70-80 years for the active layer to return to the pre-fire state (Kirdeyanov
84 et al., 2020). Forest fires also can cause significant changes in soil moisture contents,
85 which in turn affects ground thermal regimes (Nossov et al., 2013). Due to the fire-
86 induced thaw of permafrost, the charred moss layers with lowered infiltration rates,
87 lower transpiration rate and reduced evapotranspiration in severely burned areas,
88 surface soil moisture contents (generally less than 30 cm in depth) at burned sites were
89 significantly higher than those at unburned sites (Kopp et al., 2014; Potter and Hugny,
90 2020; Yoshikawa et al., 2003). However, affected by soil texture, permafrost thaw after
91 fire can also lead to a decrease in soil moisture contents (Li et al., 2022b; Nossov et al.,
92 2013). In summary, in a short term, forest fires will decrease rates of transpiration,
93 raising soil moisture contents; in a long-term (more than a decade), the increased ALT
94 and recovery of vegetation will reduce soil moisture content at burned sites as compared
95 to that at unburned sites (Yoshikawa et al., 2003). Moreover, changes in ground
96 hydrothermal regimes and ALT would decline and progressively dwindle with
97 ecosystem recovery and organic layer regrowth over time under a stable or cooling
98 climate (e.g. Holloway et al., 2020; Rocha et al., 2012).

99 It contains 1100–1500 Pg carbon in boreal permafrost regions ($1 \text{ Pg} = 10^{15} \text{ g}$),
100 approximately twice of the carbon pool in the atmosphere (Hugelius et al., 2014),
101 accounting for nearly half of the global belowground organic carbon pool (O'Donnell
102 et al., 2011a). Wildfire disturbances have important and long-term ramifications for
103 terrestrial carbon cycling and carbon stocks (Chen et al., 2022; Dieleman et al., 2022;
104 Genet et al., 2013; O'Donnell et al., 2011a, 2011b). Unlike gradual thawing, abrupt
105 changes after fires in ground hydrothermal regimes often disrupt the entire soil profile
106 and initiate or aggravate carbon loss from deep permafrost soils (Jones et al., 2015;
107 Turetsky et al., 2019). Therefore, the combustion of vegetation and the subsequent thaw
108 of permafrost have resulted in rapid releases of large amounts of carbon and nitrogen
109 into the atmosphere as greenhouse gases (Mack et al., 2011, 2021; Taş et al., 2014).
110 Furthermore, over a short time, abrupt permafrost thaw would possibly result in
111 emitting more methane than gradual thaw (Koven et al., 2015). Therefore, in the boreal

112 permafrost region, wildfire exacerbate rates of permafrost thaw and alter soil organic
113 carbon dynamics in both organic and mineral soils. In addition to soil organic carbon,
114 forest fires potentially also reduce soil nitrogen contents, inducing shifts in nutrient
115 cycling in the boreal forest and permafrost regions (Certini, 2005; Knicker, 2007; Kolka
116 et al., 2017). However, there are inconsistent reports on the effects of forest fire on soil
117 phosphorus and potassium. Some studies show a significant post-fire reduction in
118 phosphorus and potassium while other studies indicate an evident increase after light
119 burns, but a reduction after severe burns, and nearly unchanged stocks of potassium and
120 phosphorus (Gu et al., 2010; Neff et al., 2005; Zhao et al., 1994). As a result, wildfires
121 in boreal permafrost regions had been considered to trigger strong positive feedbacks
122 on climate warming *via* massive emissions of biogenic major greenhouse gases (Koven
123 et al., 2015; Ramm et al., 2023).

124 Located on the southern margin of Eastern Asian boreal forests and permafrost
125 regions, the Da Xing'anling (Hinggan) Mountains in Northeast China are prone to
126 frequent and massive wildfires. The Xing'an permafrost here is controlled or strongly
127 affected by many local factors, such as dense vegetation cover, thick organic layer,
128 stable snow cover, and anthropic development (Jin et al., 2007; Şerban et al., 2021;
129 Wang et al., 2024). The warm and thin permafrost in the Da Xing'anling Mountains in
130 Northeast China is located in the discontinuous permafrost zone. Therefore, this
131 ecosystem-dominated (driven, modified, or protected) permafrost is sensitive to climate
132 warming and wildfires (Shur and Jorgenson, 2007). Compared with the Arctic
133 permafrost region, the permafrost monitoring network in this region has been
134 established only recently, with inadequately readily accessible and shared permafrost
135 data. Similarly, the permafrost monitoring data in the burned areas in the boreal
136 permafrost region in China are meagre in comparison with those other northern
137 countries or regions, but they are increasing. Prior to the early 1980s, there was little
138 research on wildfire impacts on the permafrost environment in Northeast China. There
139 were only a few occasional fire-related geocryological studies in the early 1990s and
140 limited site-specific measurements of soil temperature and moisture content in the

141 active layer and near-surface (≤ 20 m in depth) permafrost near the Amu'er town,
142 northern Heilongjiang Province (Liang et al., 1991; Zhou et al., 1993). Moreover,
143 research on fire impacts on soil carbon and nitrogen pools and cycles in the Xing'an
144 permafrost in Northeast China has just started and is still at its fledgling stage. Due to
145 the cold and arid climate in winter and spring, complex mountain topography, and dense
146 hemiboreal vegetation in the region, fire regimes are often complex. In addition, burned
147 areas are often located in pristine forest areas far away from roads, making it
148 challenging to timely and/or readily access and study fire impacts. Therefore, it is
149 difficult to systematically understand and quantitatively evaluate the effects of wildfires
150 on ground hydrothermal regimes and carbon stocks at different spatiotemporal scales
151 (Li et al., 2021).

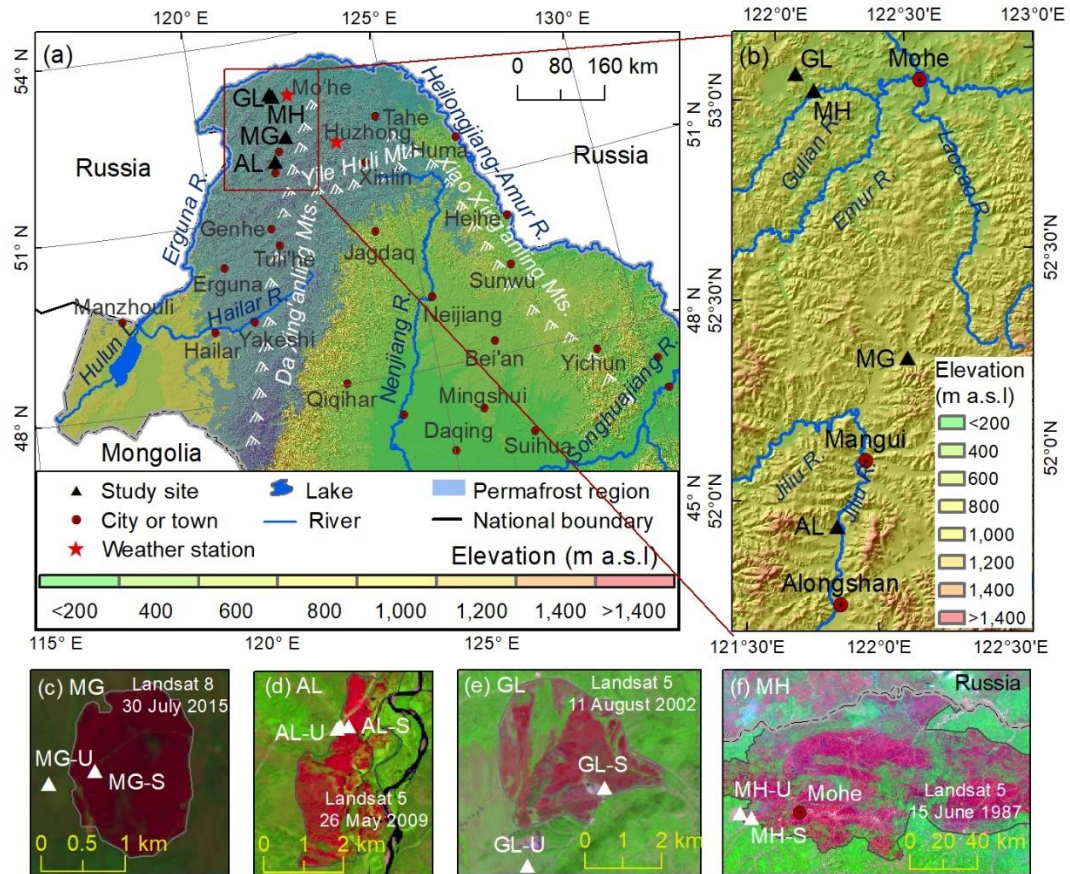

152 To address the abovementioned issues, since 2016, an observation system has been
153 gradually established for ground hydrothermal regimes and soil nutrient contents in the
154 northern Da Xing'anling Mountains. This dataset can provide important supportive data
155 for studying permafrost landscapes, carbon stocks, and boreal ecology and hydrology.
156 It can also provide important references for the management of land and water resources
157 and ecological environment after wildfire disturbances in Northeast China, particularly
158 in forested hemiboreal permafrost regions. In Section 2 of this paper, we first introduce
159 the comprehensive observation network of permafrost and soil nutrients in the northern
160 Da Xing'anling Mountains. The design of the monitoring network of ground
161 hydrothermal regimes and systematic observations of soil nutrient contents, and
162 evaluation of data quality are given in Section 2. In Section 3, observations of
163 permafrost hydrothermal regimes and soil nutrients that provide a 6-year-long dataset
164 are described and briefly interpreted with a focus on major features of the observation
165 network for better understanding of the dataset structure and contents. The data
166 availability and accessibility are provided in Section 4, and; in Section 5, major
167 conclusions and prospects. This dataset provides important input for the model
168 simulations of permafrost changes under fire disturbances and a warming climate,
169 especially those rapid and abrupt degradation of the Xing'an permafrost and resultant

170 periglacial phenomena, such as thermokarst, thaw settlement, and ground surface
171 subsidence and ponding. It is useful for analyzing the interactive hydrothermal and
172 cyclic mechanisms of the wildfires-permafrost-carbon system in the hemiboreal forest.

173 **2 Monitoring networks and data processing**

174 **2.1 Study area descriptions and monitoring networks**

175 A permafrost monitoring network has been established in four burned areas in the
176 northern Da Xing'anling Mountains in Northeast China in boreal forest and
177 discontinuous permafrost regions (Figure 1). Two are located in shrub wetlands in
178 Mo'he city (MH) and Gulian town (GL) in northern Heilongjiang Province. The other
179 two are located in larch forests in Alongshan (AL) and Mangui (MG) towns in the
180 northeastern part of Inner Mongolia. The network includes eight sites in the four burned
181 areas with two fire severity (severely burned (S) and unburned (U)) from 1987 to 2015
182 (the fire severity division method was shown in "2.2 *Fire severity*" section). The studied
183 forest fire in MH (with severely burned (MH-S) and unburned (MH-U) sites) occurred
184 on 6 May 1987, with a burned-over area of 1.01×10^6 ha; that in GL (with severely
185 burned (GL-S)) and unburned (GL-U) sites), on 28 July 2002, 1,121 ha; AL (with
186 severely burned (AL-S) and unburned (AL-U) sites), on 10 May 2009, 930 ha, and; MG
187 (with severely burned (MG-S) and unburned (MG-U) sites), on 12 July 2015, 237 ha.

188

189 Figure 1. Location of the study areas and sites in the northern Da Xing'anling Mountains, Northeast
 190 China.

191 Notes: The base map of permafrost distribution is modified from Li et al. (2022c). The light blue
 192 areas in Figure 1a is the permafrost region. Figures 1c to 1f are the false-color composite image of
 193 the remote sensing image; the burned areas are marked as pink, and the unburned areas are marked
 194 as green.

195 The study areas are characterized by a cold temperate continental climate. In the
 196 study areas of GL and MH, based on the data of nearby Mo'he weather station from
 197 1960 to 2020, mean annual air temperature (MAAT) ranged from -6.2 to -2.4°C , with
 198 an average rate of climate warming at 0.3°C per decade; annual precipitation was 274-
 199 675 mm, with a slight average wetting trend of 13.8 mm per decade. In the study areas
 200 of MG and AL, based on the data of nearby Huzhong weather station from 1974 to 2020,
 201 MAAT varied from -5.2 to -2.0°C , with the same climate warming rate as that of
 202 Mo'he ($0.3^{\circ}\text{C}/\text{decade}$); annual precipitation was 272-749 mm, showing an appreciable
 203 average wetting rate of 3.1 mm per decade. Precipitation fell concentratively in the form

204 of rain from June to August, accounting for 62%-65% of the annual total. Snow cover
 205 generally lasted from October to the next May, with maximum snow depths at 40-50
 206 cm.

207 The four study areas were selected to observe post-fire changes in permafrost
 208 features and soil nutrient conditions (Table 1). This monitoring network includes eight
 209 boreholes and soil profiles, and major elements of the observational network for ground
 210 temperature, ALT, soil moisture content (SMC), soil organic carbon (SOC), total
 211 nitrogen (TN), total phosphorus (TP), and total potassium (TK). The MAGT at the
 212 depth of zero annual amplitude (D_{ZAA} , generally at 10-15 m in depth) ranged from -3.25
 213 to -0.56°C , and measured ALT varied from 1.0 to 3.75 m. The four study areas were
 214 all found in the zones of discontinuous permafrost, with poor drainage in lowlands and
 215 intermontane basins or valleys. The soils in the study area are mainly Histosol and
 216 Gelisols (Soil Survey Staff, 2014). Before fires, vegetation was dominated by the
 217 Xing'an larch (*Larix gmelinii*) forest, generally with an understory mainly consisting
 218 of the shrubs *Ledum palustre* and *Vaccinium uliginosum*, with an organic layer of 55-
 219 60 cm in thickness. After fires, the vegetation of burned over areas became gradually
 220 dominated by white birch (*Betula platyphylla*) and dwarf bog birch (*Betula fruticosa*
 221 Pallas), with an organic layer of 20-30 cm in thickness. At severe burned sites in AL,
 222 GL, and MH, measurements of organic matter thickness were taken 7, 14, and 29 years
 223 after fires, so it was possible that the organic layer thickness exceeded 20 cm due to the
 224 re-accumulation of organic matter. At severe burned site in MG, the organic matter
 225 residue after combustion was in a fluffy state with the thickness of 20 cm. When the re-
 226 accumulation or residual organic matter exceeded 20 cm, this would slow the rate of
 227 active layer thickening and soil temperature increase after fires, as well as the
 228 permafrost would gradually recover with the re-accumulation of organic layer.

229 Table 1. Characteristics of the eight study sites for monitoring the thermal state and soil nutrients
 230 of the active layer and near-surface permafrost in the northern Da Xing'anling Mountains in

231 Northeast China

Study areas and sites	Lat	Long.	Elev.	Veget	Organic	Drainage	Fire
-----------------------	-----	-------	-------	-------	---------	----------	------

		(°N)	(°E)	(m a. s. l.)	-ation	layer thickness (cm)		severity
MG	MG-S	52.27	122.28	710	Larch forest	20	Somewhat poor	Severely burned
(Mangui)	MG-U	65	91			55	Poor	Unburned
AL	AL-S	51.88	121.90	669	Larch forest	25	Moderately good	Severely burned
(Alongshan)	AL-U	68	67			55	Poor	Unburned
GL	GL-S	53.04	122.05	582	Shrub wetland	30	Somewhat poor	Severely burned
(Gulian)	GL-U	32	04			60	Poor	Unburned
MH	MH-S	52.98	122.11	486	Shrub wetland	30	Somewhat poor	Severely burned
(Mo'he)	MH-U	59	15			60	Poor	Unburned

232 The horizontal distance between MG-U and MG-S was about 200 m, with the MG-
233 U on the edge of the burned area. Observations of ground temperatures began in
234 February 2017 (two years after fire). At MG-U in the Xing'an larch (*Larix gmelinii*)
235 dominated forest, all larch trees at MG-S were burned to death, and low shrubs and
236 herbs were found in 2022. The horizontal distance between AL-U and AL-S was less
237 than 100 m, with the AL-U on the edge of the burned area. Observations of ground
238 temperatures began in February 2017 (eight years after fire). The vegetation was the
239 Xing'an larch forest at AL-U, and; it was the broad-leaved forest (birch) at AL-S. We
240 selected GL-S and GL-U sites about 2 km apart from each other. Measurements of
241 ground temperatures began in February 2017 (15 years after fire). The vegetation was
242 the shrub wetland at GL-U and GL-S. MH-S and MH-U sites were about 5 km apart.
243 Observations of ground temperatures began in February 2017 (30 years after fire). The
244 ecosystem was characteristic of shrub wetlands at MH-U and MH-S.

245 2.2 Fire severity

246 Normalized Burn Ratio (NBR) and differential Normalized Burn Ratio (dNBR)
247 are often used to assess the forest fire severity (Cocke et al., 2005; Li et al., 2022b), and

248 the calculation formulas are as follows:

$$249 \quad NBR = (\rho_{NIR} - \rho_{MIR}) / (\rho_{NIR} + \rho_{MIR}) \quad (1)$$

$$250 \quad dNBR = NBR_{prefire} - NBR_{postfire} \quad (2)$$

251 where ρ_{NIR} and ρ_{MIR} are the reflectivity values of pixel from the near-infrared (NIR)
252 and middle-infrared (MIR) bands, and; $NBR_{prefire}$ and $NBR_{postfire}$ are the values
253 of NBR before and after fire.

254 According to the Cocke et al. (2005) and Roy et al. (2006), the $dNBR$ optimality
255 values for these average changes are 0.241 for grass and 0.57 for shrub. Therefore,
256 through vegetation burn status and the comparison with $dNBR$ values (Key and Benson,
257 2006; Escuin et al., 2008), fire severity is thus divided into four categories: severely
258 burned ($dNBR \geq 0.571$), moderately burned (0.241-0.570), lightly burned (0.051-
259 0.240), and unburned (≤ 0.050) (Cocke et al., 2005). In the lightly and moderately
260 burned areas, there were difficulties in drilling and/or monitoring due to device
261 malfunction or damage. In addition, the permafrost environment changes more
262 significantly after severe burns. Therefore, only sites of two levels of fire severity
263 (severely burned and unburned) were chosen for the abovementioned four areas
264 (Mangui/MG, Alongshan/AL, Gulian/GL and Mo'he/MH) to study post-fire changes in
265 ground hydrothermal regimes and soil nutrients.

266 **2.3 Site instrumentation and laboratory analysis**

267 At each site of unburned and severe burned, a 20-m-deep borehole was drilled and
268 instrumented in October 2016 to monitor ground temperatures (eight boreholes in total)
269 (Figure 2). Ground temperatures were monitored with 0.5-m depth intervals at depths
270 of 0–5 m and then with 1-m depth intervals at depths of 5-20 m by thermistor cables
271 permanently installed in boreholes and manually measured from February 2017. All
272 thermistors were assembled and calibrated at the Key Laboratory of Cryospheric
273 Science and Frozen Soil Engineering, Northwest Institute of Eco-Environment and
274 Resources (renamed from the merger of the former State Key Laboratory of Frozen Soil
275 Engineering and the State Key Laboratory of Cryosphere Science, Cold and Arid

276 Regions Environmental and Engineering Research Institute), Chinese Academy of
277 Sciences. Since February 2017, ground temperatures at these boreholes were manually
278 measured thrice monthly (Table 2), or occasionally once or twice monthly due to traffic
279 difficulty or control, by a multi-meter Fluke 189[®] device. According to the measured
280 soil temperatures during the observation period, the isotherms of soil temperature in the
281 vertical profile at depths of 0-20 m were drawn, and then the 0°C isotherms were
282 delineated for each borehole. The values of ALT were then determined, using linear
283 extrapolation of seasonally and progressively changing ground temperature distribution
284 with depth, for each borehole and each year according to the deepest position of the 0°C
285 isotherms in the year.

286
287 Figure 2. Photos of the study sites with different vegetation cover and the position of the 20 m deep
288 boreholes for monitoring the ground temperature in the northern Da Xing'anling Mountains in
289 Northeast China in 3-5 July 2022.

290 Notes: Figures 2a and 2b were the borehole for observation of ground temperature at Xing'an larch
291 forest severe burned and light burned sites in MG; Figures 2c and 2d were the borehole for
292 observation of ground temperature in a Xing'an larch forest at severe burned and light burned sites
293 in AL; Figures 2e and 2f were the borehole for observation of ground temperature in shrub wetlands
294 at severe burned and light burned sites in GL; Figures 2g and 2h were the borehole for observation
295 of ground temperature at shrub wetlands severe burned and light burned sites in MH.

296 Table 2. Monitoring data for the eight sites of soil nutrients and ground temperature boreholes for studying fire impacts on the permafrost environment in the northern
 297 Da Xing'anling Mountains in Northeast China

Study sites	Monitoring depths (m)			Time period	Monitoring frequency
	Soil nutrients	Soil gravimetric moisture content (SMC)	Ground temperature

298 Notes: Soil nutrients and SMC were observed once in 2016, and soil temperatures were observed thrice monthly in 2017-2022.

299 While drilling in 2016, soil samples were collected from depths of 0-9.4 m at
300 intervals of 0.1-3.0 m, with a total of 402 soil samples. Three replicas were collected at
301 the same depth and then three samples were evenly mixed into one. At depths of 0-3.0
302 m, samples were collected every 10 cm in depth in soil strata with more significant
303 changes of soil organic matter and lithology near the ground surface. At depths of 3.0-
304 9.4 m, samples were collected based on lithological similarity or changes in soil or rock
305 strata, rather than at an equal depth interval of 0.1 m. Therefore, at depths of 0-3 m,
306 there were generally a set of data at a regular depth interval of 10 cm, but at depths of
307 3-10 m, the depth intervals of datasets varied substantially. One part of the soil samples
308 was collected using a cutting ring and stored in an 100-cm³ aluminum specimen box
309 and immediately weighed (soil wet weight). Then, the samples were transported to the
310 laboratory and dried at 105°C to obtain soil dry weight. Finally, gravimetrically-based
311 SMC was calculated by the mass of soil before and after drying. The other part of the
312 soil samples was collected and stored in zip-lock bags and timely brought back to the
313 laboratory for air-drying, then passed through a 2-mm sieve for chemical analysis. SOC
314 and TN contents were measured by potassium dichromate oxidation reduction and
315 Kjeldahl nitrate boiling fluid injection methods, respectively (Nelson et al., 1982). TP
316 and TK contents were determined by the methods of Mo-Sb colorimetry and flame
317 photometry, respectively (Sun et al., 2011). These data are shown as mean ± standard
318 error (SE). Changes in ground temperatures and soil chemical properties were analyzed
319 using the space-for-time chronosequence approach (Mack et al., 2021).

320 **2.4 Data quality check**

321 The measurement accuracy of ground temperature was ±0.05°C in the range of
322 -30 to +30°C, but ± 0.1°C in those of -45 to -30°C and +30 to +50°C. From 2020 to
323 2022, due to the breakout and persistence of the COVID-19 pandemic, some data were
324 not timely collected, affecting the sampling intervals. Ground temperature data were
325 collected manually thrice monthly since February 2017, and after the outbreak of the
326 COVID-19 pandemic, the data were recorded once or twice monthly. In addition, some
327 data were missing because of damaged, broken, or destroyed probes, solar panel

328 batteries, or dataloggers. From 6 February 2017 to 22 November 2022, a total of 28,890
329 pieces of data were collected, of which 178 NA (not available) data were resulted from
330 probe damage, thus 28,712 valid data were collected. All the missing data were near
331 the ground surface, at a soil layer at depths between 0 and 5 cm. At MG-U, AL-U, AL-
332 S, GL-S, and MH-S, all data were available. Of the 178 NA data, 74 were at MG-S
333 (from 17 September 2019 to 22 November 2022), 52 at GL-U (from 20 July 2019 to 13
334 February 2022), and 52 at MH-U (from 20 July 2019 to 13 February 2022) sites. Data
335 of soil temperatures from manually monitored boreholes were quality-controlled for
336 each measurement. Some studies have also shown that this method of monitoring
337 ground temperature using drilling and probes is one of the most accurate, reliable, and
338 intuitive methods for long-term monitoring of permafrost data (Chang et al., 2022; Li
339 et al., 2022a, 2024; Zhao et al., 2021). Before the analysis of soil nutrient data and SMC
340 data, we conducted outlier tests to ensure the accuracy of the data. These tests showed
341 that all the data have no outliers and the samples are representative. There was a total
342 of 840 soil nutrient data and 195 SMC data.

343 **3 Data descriptions and evaluation**

344 **3.1 Changes in ground temperatures of near-surface permafrost**

345 Ground temperatures at depths of 0-20 m in the active layer and near-surface
346 permafrost showed remarkable seasonal dynamics (Figures 3 and 4). The amplitudes of
347 changes in ground temperature decreased exponentially with increasing depth. At
348 depths of 0-1 m, changes in MAGT at eight sites were larger 1.5-10.2°C than those at
349 1-20 m (Figures 3a to 3d).

350

351

Figure 3. Mean annual ground temperatures (MAGTs) from 2017 to 2022 at the unburned and

352

severely burned sites in the four areas on the western flank of the northern Da Xing'anling

353

Mountains in Northeast China

354

355

Figure 4. Variability of ground temperatures at depths of 0–20 m at Xing'an larch forest sites in

356

Mangui (MG) and Alongshan (AL) on the western flank of the northern Da Xing'anling Mountains

357

in Northeast China during the period from 2017 to 2022.

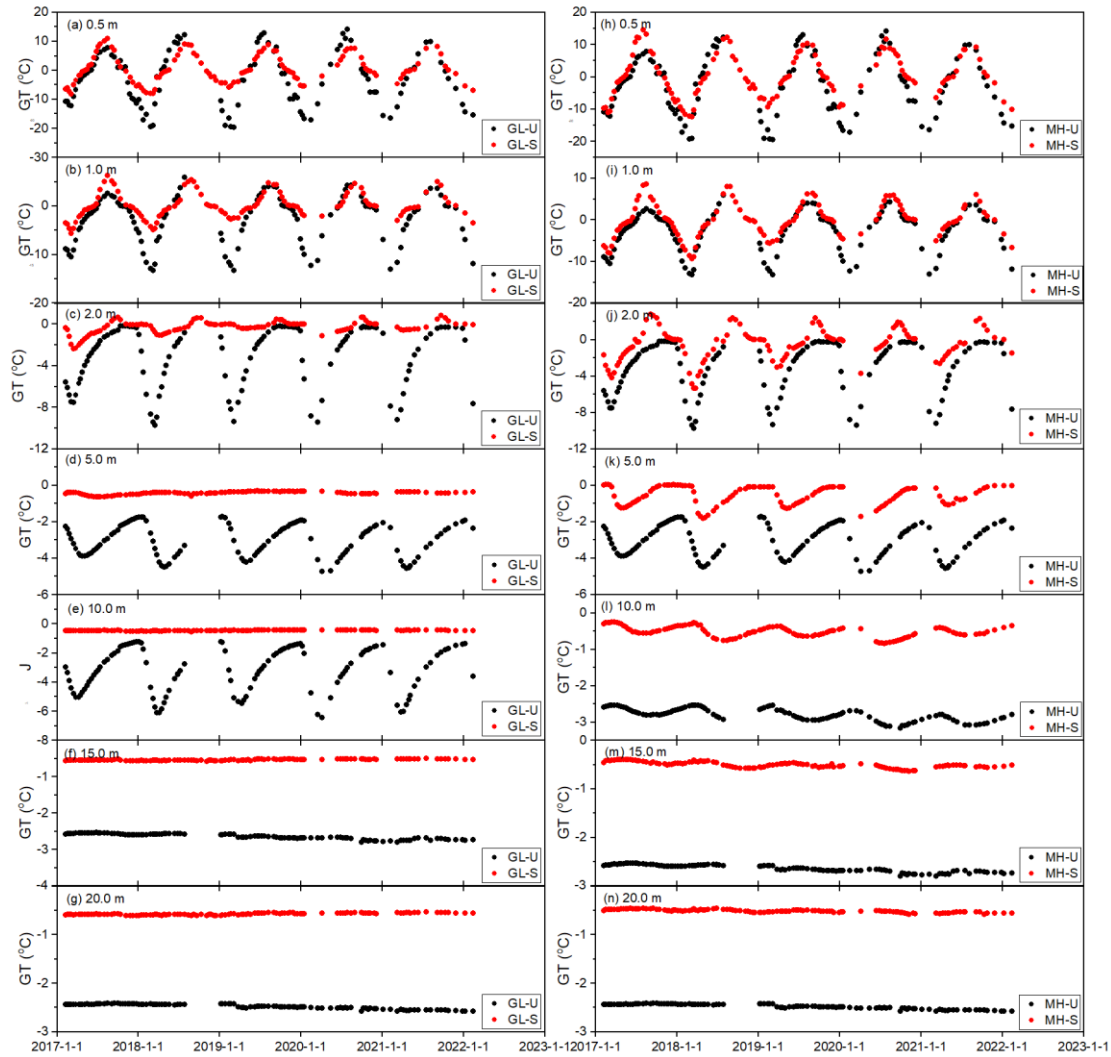

358 Notes: The symbol U stands for the unburned site, S for the severely burned site, and; GT, for ground
 359 temperature. Figures 4a to 4g were the changes in ground temperatures in Mangui (MG) 2 to 7 years
 360 after fire; Figures 4h to 4n, those in Alongshan (AL) 8 to 13 years after fire.

361 MAGTs lowered with increasing depths, the temperature difference between 0.5
 362 and 20 m in depth was 0.2-2.1°C (Table 3). From 2017 to 2022, ground temperature
 363 fluctuated in a sinusoidal pattern at depths of 0.5 to 2.0 m, and this dynamic change
 364 gradually disappeared with increasing depth (Figures 3a to 3g and 5a to 5g). At the
 365 depth of 5 m, ground temperature was subzero or perennially cryotic (Figures 4d, 4k,
 366 5d, and 5k). At eight sites, from 2017 to 2022, ground temperatures showed an
 367 increasing trend of 0.01-0.69°C/yr at depths of 0.5-20 m. The increase rate was the
 368 largest at AL-U (0.03-0.69°C/yr), and; the lowest, at AL-S and GL-S (all were 0.01-
 369 0.37°C/yr) (Figures 4a to 4g and Figures 5a to 5g).

370 Table 3. Mean annual ground temperatures (MAGTs) at each of the seven measured depths at
 371 unburned and severely burned sites in the four areas on the western flank of the northern Da
 372 Xing'anling Mountains in Northeast China during the period from 2017 to 2022

Depth (m)	0.5		1.0		2.0		5.0		10		15		20	
Fire severity	U	S	U	S	U	S	U	S	U	S	U	S	U	S
MG	0.2	-0.6	-1.5	-0.8	-1.6	-1.1	-1.7	-1.4	-1.8	-1.6	-1.9	-1.7	-1.9	-1.7
AL	-2.2	-0.3	-2.8	-0.5	-2.9	-0.6	-2.9	-0.6	-2.9	-0.7	-2.9	-0.9	-2.9	-0.9
GL	-2.7	0.5	-2.9	0.1	-3.1	-0.3	-3.1	-0.4	-2.8	-0.5	-2.6	-0.5	-2.5	-0.6
MH	-2.7	0.2	-2.9	-0.2	-3.1	-0.5	-3.1	-0.6	-2.8	-0.5	-2.6	-0.5	-2.5	-0.5

373 Notes: U stands for unburned sites, and; S, severely burned sites.

374

375 Figure 5. Variations in ground temperatures at depths of 0-20 m at shrub wetlands sites in Gulian
 376 (GL) and Mo'he (MH) on the western flank of the northern Da Xing'anling Mountains in Northeast
 377 China during the period from 2017 to 2022.

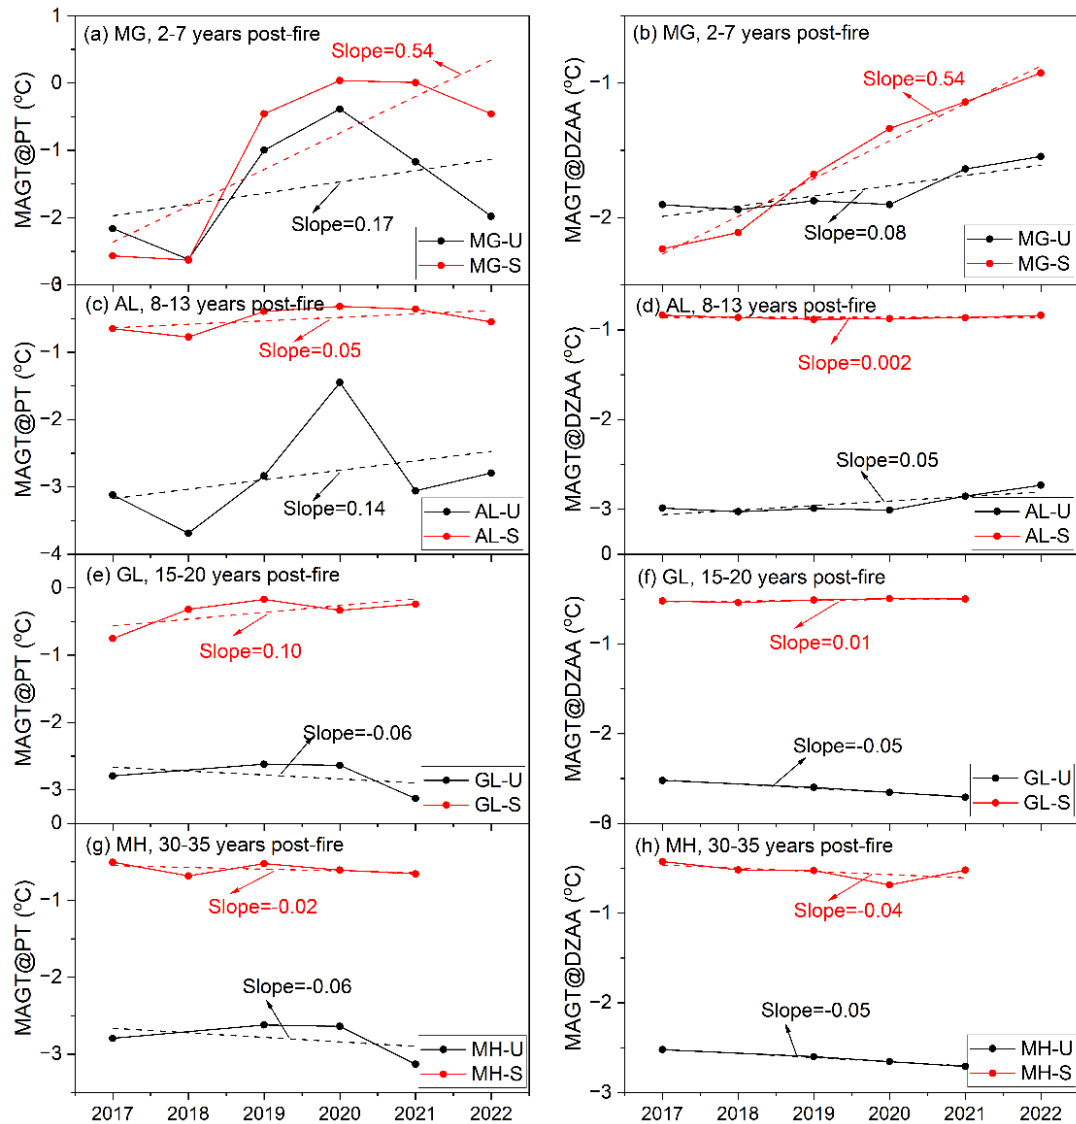

378 Notes: The symbol U stands for the unburned site; S, for the severely burned site, and; GT, for
 379 ground temperature. Figures 5a to 5g were changes in ground temperatures in GL 15-20 years after
 380 fire; Figures 5h to 5n, those in MH 30-35 years after fire.

381 **3.2 Changes in MAGTs at the permafrost table (MAGT_{PT}) and D_{ZAA} (MAGT_{DZAA})**

382 MAGTs at the permafrost table (MAGT_{PT}) and at the D_{ZAA} (MAGT_{DZAA}) can truly
 383 reflect the changing characteristics of permafrost thermal regimes. Therefore, in this
 384 section, we have chosen MAGT_{PT} and MAGT_{DZAA} to briefly analyze changes in ground
 385 thermal regimes. When the temperature probe was missing at the actual depth of the

386 permafrost table or the D_{ZAA} , $MAGT_{PT}$ and $MAGT_{DZAA}$ were derived from
387 interpolation of adjacent ground temperatures.

388 At the eight monitored sites, the burial depths of permafrost table ranged between
389 1.5 and 4.5 m, and the D_{ZAA} between 10 and 16 m. From 2017 to 2022, except for GL-
390 U, MH-U and MH-S sites, $MAGT_{PT}$ and $MAGT_{DZAA}$ decreased gradually (-0.02 to
391 $-0.06^{\circ}\text{C}/\text{yr}$), while at other sites increased at rates of 0.01 - $0.54^{\circ}\text{C}/\text{yr}$ (Figure 6). The
392 ground warming rates of $MAGT_{PT}$ and $MAGT_{DAZZ}$ were highest at the MG-S site (both
393 at $0.54^{\circ}\text{C}/\text{yr}$), and lowest at the GL-S site (0.10 and $0.01^{\circ}\text{C}/\text{yr}$) (Figures 6a and 6b).
394 From 2017-2022, the highest differences in $MAGT_{PT}$ and $MAGT_{DAZZ}$ were 2.6 and 1.3°C
395 at the MG-S site, respectively, and the lowest were 0.2 and 0.1°C at MH-S and AL-S
396 sites, respectively (Figures 6a, 6d and 6h).

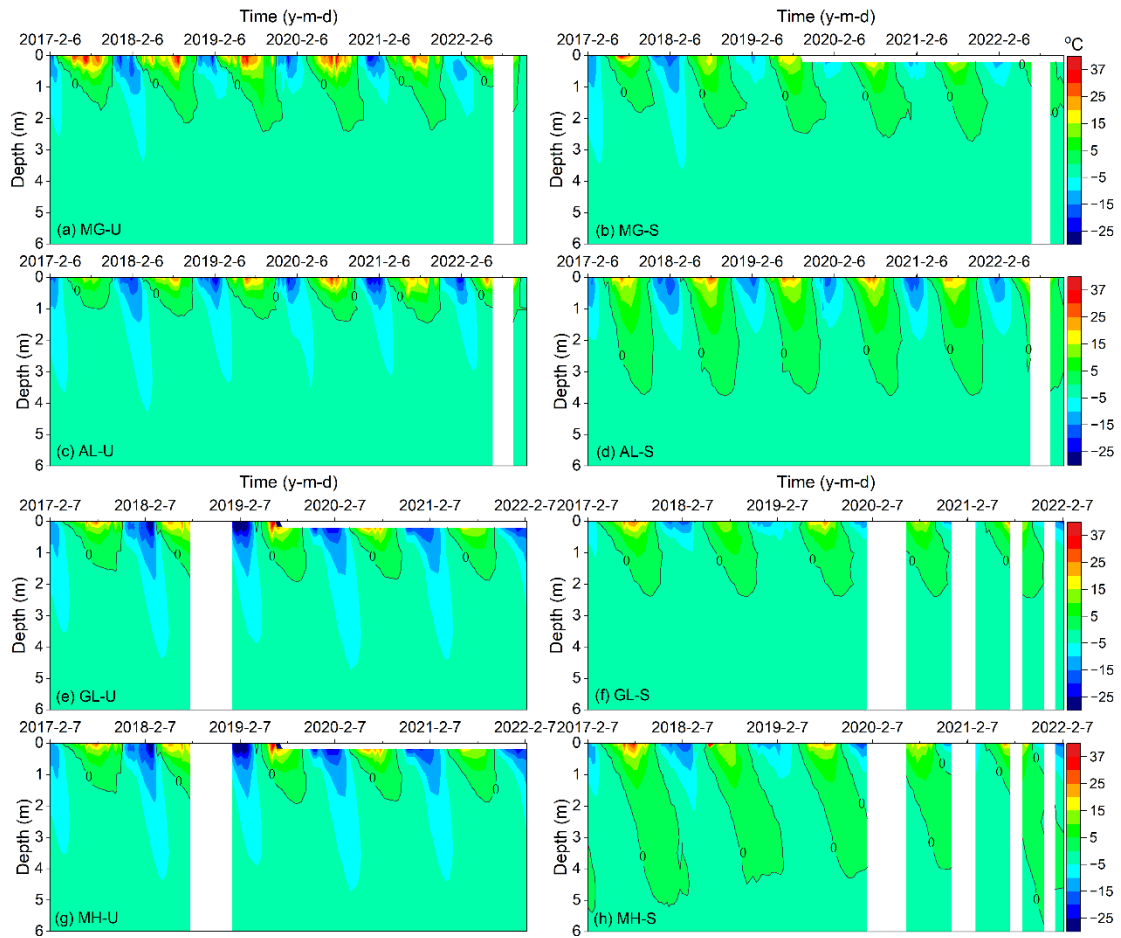

397

398 Figure 6. Variations in mean annual ground temperatures at the permafrost table (MAGT_{PT}) and the
 399 depth of zero annual amplitude (D_{ZAA}) (MAGT_{DZAA}) at eight sites in the four study areas (Mangui
 400 or MG, Alongshan or AL, Gulian or GL, and Mo'he or MH) on the western flank of the northern
 401 Da Xing'anling Mountains in Northeast China during 2017-2022.

402 Notes: U stands for unburned sites, and; S, severely burned sites.

403 3.3 Active layer thickness (ALT) data

404 ALT, defined as the annual maximum depth of seasonal thaw penetration, was
 405 determined according to the deepest position of the 0°C isotherms in a year. Although
 406 some data were missing, the change trends of ALT were still obvious (Figure 7).

407

408 Figure 7. Variability of ground temperatures isotherms at eight sites in Mangui (MG), Alongshan
 409 (AL), Gulian (GL), and Mo'he (MH) on the western flank of the northern Da Xing'anling Mountains
 410 in Northeast China during 2017-2022.

411 Notes: U stands for the unburned sites, as in insets a (site MG-U), c (site AL-U), e (site GL-U), and
 412 g (site MH-U), and S, the severely burned sites, as in insets b (site MG-S), d (site AL-S), f (site GL-
 413 S), and h (site MH-S).

414 ALT was between 1.0 and 5.2 m at the eight sites from 2017 to 2022, and the
 415 maximum average of ALT was 4.5 m at MH-U and the minimum was 1.6 m at AL-U.
 416 Compared with the other seven sites, MH-S has the largest ALT, with the maximum
 417 ALT at 5.2 m in 2017. From 2017 and 2022, only at the MH-S site, ALT decreased at a
 418 rate of 36.5 cm/yr, while at the other sites it increased at rates of 0.1-20.5 cm/yr. The
 419 increase rate of ALT at MG-S was the fastest, and; at AL-S, the slowest (Figure 8).

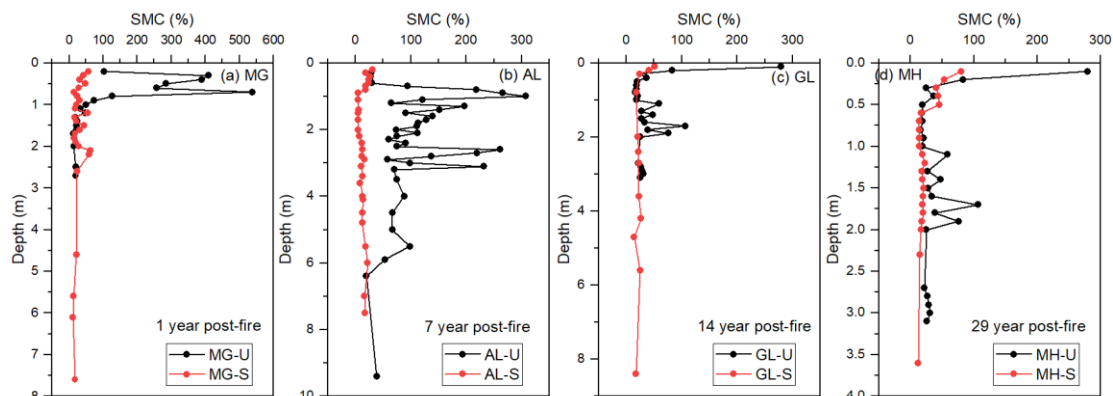

420

421 Figure 8. Variation characteristics of active layer thickness (ALT) from 2017 to 2022 at eight sites
 422 of the four study areas in Mangui (MG), Alongshan (AL), Gulian (GL), and Mo'he (MH) on the
 423 western flank of the northern Da Xing'anling Mountains in Northeast China during 2017-2022.
 424 Notes: U stands for the unburned site, and S, the severely burned site.

425 3.4 Variations in gravimetric soil moisture content (SMC)

426 At MG-U and AL-U sites, SMC decreased with increasing depth, especially in the
 427 active layer and near-surface permafrost, or in the vicinity of the permafrost table
 428 (Figure 9). For example, at AL-U, SMC decreased at a rate of 8.6%/m and average
 429 SMC was $108.2 \pm 11.7\%$ at depths of 0-9.4 m (Figure 9b). At the depths (0-3 m) with
 430 higher SMC, the soil contains massive ice crystals and a large amount of segregated ice,
 431 with ice lenses of 0.1–5.0 cm in thickness. For example, at GL-U, SMC was higher at
 432 the junction of the bottom of the active layer and the upper layer of transient permafrost
 433 (1-2 m in depth) due to a large amount of segregated ice (0.2-5.0 cm thick) immediately
 434 under the permafrost table. At MG-S, AL-S, GL-S, and MH-S sites, changes in SMC

435 were inconspicuous, only at depths of 0-0.5 m, with a slight decreasing trend. At depths
 436 of 0.5-9.4 m, differences in SMC were minor (Figure 9). At MG-S, SMC fluctuated
 437 between 11.7-63.2% at depths of 0.6-7.6 m, with average SMC at $27.5\pm 3.2\%$ (Figure
 438 9a). At AL-S, GL-S, and MH-S sites, SMC fluctuated between 4.7-26.6% at depths of
 439 0.6-8.4 m, with average SMC of 17.1-21.1%.

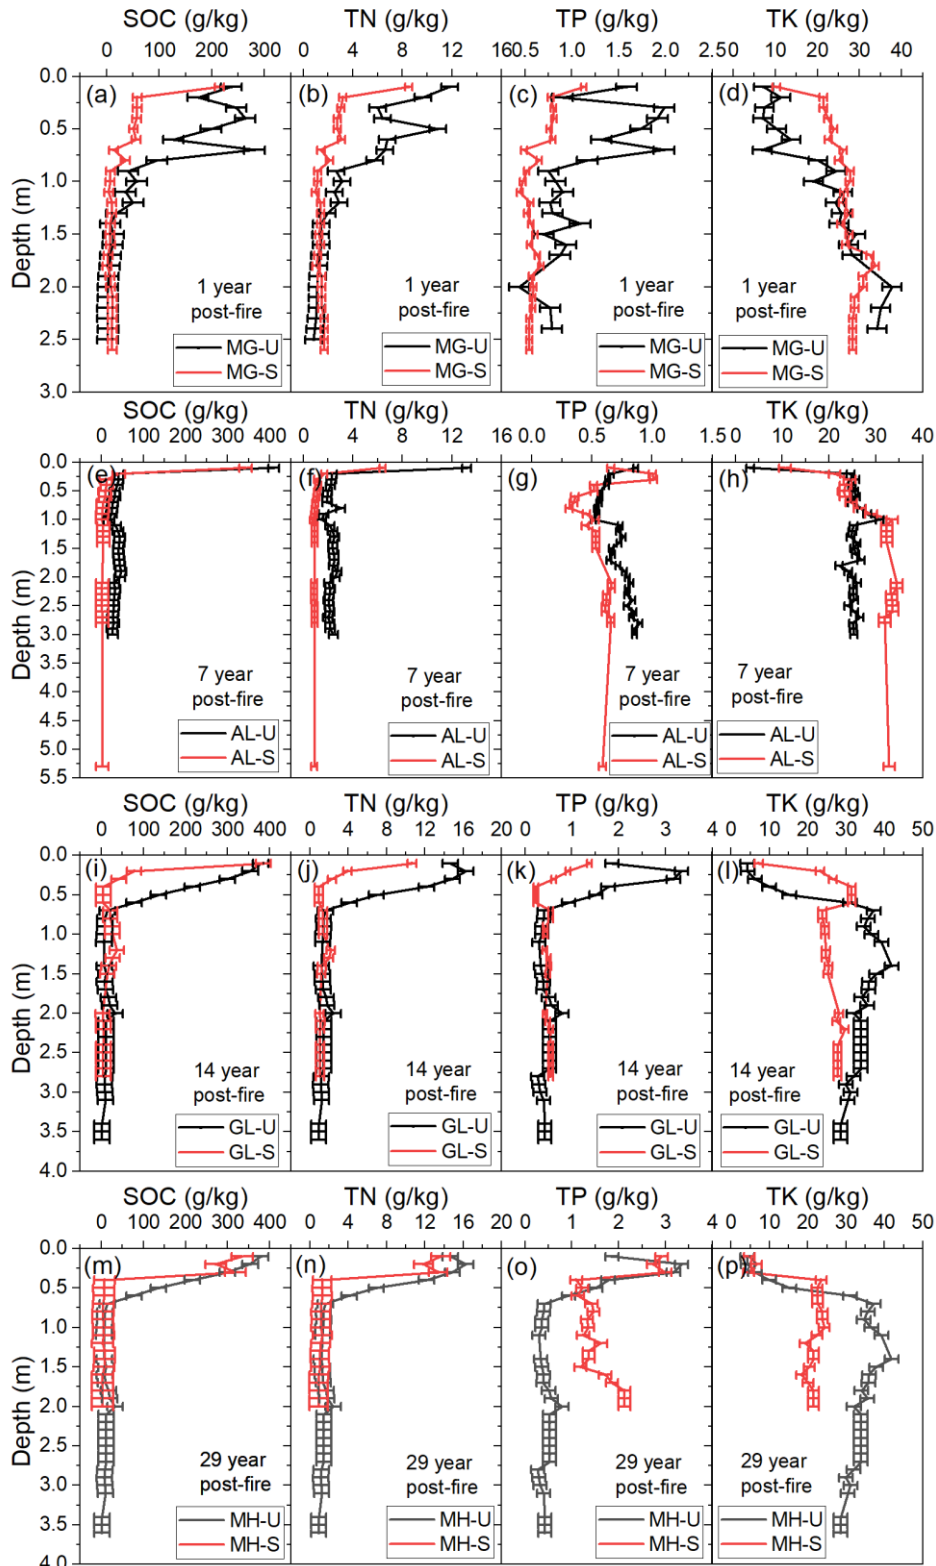

440

441 Figure 9. Variations in gravimetrically-based soil moisture contents (SMC) with different fire severity at eight sites in Mangui (MG), Alongshan (AL), Gulian (GL), and Mo'he (MH) on the
 442 western flank of the northern Da Xing'anling Mountains in Northeast China in 2016. Notes: The
 443 symbol U stands for unburned, S for severely burned, and; SMC, for soil gravimetric moisture
 444 content.
 445

446 3.5 Variations in soil nutrients

447 The contents of SOC and TN decreased with increasing depths. A large amount of
 448 SOC and TN were stored in the active layer (0-1.3 m), especially in the soil organic
 449 layer (0-0.5 m) (Figures 10a to 10n). The change trends of SOC and TN were consistent.
 450 For example, at MG-U, at depths of 0-1.3 m, averages of SOC and TN were 140.5 ± 26.9
 451 and 5.9 ± 0.9 g/kg, respectively; at depths of 1.3-2.5 m, changes in SOC and TN were
 452 relatively smooth, fluctuating between 2.0-13.3 and 0.9-1.5 g/kg, with averages at
 453 5.4 ± 1.1 and 1.2 ± 0.1 g/kg, respectively (Figures 10a and 10b).

454

455 Figure 10. Variations in soil nutrients at eight sites in Mangui (MG, a to d),
 456 Alongshan (AL, e to h), Gulian (GL, i to l), and Mo'he (MH, m to p) on the western flank of the northern Da Xing'anling
 457 Mountains in Northeast China in 2016.

458 Notes: The symbol U stands for unburned, and S for severely burned. SOC stands for soil organic
 459 carbon; TN, for total nitrogen; TP, for total phosphorus, and; TK, for total potassium.

460 TP contents decreased up to 1.0 m in depth, and changes in TP were minor at
461 depths of 1.0-5.3 m (Figures 10c, 10g, 10k, and 10o). For example, at MG-S, TP
462 decreased at a rate of 0.56 g/kg/m at depths of 0-1.0 m, with an average of 0.7 ± 0.1 g/kg
463 (Figure 10c); TP fluctuated between 0.4 and 0.7 g/kg at depths of 1.1-2.6 m, with an
464 average of 0.6 ± 0.01 g/kg. The change trends of TK were opposite with TP because TK
465 contents increased downwards (Figures 10d, 10h, 10l, and 10p). The contents of TK
466 were all below 41.8 g/kg. For example, at MG-U, TK increased at a rate of 14.1 g/kg/m,
467 while TP decreased at a rate of 0.5 g/kg/m (Figures 10c and 10d).

468 **4. Data availability**

469 The dataset of ground temperature, ALT, SMC, SOC, and contents of TN, TP, and
470 TK can be freely downloaded and is available from the National Tibetan Plateau/Third
471 Pole Environment Data Center (<https://doi.org/10.11888/Cryos.tpdc.300933>, Li and Jin,
472 2024). The dataset was classified into three categories: ground temperatures (at MG-U,
473 MG-S, AL-U, AL-S, GL-U, GL-S, MH-U, and MH-S), soil moisture contents (SMCs),
474 and soil nutrient contents (SOC, TN, TP, and TK).

475 **5. Conclusions**

476 The Da Xing'anling (Hinggan) Mountains in Northeast China are located on the
477 southern margin of the Eastern Asia permafrost zone and boreal forest belt. It is an area
478 where fires occur frequently and the thermal state of permafrost is sensitive to fire
479 disturbances. To study fire effects on the permafrost environment, a monitoring network
480 has been established in Northeast China since 2016. Therefore, a long-term field dataset
481 on ground hydrothermal regimes and soil nutrients has been obtained. This dataset fills
482 a gap in a monitoring study of fire effects on the permafrost environment in the
483 hemiboreal forest zone in Northeast China. These data include ground temperatures at
484 depths of 0-20 m, SMC at depths of 0-9.4 m, and contents of SOC, TN, TP, and TK at
485 depths of 0-3.6 m. The data were collected from eight sites in four burned areas (MG
486 in Mangui, AL in Alongshan, GL in Gulian, and MH in Mo'he) with two categories of
487 fire severity (severely burned and unburned) from 2016 to 2022.

488 Long-term monitoring data in the northern Da Xing'anling Mountains in Northeast

489 China have shown a degrading permafrost under the disturbances of climate change
490 and frequent forest fires. This is evidenced by rising ground temperature, thickening
491 active layer, and evidently changing SMC and soil nutrient contents. The 6-year long
492 dataset presented in this study has a high-quality time series with only a few missing
493 data. This valuable and hard-won dataset of forest fires and permafrost is worth
494 maintaining and improving in the future. This study provides important basic data for
495 the protection of the ecosystem-dominated Xing'an permafrost and herewith boreal
496 permafrost ecosystems. Furthermore, it is useful for more accurate prediction of fire-
497 induced permafrost changes and for more accurate estimating and better-managing soil
498 carbon stocks. It also provides an important reference for the initiatives of carbon
499 neutralization and carbon peaking control and the assessment of infrastructure safety
500 under fire threats.

501 **Author contributions.** XL and HJ designed and conducted this research. XL compiled
502 the dataset, performed the data analysis, and wrote the manuscript. RH, HW, XC, RŞ, and ZT
503 participated in the fieldwork. HJ, QF, QW, DL and RŞ improved the writing. XL prepared the
504 manuscript with contributions from all co-authors.

505 **Competing interests.** The authors declare no conflict of interest.

506 **Disclaimer.** Publisher's note: Copernicus Publications remains neutral with regard to
507 jurisdictional claims in published maps and institutional affiliations.

508 **Acknowledgments.** We would like to thank all the scientists and students who
509 participated in the fieldwork. We thank the two anonymous reviewers and editors for
510 their thorough reviews and insightful comments that improved the paper. We also are
511 grateful to Professor Xin Li for his encouragement, guidelines, and review of the
512 proposal for writing up this paper and preparation of the datasets.

513 **Financial support.** This research has been supported by the National Natural
514 Science Foundation of China (Grant Nos. 42471166 and 32241032); Heilongjiang
515 Excellent Youth Fund (Grant No. YQ2022D002), National Natural Science Foundation
516 of China (Grant No. 42101408), and; Fundamental Research Fund for the Central

517 Universities (Grant Nos. 2572023CT01 and 2572021GT08). Raul-David Șerban
518 received funding from the Autonomous Province of Bozen/Bolzano-Department for
519 Innovation, Research and University (Grant No. 13585/2023).
