20 **Abstract.** Constructing a highly-resolved comprehensive emission dataset for China is challenging due to limited availability
21 of refined information for parameters in a unified bottom-up framework. Here, by developing an integrated modeling
22 framework, we harmonized multi-source heterogeneous data including several up-to-date emission inventories at national and
23 regional scale, and for key species and sources in China, to generate a 0.1 °resolution inventory for 2017. By source mapping,
24 species mapping, temporal disaggregation, spatial allocation and spatial-temporal coupling, different emission inventories are
25 normalized in terms of source categories, chemical species, and spatiotemporal resolutions. This achieves the coupling of
26 multi-scale, high-resolution emission inventories with the MEIC (Multi-resolution Emission Inventory for China), forming a
27 high-resolution INTegrated emission inventory of Air pollutants for China (i.e., INTAC). We find that the INTAC provides
28 more accurate representations for emission magnitudes and spatiotemporal patterns. In 2017, China's emissions of SO₂, NO_x,
29 CO, NMVOC, NH₃, PM₁₀, PM_{2.5}, BC, and OC are 12.3, 24.5, 141.0, 27.9, 9.2, 11.1, 8.4, 1.3 and 2.2 Tg, respectively. The
30 proportion of point source emissions for SO₂, PM₁₀, NO_x, PM_{2.5} increases from 7–19% in MEIC to 48–66% in INTAC,
31 resulting in improved spatial accuracy, especially mitigating overestimations in densely populated areas. Compared to MEIC,
32 INTAC reduces mean biases in simulated concentrations of major air pollutants by 2–14 µg/m³ across 74 cities against ground
33 observations. The enhanced model performance by INTAC was particularly evident at finer grid resolutions. Our new dataset
34 is accessible at <http://meicmodel.org.cn/intac>, and it will provide a solid data foundation for fine-scale atmospheric research
35 and air quality improvement.

36

37 **1 Introduction**

38 In recent years, China has achieved remarkable progress in improving air quality and public health through the active
39 implementation of clean air policies (Liu et al., 2020; Xiao et al., 2022; Zhang and Geng, 2019; Zhang et al., 2019a). To further
40 unlock the potential of targeted clean air actions, there is an urgent need for an accurate and detailed depiction for emissions,
41 encompassing their magnitudes and spatial-temporal patterns. Developing a reliable highly-resolved emission inventory for
42 China is also crucial for studies of atmospheric chemistry and climate change (Cheng et al., 2021a; Geng et al., 2021; Zhang
43 et al., 2019a).

44 The construction of high-resolution emission inventories for China poses significant challenges due to the diversity and
45 complexity of emission sources and technology distributions. Additionally, the limited availability of localized measurements
46 for emission factors (EFs) and source profiles, along with exact location of the emission facilities, further compounds the
47 difficulties (Li et al., 2017a). The widely-used bottom-up approach involves the establishment of a unified framework that
48 encompasses source categories, chemical speciation processes, spatial-temporal allocation profiles and emission estimation
49 methods (An et al., 2021; Huang et al., 2021). However, achieving both wide coverage and high accuracy in compiling an
50 emission inventory for China through this approach remains a formidable task for individual research institutions.

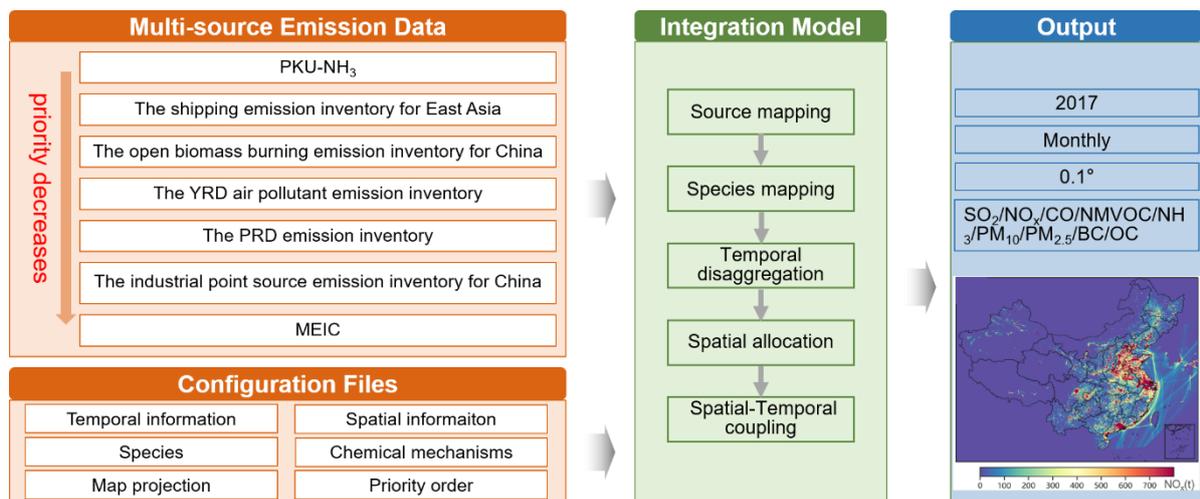

51 Comprehensive national-scale emission inventories developed using the unified framework typically provide extensive
52 coverage of space, species and sectors (Li et al., 2017a; Li et al., 2023b), but tend to exhibit limitations in spatial accuracy (Wu
53 et al., 2021; Zhao et al., 2015; Zheng et al., 2021; Zhou et al., 2017b). Previous studies have indicated that the spatial allocation
54 in large-scale emission inventories rely on spatial proxies (e.g., population, road networks) rather than latitude-longitude
55 coordinates of emission sources due to the unavailability of extensive spatial information (Li et al., 2017b; Zhang et al., 2009).
56 The assumption of a linear correlation between emissions and spatial proxies might lead to an overestimation of emissions in
57 urban areas, especially at scales finer than 0.25° (Wu et al., 2021; Zheng et al., 2021; Zheng et al., 2017). Biases introduced
58 by the proxy-based method are found to be propagated as the grid size diminishes, resulting in uncertainties for chemical
59 transport models (CTMs) (Zheng et al., 2021; Zheng et al., 2017).

60 Emission inventories focused on a specific region (An et al., 2021; Huang et al., 2021; Liu et al., 2018), sector (Chen et al.,
61 2016; Deng et al., 2020; Zhou et al., 2017a) or key species (Huang et al., 2012b; Li et al., 2021; Wang et al., 2023) under the
62 aforementioned unified framework demonstrate enhanced accuracy, but fail to achieve comprehensive coverage. These
63 inventories assimilate substantial detailed foundational data from various statistical dataset, on-site measurements or surveys
64 to represent real-world emission magnitudes, including energy consumption, removal efficiencies, and localized speciation
65 profile (An et al., 2021; Huang et al., 2021; Liu et al., 2018). Innovative data, such as measurements from continuous emission
66 monitoring systems (Bo et al., 2021; Tang et al., 2023; Wu et al., 2022), or methodologies like process-based models (Kang
67 et al., 2016; Zhao et al., 2020) are implemented to enable a more accurate characterization of complex emission dynamics.
68 Facility-level geographic location is incorporated to optimize the representation of spatial patterns (Liu et al., 2015a; Wang et

69 al., 2019; Wu et al., 2023). The reliability of these local-scale, sector- or species-specified inventories has been validated
70 against satellite and ground-based measurements (Liu et al., 2016a; Zhang et al., 2021; Zheng et al., 2019).
71 The other strategy for developing bottom-up emission inventories is commonly known as the integrated method. This method
72 consolidates multiple emission datasets for specific regions, species or sectors into a unified product, ensuring extensive
73 coverage (Li et al., 2017b). Taking advantage of existing inventories derived from localized data and advanced methods, the
74 integrated method facilitates the efficient generation of highly-resolved emission inventories at large scales. However, the
75 heterogeneity of different emission datasets presents challenges for the fusion, manifested in diverse data formats, sector
76 categories, species, spatial-temporal resolution. In recent years, there has been growing interest in adopting the integrated
77 approach to enrich inventories with local insights, particularly at the global (Crippa et al., 2023; Janssens-Maenhout et al.,
78 2015) and Asian scales (Kurokawa et al., 2013; Li et al., 2023a; Li et al., 2017b; Zhang et al., 2009). Researches on establishing
79 integrated inventories for China are constrained due to the inherent complexity and challenging accessibility of the data. These
80 efforts are concentrated in specific regions, such as **the Yangtze River Delta (YRD)** (An et al., 2021).
81 In this work, with the support of several research institutions, we use an emission integration model to construct a high-
82 resolution integrated emission inventory at a spatial resolution of 0.1° for China in 2017, denoted as INTAC. The challenges
83 associated with coupling multi-source heterogeneous data are addressed through the implementation of an inventory
84 integration framework. Then, leveraging the strengths of inventories enriched with local knowledge, we compile a
85 comprehensive highly resolved emission product to enhance the accurate representation of emissions from crucial regions,
86 sectors and species. Finally, the improved accuracy of emission magnitude and spatial distribution is evaluated using
87 atmospheric chemistry models.

88 **2 Methodology and data**

89 Figure 1 illustrates the schematic diagram of the integration process of INTAC. We collect seven emission inventories—MEIC
90 developed by Tsinghua University (Li et al., 2017a; Zheng et al., 2018), the industrial point source emission inventory for
91 China by the MEIC team (Zheng et al., 2021; Zheng et al., 2017), the YRD air pollutant emission inventory led by Nanjing
92 University (An et al., 2021; Zhou et al., 2017b), the Pearl River Delta (PRD) emission inventory by Jinan University (Huang
93 et al., 2021; Sha et al., 2021), the open biomass burning emission inventory in China by Peking University (Huang et al., 2012a;
94 Liu et al., 2015b; Song et al., 2009; Yin et al., 2019), the shipping emission inventory in East Asia by Tsinghua University
95 (Liu et al., 2016b; Liu et al., 2019), and the high-resolution ammonia emission inventory in China (PKU-NH₃) by Peking
96 University (Huang et al., 2012b; Kang et al., 2016). The details of these inventories and the rationale for choosing them will
97 be described in Sect. 2.1.

98 **Figure 1: Methodology framework of the INTAC inventory development.**

99 An integration model is then established to merge together emission inventories with different sectors, species, spatial-temporal
 100 resolution and formats (i.e., point, area, and gridded forms). The integration process consists of five steps: source mapping,
 101 species mapping, temporal disaggregation, spatial allocation, and spatial-temporal coupling, as detailed in Sect. 2.2. Based on
 102 the priority order, multi-source emission inventories are assembled at the standardized species, sector, and grid levels, yielding
 103 a standardized data cube. Ultimately, the integrated emission inventory INTAC is created for China, featuring a resolution of
 104 0.1 ° on a monthly scale and covering nine air pollutants (i.e., SO₂, NO_x, CO, NMVOC, NH₃, PM₁₀, PM_{2.5}, BC, OC).

105 2.1 Components of the integrated emission inventory INTAC

106 Table 1 lists the essential details about the seven inventories and priority order utilized for integration. Given MEIC's extensive
 107 coverage across species, sectors, and spatial domains, it functions as the default inventory in our integration, supplementing
 108 the missing data in other inventories. The remaining six inventories can be categorized into three types in sequence: point-
 109 source-based inventory (ranked sixth), regional inventories (ranked fifth and fourth), and process-based inventories (ranked
 110 third to first). The point-source-based inventory can directly correct the spatial misallocation of industrial emissions in MEIC
 111 at fine scales (Zheng et al., 2021; Zheng et al., 2017). The regional inventories further enhance local investigations of individual
 112 emission sources and simultaneously refine estimation methods for mobile and area sources (Gu et al., 2023; Zhao et al., 2018;
 113 Zhou et al., 2017b). Process-based inventories typically adopt advanced methods to improve the characterization for emission
 114 processes and parameters specific to particular sectors or species, thereby providing emission totals and distributions that are
 115 more in line with measurements (Huang et al., 2012a; Huang et al., 2012b; Kang et al., 2016; Liu et al., 2016b; Liu et al., 2019;
 116 Liu et al., 2015b; Song et al., 2009; Yin et al., 2019).

117 Table 1: List of emission inventories collected in this work.

Priority ranking	Emission inventory and developer	Year	Resolution	Region	Resolution	Species
1	PKU-NH ₃ (Peking University)	1980– 2017	Monthly	Mainland China	0.1 °	NH ₃
2	The shipping emission inventory for East Asia (Tsinghua University)	2017	Annually	East Asia	0.1 °	SO ₂ /NO _x /CO/NMVOC/ PM _{2.5} /BC/OC
3	The open biomass burning emission inventory for China (Peking University)	1980– 2017	Daily	Mainland China	~1km	SO ₂ /NO _x /CO/NMVOC/ NH ₃ /PM ₁₀ /PM _{2.5} /BC/OC
4	The PRD emission inventory (Jinan University)	2017	Monthly	PRD	0.05 °	SO ₂ /NO _x /CO/NMVOC/ NH ₃ /PM ₁₀ /PM _{2.5} /BC/OC
5	The YRD emission inventory (Nanjing University/Shanghai Academy of Environmental Sciences/Jiangsu Provincial Academy of Environmental Science)	2017	Annually	YRD	0.1 °	SO ₂ /NO _x /CO/NMVOC/ NH ₃ /PM ₁₀ /PM _{2.5} /BC/OC
6	The industrial point source emission inventory for China (Tsinghua University)	2012– 2018	Monthly	Mainland China	~1km	SO ₂ /NO _x /CO/NMVOC/ NH ₃ /PM ₁₀ /PM _{2.5} /BC/OC
7	MEICv1.3 (Tsinghua University)	2008– 2017	Monthly	Mainland China	0.25 °	SO ₂ /NO _x /CO/NMVOC/ NH ₃ /PM ₁₀ /PM _{2.5} /BC/OC

118 **2.1.1 MEIC**

119 The integrated inventory INTAC is built upon MEIC, a comprehensive database with extensive coverage across time periods,
120 space, species, and sectors. Developed by Tsinghua University since 2010 (<http://meicmodel.org.cn>) (Li et al., 2017a; Zheng
121 et al., 2018), the MEIC provides monthly emissions for air pollutants and CO₂ in China from 1990 to the present at a resolution
122 of 0.25 ° × 0.25 °. It caters to the demand for timely and accurate estimates of atmospheric emissions, gaining widespread
123 adoption by both domestic and international research institutions. We use 2017 emissions from MEIC v1.3 in this study.
124 MEIC employs several strategies to improve emission estimation parameters. This includes categorizing emission sources
125 across ~800 sectors, utilizing a technology- and big-data-driven approach for dynamic emission characterization, and

126 employing a localized emission factor database (Li et al., 2017a; Zheng et al., 2018). Emission estimates for power, on-road,
127 and residential sources are enhanced through the use of unit-level data (Liu et al., 2015a), county-level emission estimates
128 (Zheng et al., 2014), and integration of extensive household surveys (Peng et al., 2019), respectively. MEIC builds an database
129 encompassing temporal allocation profiles (ranging from yearly to monthly, daily, and hourly) (Li et al., 2017b), spatial
130 allocation proxies (from province to county, and further to grids) (Geng et al., 2017; Li et al., 2017b; Zheng et al., 2017), and
131 a speciation framework for NMVOC involving five mechanisms (CB-IV, CB05, SAPRC-07, SAPRC-99, and RADM2) (Li et
132 al., 2014) (Li et al., 2014) to support the development of model-ready gridded emissions.
133 Among the seven inventories, MEIC has the lowest priority, and is only considered when the other six cannot provide necessary
134 emissions for a specific city and source.

135 **2.1.2 The industrial point source emission inventory for China**

136 The proxy-based method used for spatial allocation in MEIC introduces biases in emission mapping, especially at kilometer
137 scale (Zheng et al., 2021; Zheng et al., 2017). To significantly reduce the uncertainty, we merged an industrial emission
138 inventory with detailed information on ~100,000 facilities into INTAC.

139 Compiled by Tsinghua University for the year 2013 (Zheng et al., 2021) and updated by the MEIC team for 2017, this point-
140 based inventory combines three databases investigated under the guidance of the Chinese government, offering a
141 comprehensive overview of industrial facilities. It includes details on locations, activity rates, production technology, end-of-
142 pipe pollution control devices, and other parameters. **It is worth noting that the facility-level activity data was corrected using
143 provincial activity data from MEIC as a total constraint to be consistent with national totals from statistics (Zheng et al., 2021).**

144 The facility-level, technology-based approach allows for dynamic tracking of emission fluctuations resulting from
145 technological advancements and tightening emission regulations. Crucially, the use of facility geolocations rather than relying
146 on spatial proxies like urban population enables the derivation of gridded industrial data at a resolution of ~1 km. This approach
147 significantly avoids misallocating emissions from rural to urban areas at fine grids, as supported by previous studies
148 demonstrating its effectiveness in mitigating simulated biases in air pollutant concentrations within densely populated regions
149 (Zheng et al., 2021). For temporal variations, it employs the same monthly profiles as MEIC, including the production of
150 various industrial goods or **Gross Domestic Product (GDP)**, as outlined in Li et al. (2017b). The NMVOC speciation also
151 aligns with the MEIC model. This inventory takes priority over MEIC, indicating that only few industrial sources not covered
152 in this inventory are substituted with MEIC.

153 **2.1.3 The YRD air pollutant emission inventory**

154 Regional emission inventories in YRD provide a more accurate representation of emissions compared to the national-scale
155 MEIC, as proven by ground and satellite observations (Yang and Zhao, 2019; Zhang et al., 2021; Zhao et al., 2017a; Zhao et
156 al., 2018; Zhao et al., 2020; Zhou et al., 2017b). This improvement is attributed to the avoidance of outdated or non-localized
157 emission calculation parameters, commonly present in large-scale inventories like MEIC. Here, we merge the 2017 YRD air

158 pollutant emission inventory into INTAC for state-of-the-art estimates for rapidly changing emissions over this core area (An
159 et al., 2021; Gu et al., 2023; Zhou et al., 2017b).
160 Localized field surveys and measurements greatly enhance the reliability of calculation parameters within the YRD inventory.
161 Highly-resolved emissions for the power sector are acquired through on-site monitoring with high temporal resolution (Zhang
162 et al., 2019b), rather than relying on static and outdated average emission factors. Facility-level information (e.g., the removal
163 efficiencies) obtained from local investigation and a segment-based industrial process method enhances the understanding of
164 both the quantity and spatial patterns of industrial emissions. Considering meteorological factors and land use conditions
165 during agricultural processes results in more accurate seasonal and spatial distributions of NH₃ emissions. (Zhao et al., 2020).
166 An investigation of in-use machinery is conducted to capture the seasonal emission patterns from off-road machines (Zhang
167 et al., 2020). Real-world surveys are performed to determine grain straw ratios and household burning proportions, facilitating
168 the quantification of emissions from biomass-fueled stoves. The PM_{2.5} and NMVOC speciation profiles are updated based on
169 multi-instrument sampling and analysis in both current and previous studies (Huang et al., 2018; Zhao et al., 2017a), satisfying
170 the needs for simulating PM_{2.5} chemical components and O₃. The YRD inventory is collected with a spatial resolution of 0.1
171 degree and an annually temporal resolution in this study. Only CB05 VOC species are collected.

172 **2.1.4 The PRD emission inventory**

173 The regional emission inventories in the PRD region have demonstrated enhanced reliability compared to previous studies
174 (Huang et al., 2021; Sha et al., 2021; Zheng et al., 2012). The PRD emission inventory in this study captures spatial and
175 temporal variations within the PRD region under emission control policies, serving as a foundation for supporting air quality
176 modeling (Huang et al., 2021; Sha et al., 2021).

177 The PRD inventory exhibits notable accuracy improvements, achieved through big data-driven estimation methods, updated
178 spatial-temporal allocations, and localized NMVOC speciation profiles. Gridded hourly open biomass burning emissions are
179 quantified by fusing the fire radiative power data from three satellites, and hourly shipping emissions are estimated using high-
180 frequency Automatic Identification System (AIS) records. Thirty-one monthly profiles and ten spatial proxies are updated to
181 reflect spatial-temporal patterns of emissions influenced by economic growth and energy consumption adjustment.
182 Approximately 90% of industrial emissions are disaggregated using exact locations, and novel proxies (e.g., farmland
183 production potential) have been developed for several sectors. The NMVOC speciation is carried out through massive localized
184 measurements and literature reviews, manifested as a collection of 480 NMVOC source profiles across eight sectors and 380
185 species. The species relevant to the SAPRC-07 chemical mechanism are collected in this work. Additionally, the inventory
186 encompasses 800 source categories, placing particular emphasis on incorporating new sectors relevant to VOC emissions.
187 Activity rates are improved through extensive field surveys and data mining efforts, involving investigations of production
188 data for 10,000 industrial plants and the gathering of activity-relevant information for 50 million vehicles. Emission factors
189 that reflect local context are obtained or revised based on source measurements and latest research findings. These updates

190 help mitigate uncertainties in emission estimates for the PRD region. The PRD inventory is initially collected at a monthly
191 resolution and a spatial resolution of 0.05 °, with detailed spatial-temporal allocation proxies outlined in Huang et al. (2021).

192 **2.1.5 The open biomass burning emission inventory in China**

193 As a significant source of CO₂, BC, OC and other pollutants, open biomass burning profoundly influences air quality, climate
194 change, and human health (Reisen et al., 2013). A case study in summer 2011 for the YRD region revealed that during a severe
195 haze episode, open biomass burning contributed to 37%, 70%, and 61% of PM_{2.5}, OC, and EC emissions, respectively (Cheng
196 et al., 2014). To address the absence of this source in MEIC, we integrate a high-resolution open biomass burning emission
197 inventory from Peking University into INTAC (Huang et al., 2012a; Liu et al., 2015b; Song et al., 2009; Yin et al., 2019).

198 The inventory applies satellite observations to tackle considerable uncertainties tied to provincial statistical data and overcome
199 the coarse resolution found in previous studies (Ni et al., 2015). The estimation of biomass consumption in the inventory is
200 based on the fire radiative energy (FRE) approach, which depends on the energy emitted by fires. This approach helps reduce
201 the biases introduced by burned areas algorithms, especially for small-scale fires. The inventory utilizes the high spatial
202 resolution land cover dataset GlobeLand30 derived from multispectral images to classify biomass fuel types. Eventually, daily
203 emissions from forest, grassland, cropland and shrubland are calculated at a 1-kilometer resolution. The reasonableness is
204 validated by comparing with other datasets, such as the fourth version of the Global Fire Emissions Database. The initially
205 collected inventory lacks model-ready VOC species.

206 **2.1.6 The shipping emission inventory in East Asia**

207 In recent years, maritime trade in the East Asian region has significantly increased (Trade and Development, 2014), resulting
208 in a surge in shipping emissions with substantial impacts on air quality and climate. Previous studies have indicated that East
209 Asian shipping emissions accounted for 16% of the global total in 2013. Shipping emissions made a growing contribution to
210 the rise in annual mean PM_{2.5} concentrations, reaching levels as high as 5.2 µg/m³ in 2015 (Lv et al., 2018). To address the
211 omission of this emission source in the MEIC, we integrate the shipping emission inventory in East Asian for 2017 into INTAC
212 (Liu et al., 2016b; Liu et al., 2019).

213 The inventory introduces an innovative approach based on comprehensive and dynamic ship activity data. A static dataset of
214 approximately 66,000 vessels is compiled as a foundation, using information from Lloyd's Register and China Classification
215 Society. This dataset encompasses various ship properties, including ship category, hull shape, engine rotational speed, engine
216 capacity, maximum speed capability, build year, and more. High quality AIS data is used to capture ship activities,
217 incorporating the Maritime Mobile Service Identification identifier, geographical location, real-time speed, and time-related
218 information. The AIS data is also employed to generate gridded emissions from shipping at a spatial resolution of 0.1 °. The
219 inventory enhances our comprehension of regional-level shipping emissions and significantly alleviates biases arising from
220 the misallocation of marine fuels, as observed in global studies (Endresen et al., 2007). The collected shipping inventory
221 provides emissions at an annually resolution for seven species, including SO₂, NO_x, CO, NMVOC, PM_{2.5}, BC, and OC.

222 **2.1.7 PKU-NH₃**

223 As a prominent alkaline component in the atmosphere, ammonia plays a crucial role in atmospheric chemistry, terrestrial and
224 aquatic ecosystems through its participation in atmospheric reactions and deposition processes. This study integrates PKU-
225 NH₃, a high-resolution ammonia emission inventory for China developed by Peking University. PKU-NH₃ is designed to track
226 the evolution of NH₃ emissions amid the rapid increase in grain and meat production in China over the past few decades
227 (Huang et al., 2012b; Kang et al., 2016). This inventory offers a better grasp on NH₃ emissions in China through the application
228 of a processed-based method and more reliable emission factors, in contrast to previous studies (Kurokawa et al., 2013; Li et
229 al., 2017b). Top-down NH₃ inversion through satellite observations provides additional validation for the accuracy of PKU-
230 NH₃ (Paulot et al., 2014).

231 Earlier studies of NH₃ emissions commonly used fixed EFs, overlooked some ammonia emission sources, and had coarse
232 resolutions (Ohara et al., 2007; Streets et al., 2003). Unlike previous approaches, the PKU-NH₃ incorporates dynamic and
233 multifactorial EFs and more comprehensive emissions sources. The determination of emission factors takes into account
234 various parameters related to local conditions and agricultural practices. When estimating NH₃ emissions of synthetic fertilizer
235 application, the model considers five types of fertilizers, as well as factors such as soil acidity, ambient temperature, fertilizer
236 application technique and dosage, wind speed, and in-situ measurements of NH₃ flux. For livestock waste, NH₃ emissions are
237 calculated using a mass-flow approach across four phases of manure management, considering variables such as animal rearing
238 types, temperature and wind speed. In addition, NH₃ emissions from other small sources are also quantified, including
239 agricultural soil, nitrogen-fixing crop, crop residue compost, excretion of rural populations, open biomass burning, waste
240 disposal, gasoline vehicles, diesel vehicles, and industrial processes. The NH₃ emissions are allocated from provinces into 0.1 °
241 grids based on spatial proxies such as land cover, rural population, and other relevant indicators. Monthly emission factors
242 shaped by meteorological conditions are used to calculate NH₃ emissions from fertilizer application and livestock source at a
243 monthly level.

244 **2.2 The integration of multi-source heterogeneous data**

245 In the integration process, seven heterogeneous inventories are first normalized in terms of emission sources, species, spatial-
246 temporal resolutions, and then integrated following a priority order to produce a standardized, highly-resolved data cube.

247 **2.2.1 Source mapping**

248 To merge inventories under a unified emission source classification system, the emission sources in the MEIC model are
249 categorized into 88 standard sectors for mapping (Table S1). The first-level category comprises 10 subcategories, namely,
250 stationary combustion, industrial process, mobile source, solvent use, agriculture, dust, biomass burning, storage and
251 transportation, waste treatment and other sources. These are then further subdivided into 88 second-level sources, which take
252 industrial classification for national economic activities for reference. For example, the industrial process sector encompasses

253 emission sources such as the manufacturing of non-metallic mineral products, manufacturing of chemical fibers, manufacturing
254 of foods, smelting and pressing of ferrous metals, and more. In the initial step of integration, the sectors in each emission
255 inventory are mapped to the standardized two-level sources.

256 **2.2.2 Species mapping**

257 Then, non-methane volatile organic compounds (NMVOC), particulate matter (PM), and NO_x in each inventory are converted
258 into model-ready species to support CTMs. The species mapping process is grounded in the chemical species mapping methods
259 in MEIC model (Li et al., 2017b; Li et al., 2014). The model supports aerosol chemical schemes such as AER05 and AER06.
260 NO_x emissions are allocated to NO and NO_2 emissions based on ground observations. The step-by-step NMVOC speciation
261 framework developed in Li et al. (2014) is employed to generate emissions for various gas-phase chemical mechanisms
262 commonly used in CTMs, including CB-IV, CB05, SAPRC-07, SAPRC-99 and RADM2. The framework incorporates an
263 explicit assignment approach and updated profiles based on both local measurements and the SPECIATE database v.4.5. The
264 sources abundant with oxygenated volatile organic compounds (OVOC) are identified, and the incomplete profiles with
265 missing OVOC fractions are corrected. The accurate speciation mapping helps reduce uncertainties in model-ready emissions.
266 For inventories providing speciated VOC emissions for certain mechanisms (e.g., the YRD inventory for CB05, PRD inventory
267 for SAPRC-07), we directly use their emissions, or alternatively, utilize MEIC's speciation framework to generate model
268 species for the five chemical mechanisms.

269 **2.2.3 Temporal disaggregation**

270 The seven emission inventories are collected at different temporal resolutions (Table 1) and need to be temporally allocated to
271 a unified monthly scale for integration. Monthly emissions from PKU- NH_3 , the PRD inventory, the industrial point source
272 inventory and MEIC can be directly used for data merge. Daily-level open biomass burning emission inventory for China is
273 aggregated to monthly scales through summation. For annually inventory (e.g., the YRD inventory), sector-specific monthly
274 profiles derived from the MEIC model are used for disaggregation (Li et al., 2017b). For instance, monthly power generation
275 data from the National Bureau of Statistics describe variations in monthly power emissions. Industrial production or GDP from
276 the National Bureau of Statistics are employed to account for monthly emission fluctuations related to industrial heating,
277 boilers, cement, iron and steel, and other industrial processes. Monthly emission factors calculated by the International Vehicle
278 Emissions model are applied to on-road vehicles. Considering the insignificant monthly variations of Automatic Identification
279 System data for marine shipping, the annual shipping emissions are uniformly disaggregated across the months.

280 **2.2.4 Spatial allocation**

281 The seven inventories are in different data formats, including point source and gridded formats at varying resolutions,
282 necessitating spatial harmonization for integration. **Although the industrial point source inventory and the open biomass
283 burning inventory can accurately pinpoint the specific geographic locations of emission sources, the other five inventories rely**

284 on numerous spatial proxies to disaggregate emissions into grids, which inevitably introduce uncertainties at very fine
285 resolutions. Therefore, we re-grid the final product to 0.1 °to ensure high level spatial accuracy. Gridded emissions finer than
286 0.1 °resolution are aggregated to 0.1 °, which is performed in the open biomass burning inventory and the PRD inventory. For
287 the industrial point source inventory, latitude and longitude coordinates are employed to directly position them within grid
288 locations. Area sources in MEIC are allocated to grids using spatial proxies within the MEIC model (Li et al., 2017b). For
289 instance, industrial sources are assigned to grids based on urban population (Schneider et al., 2009). The road network (Zheng
290 et al., 2014) serves as a proxy for disaggregating emissions of on-road vehicles, while rural population (Schneider et al., 2009)
291 is used as the proxy for fertilizer and livestock sources. It's important to mention that uncertainties may arise at city borders if
292 emissions from adjacent cities come from different inventories during the integration process. To mitigate biases introduced
293 by border issues, all emissions at 0.1 ° resolution are first uniformly downscaled to 1 km for the spatial-temporal coupling
294 process, and then re-gridded back to 0.1 ° for the final product.

295 **2.2.5 Spatial-temporal coupling**

296 Finally, following the procedures outlined in Sections 2.2.1 to 2.2.4, all inventories are preprocessed to a standardized format,
297 encompassing 88 sectors, various species, a spatial resolution of 1 km, and a monthly temporal resolution. This preprocessing
298 prepares the inventories for merging, ultimately resulting in the generation of a standardized data cube.
299 The integration is carried out at source-by-source, species-by-species, and grid-by-grid levels, with the process guided by the
300 priority order of each inventory (Table 1). MEIC serves as the default inventory in our integration, offering extensive spatial
301 and species coverage, along with spatial proxies, temporal profiles, and NMVOC speciation methods within the model. The
302 remaining six emission inventories are assigned a predefined priority order. The industrial point source emission inventory for
303 China takes precedence over industrial emissions in MEIC, substituting proxy-based spatial allocation with precise
304 geographical coordinates. This extends the applicability of MEIC from a resolution greater than 0.25 ° to finer scale (Zheng et
305 al., 2021; Zheng et al., 2017). To achieve fine-grained emission characterization in critical areas, the YRD and PRD emission
306 inventory enriched with localized data and advanced methods are incorporated to update emissions in these areas. While MEIC
307 comprehensively estimates emissions for ~800 source categories in China, there may still be omissions for certain emission
308 sources. The inclusion of inventories for open biomass burning and East Asian shipping helps partially fill this gap. The PKU-
309 NH₃, generated by a process-based model to provide a comprehensive understanding of China's NH₃ sources, is utilized to
310 replace all NH₃ emissions in other inventories. The prioritization is performed city by city. For emissions of a particular species
311 from a specific emission sector, when multiple inventories overlap in city grids, the estimates from the highest-priority
312 inventory is selected as the final emissions. Through this step, the integrated inventories are developed based on the configured
313 output settings, such as map projection and spatial-temporal attributes.

314 **2.3 Evaluation of the emission inventory using WRF/CMAQ model**

315 We apply Weather Research and Forecasting Version 3.9 (WRFv3.9) and Community Multiscale Air Quality Version 5.2
316 (CMAQ5.2) as the air quality simulation systems. Two nested simulation domains with horizontal resolutions of 36 and 12
317 km are used (Fig. S1). The mother domain (172×127 cells) covers the entire China and parts of the neighboring countries,
318 and the nested domain (226×241 cells) includes the heavily polluted Eastern China. Four-month (January, April, July, and
319 October) simulations in 2017 is carried out, with a 7-day spin-up period preceded each month. The vertical resolution in WRF
320 is set with 45 sigma levels ranging from the surface up to 100 hPa. Subsequently, it is collapsed into 28 layers through the
321 Meteorology-Chemistry Interface Processor (MCIP) before being input into CMAQ.

322 The configuration of WRF and CMAQ model in this study follows Cheng et al. (2019). The meteorological initial and boundary
323 conditions for the simulation are provided by the final reanalysis data from the National Centers for Environmental Prediction
324 (NCEP-FNL, <https://rda.ucar.edu/datasets/ds083.2/>). The schemes for shortwave radiation, longwave radiation, land surface
325 processes, boundary layer, cumulus parameterization, and cloud microphysics are selected as the New Goddard scheme (Chou
326 et al., 1998), RRTM scheme (Mlawer et al., 1997), Pleim–Xiu surface layer scheme (Xiu and Pleim, 2001), ACM2 PLB
327 scheme (Pleim, 2007), Kain-Fritsch scheme (Kain, 2004), and WSM6 scheme (Hong and Lim, 2006), respectively.
328 Observational nudging and soil nudging are employed to enhance the meteorological simulation. Regarding CMAQ model,
329 the chemical mechanisms for gas-phase, aqueous-phase, and aerosol are configured as CB05, the Regional Acid Deposition
330 Model (RADM), and AERO6, respectively. Photolysis rates are calculated online using the simulated aerosols and ozone
331 concentrations. Anthropogenic emissions outside China are taken from MIX inventory (Li et al., 2017b). The integrated
332 inventory INTAC and MEIC are used for comparison within China. Biogenic emissions are calculated using the Model of
333 Emissions of Gases and Aerosols from Nature version 2.1 (MEGANv2.1), while dust and lightning emissions are not
334 considered in this study.

335 The performances of WRF for the meteorological parameters are evaluated against the Integrated Surface Database (ISD) from
336 the National Climatic Data Center (NCDC) of the National Climate Data Center (<ftp://ftp.ncdc.noaa.gov/pub/data/noaa/>).
337 Evaluation metrics include correlation coefficient (R), mean bias (MB), root mean square error (RMSE), normalized mean
338 bias (NMB), and normalized mean error (NME). Table S2 demonstrates good agreement between WRF model results and
339 ground-level observations. Similar configurations have been also validated in previous studies (Cheng et al., 2019; Cheng et
340 al., 2021a; Cheng et al., 2021b). CMAQ modeling results are assessed using hourly observed concentrations of air pollutants
341 obtained from the China National Environmental Monitoring Center (<http://www.cnemc.cn/>).

342 3 Results

343 3.1 China's emission characteristics in 2017

344 We utilized the integrated emission inventory to analyze pollutant emissions in China for the year 2017. Major air pollutant
345 emissions were estimated as follows: 12.3 Tg SO₂, 24.5 Tg NO_x, 141.0 Tg CO, 27.9 Tg NMVOC, 9.2 Tg NH₃, 11.1 Tg PM₁₀,
346 8.4 Tg PM_{2.5}, 1.3 Tg BC, and 2.2 Tg OC. The emission data, organized into power, industry, residential, transportation,
347 agriculture, solvent use, shipping, and open biomass burning sectors, are available for download from
348 <https://doi.org/10.5281/zenodo.10459198> (Wu et al., 2024) and <http://meicmodel.org.cn/intac>. The following sections will
349 characterize emissions in detail across sectors, fuel types, and spatial distributions.

350 3.1.1 By sectors

351 Table 2 displays emissions specific to power, industry, residential, transportation, agriculture, solvent use, shipping, and open
352 biomass burning sectors in the integrated emission inventory INTAC. For pollutants primarily originating from fuel
353 combustion and industrial processes (e.g., SO₂, NO_x, CO, PM₁₀, and PM_{2.5}), the power, industry, and transportation sources
354 make a significant contribution to their emissions, ranging from 56% to 83%. Industrial sources take a leading role in various
355 atmospheric pollutants, contributing more than 30% for SO₂, NO_x, CO, NMVOC, PM₁₀, and PM_{2.5} emissions. Due to low
356 combustion efficiency and a lack of emission control measures, residential sources exhibit a high emission factor for products
357 of incomplete combustion, leading to 40% of CO emissions, 48% for BC, and 73% for OC. Solvent sources exclusively
358 produce NMVOC emissions, constituting 33% to the overall emissions. The complexity of VOC emission origins is evident
359 in the diverse range of contributing sources. Agricultural sources dominate NH₃ emissions, comprising an 83% share of total
360 emissions. As described in Sect. 2.1.7, the PKU-NH₃ incorporates a wide variety of NH₃ sources, providing a more
361 comprehensive understanding of the sectors contributing to NH₃ emissions. Insignificant sources may exert large influence in
362 specific regions or periods, such as during large wildfires or in cities with heavy traffic. Additionally, the contribution of the
363 supplemented open biomass burning source cannot be overlooked, especially for OC (7%) and NMVOC (6%).

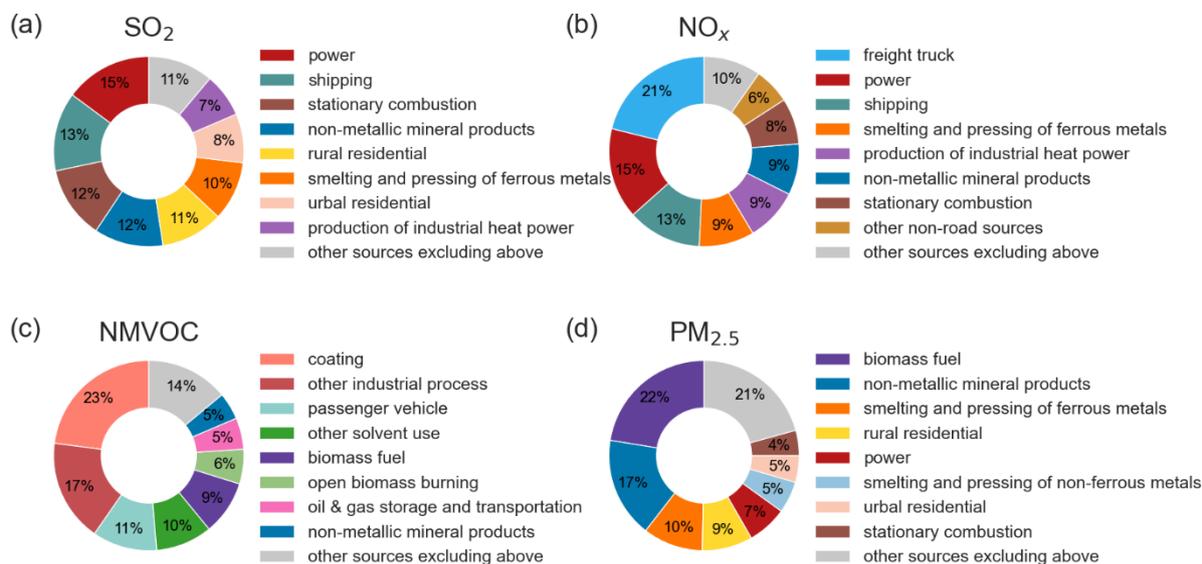

364 Figure 2 consolidates 88 standardized emission sources into 25 categories, allowing for a more detailed analysis of sectoral
365 emission patterns compared to Table 2. Owing to substantial coal use in industrial and power sectors, along with sulfur-rich
366 ship fuels, prominent contributors to SO₂ emissions include power, shipping, stationary combustion, and manufacture of non-
367 metallic mineral products sources, accounting for 15%, 13%, 12%, and 12% respectively to total SO₂ emissions. This indicates
368 that achieving further reductions in SO₂ emissions will require the implementation of more energy-efficient, end-of-pipe
369 control measures, and adoption of low-sulfur fuels. The dominant origins of NO_x emissions are from the **freight truck**, power
370 generation, and shipping sectors, representing 21%, 15%, and 13% of the total emissions. Both **freight trucks** and vessels
371 extensively use compression ignition engines, prone to generating NO_x emissions under high-temperature and oxygen-rich
372 conditions. Implementing strict vehicle standards is crucial to effectively reduce NO_x emissions from exhaust gases. Coatings,
373 other industrial processes, and passenger vehicle sources constitute 51% of anthropogenic NMVOC emissions. The major

374 contributors to primary PM_{2.5} emissions include biomass fuel, the manufacture of non-metallic mineral products, and the
 375 smelting and pressing of ferrous metals source, making up 22%, 17%, and 10% of the total emissions, respectively. It's
 376 noteworthy that the use of biomass fuels (e.g., rice straw, firewood) for cooking or heating in rural areas results in considerable
 377 PM_{2.5} emissions, especially in provinces like Sichuan, Anhui, Shandong, and Heilongjiang.

378

379 **Table 2: Anthropogenic emissions of air pollutants by sectors in the 2017 INTAC inventory for China (Units: Gg).**

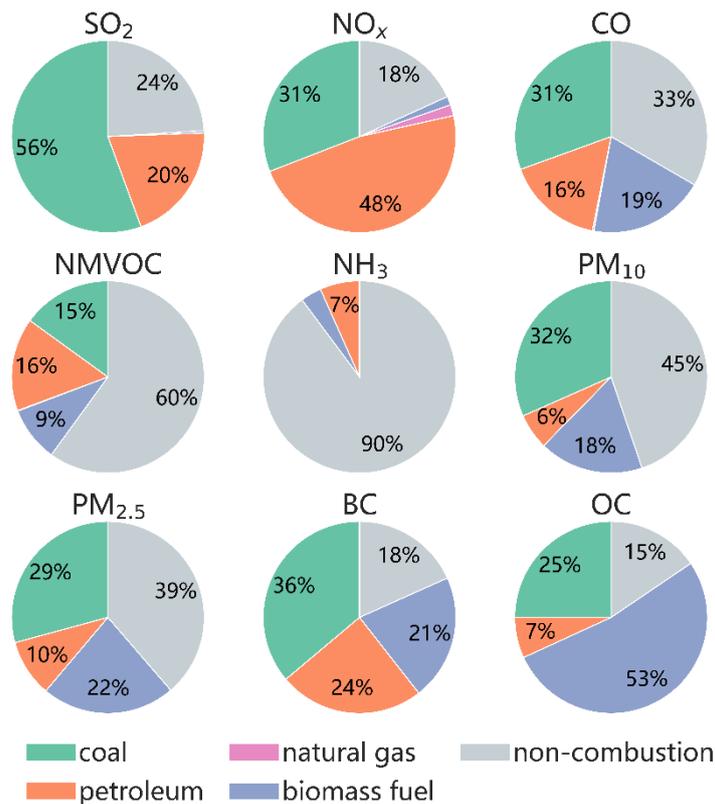

Sectors	SO ₂	NO _x	CO	NMVOC	NH ₃	PM ₁₀	PM _{2.5}	BC	OC
Power	1822	3790	4909	152	14	981	568	6	0
Industry	6066	8800	52828	8824	249	5603	3620	308	285
Residential	2361	861	55895	3676	629	3516	3088	606	1649
Transportation	341	7751	22597	4123	619	533	493	257	95
Agriculture	0	0	0	0	7609	0	0	0	0
Solvent	0	0	0	9255	0	0	0	0	0
Shipping	1642	3077	391	191	2	73	264	43	49
Open biomass burning	21	215	4403	1659	76	409	355	35	167
Total	12253	24494	141023	27881	9198	11117	8388	1255	2245

380 **Figure 2: Sector-specific distributions of emissions in the 2017 INTAC inventory for China.** (a), (b), (c) and (d) represent the sectoral
 381 contributions for SO₂, NO_x, NMVOC and PM_{2.5}, respectively. The figure only displays the top eight contributing sources, while sources
 382 excluding these are categorized as “other sources”.

383 **3.1.2 By fuel types**

384 Figure 3 illustrates the proportions of major air pollutant emissions in 2017 for each fuel type. Fossil fuel combustion
 385 significantly dominates the emissions of PM₁₀, PM_{2.5}, CO, BC, SO₂, NO_x, with proportion ranging from 38% to 80%. The coal
 386 combustion accounts for 56% of SO₂ emissions, with power, residential activities and industrial production as the primary
 387 emitter. Meanwhile, petroleum combustion, mainly from marine vessels, constitutes 20% of SO₂ emissions. For NO_x emissions,
 388 petroleum combustion contributes 48% of the total, predominantly arising from **freight trucks** (5.2 Tg), marine vessels (3.1
 389 Tg), and passenger vehicles (1.0 Tg). Coal combustion processes, such as power (3.6 Tg) and industrial boiler (2.2 Tg) also
 390 result in substantial NO_x emissions (31%). The biomass fuel source causes 53% of OC emissions. Emissions of NMVOC and
 391 NH₃ are primarily associated with non-combustion processes.

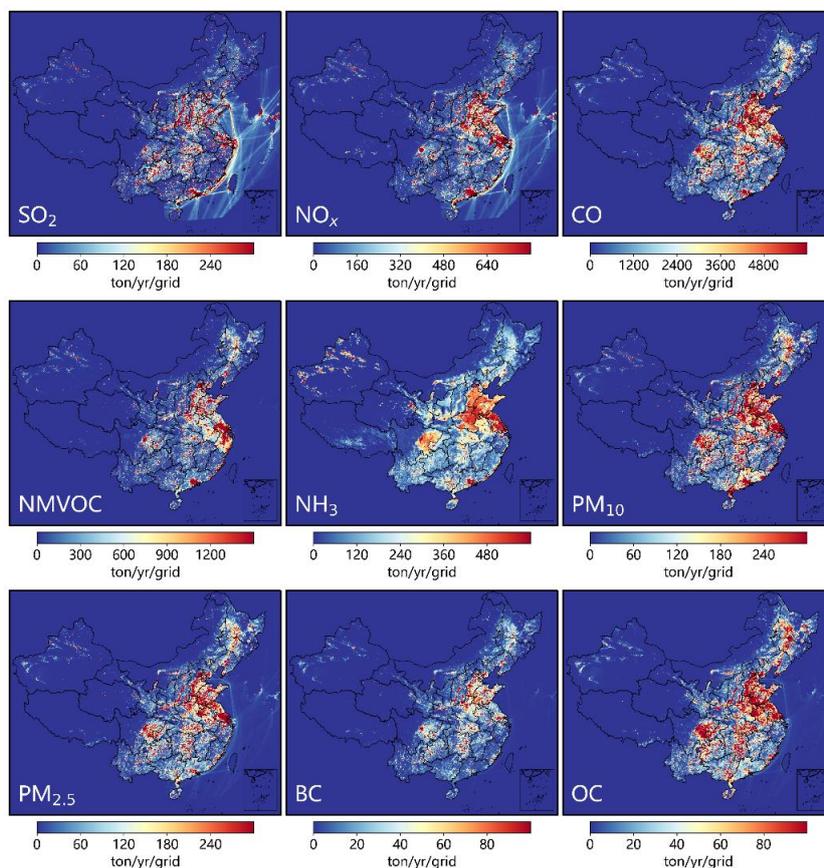

392 **Figure 3: Fuel-specific distributions of major air pollutant emissions in the 2017 INTAC inventory for China.**

393 **3.1.3 Spatial distribution**

394 We present the gridded emission maps of major air pollutants in Fig. 4. Emissions from anthropogenic sources in China exhibit
 395 significant spatial heterogeneity. Due to economic growth and industrial activities, air pollutant emissions are primarily
 396 concentrated in the central and eastern regions of China, especially in economically developed urban clusters such as **the**
 397 **Beijing-Tianjin-Hebei (BTH)** region, the YRD, the PRD, as well as in regions like Sichuan and Chongqing. These four key

398 areas, as depicted in Fig. S2, collectively account for 26%, 34%, 35%, 37%, 35%, 33%, 27%, 27%, and 29% of the national
399 emissions of SO₂, NO_x, CO, NMVOC, NH₃, PM₁₀, PM_{2.5}, BC, and OC, respectively. Moreover, the emission maps at a fine
400 spatial resolution of 0.1° × 0.1° present the local variations in emission patterns, identifying numerous hotspots in small areas
401 and showcasing distinct gradients in emissions. Table 3 shows the provincial-level emissions (except Hong Kong, Macao, and
402 Taiwan), and a map depicting provincial boundaries is displayed in Fig. S2. The emission levels in specific provinces are
403 determined by factors such as resource endowments, industrial structure, energy consumption, and emission control measures.
404 Taking SO₂ as an example, the top five provinces are Shanxi, Shandong, Hebei, Guizhou, and Inner Mongolia, collectively
405 accounting for 36% of the national total SO₂ emissions. The Guizhou Province, located in the southwest of China, is
406 characterized by high-sulfur coal and a relatively gradual implementation of pollution control measures, which results in
407 elevated SO₂ emissions. In other four provinces, large scale heavy industries have led to substantial coal consumption and
408 correspondingly higher SO₂ emissions. Provinces with a less industry-focused economic structure and lower energy
409 consumption, including Tianjin, Hainan, Qinghai, Beijing, and Tibet, exhibit the lowest SO₂ emissions, accounting for
410 approximately 2% of the national total.

411 **Figure 4: Spatial distributions of major air pollutant emissions in the 2017 INTAC inventory for China.**

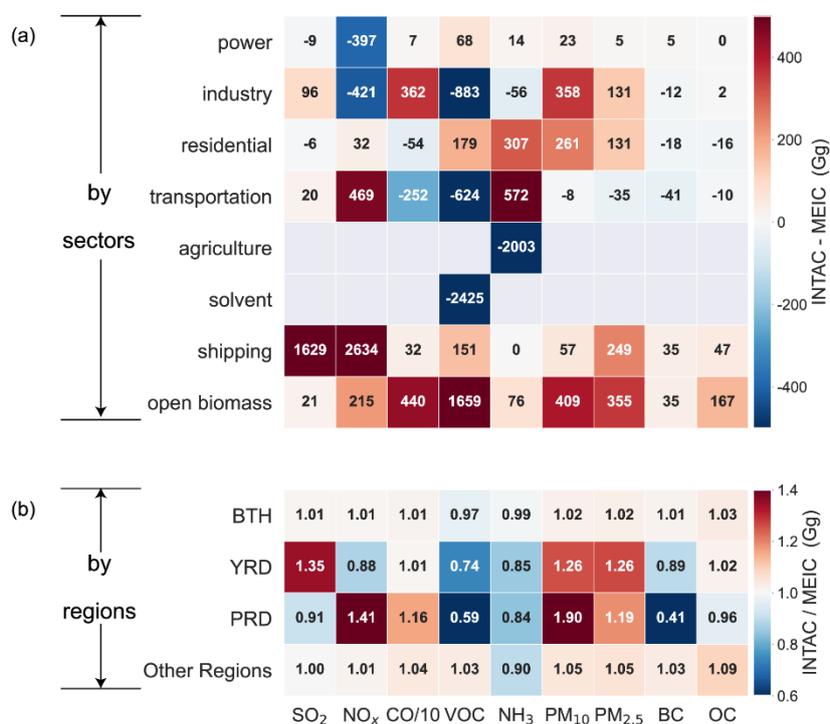

412 **Table 3: Anthropogenic emissions of air pollutants by provinces in the 2017 INTAC inventory for China (Units: Gg).** The shipping
 413 emission inventory in East Asia is not included.

Sectors	SO₂	NO_x	CO	NM VOC	NH₃	PM₁₀	PM_{2.5}	BC	OC

414 **3.2 Improved accuracy of China’s anthropogenic emissions by INTAC**

415 **3.2.1 Comparison of emission magnitudes in INTAC with MEIC across sectors and regions**

416 The INTAC inventory improves the representation of anthropogenic air pollutant emissions by incorporating a large number
 417 of industrial point sources, integrating high-resolution regional inventories, and supplementing missing emission sources in
 418 MEIC. Remarkable differences between INTAC and MEIC are illustrated in Fig. 5 across regions and sectors. Compared to
 419 MEIC, the INTAC inventory shows higher level of 16.7%, 11.5%, 10.8%, 11.0%, and 9.1% for SO₂, NO_x, PM₁₀, PM_{2.5}, and
 420 OC emissions, respectively. However, it indicates lower levels of 6.3% and 10.6% for NMVOC and NH₃. CO and BC
 421 emissions exhibit good agreement between the two inventories, with differences lower than 3.9%. In comparison to MEIC, the
 422 supplementary emission sources in INTAC—specifically, open biomass burning and marine shipping—account for the
 423 majority of increased emissions, contributing 95%, 89%, and 74% for SO₂, CO, and PM_{2.5}, respectively. Additionally, the
 424 incorporation of PKU-NH₃ in INTAC leads to a 21% decrease in NH₃ emissions from agricultural sources, while NH₃
 425 emissions from residential sources and transportation increase by 99% and 13.1 times, respectively. Such difference in
 426 agricultural sources is mainly caused by the estimates of synthetic fertilizer (Kang et al., 2016), particularly concerning the
 427 treatment of fertilizer types and corresponding emission factors.

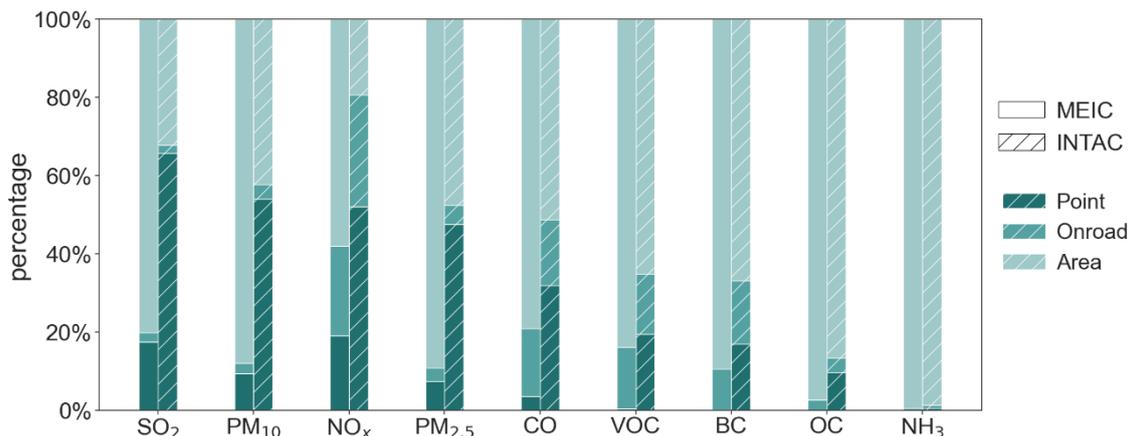

428 **Figure 5: Inter-comparisons of emission estimates between the INTAC inventory and MEIC.** (a) shows the difference by sectors, and
 429 (b) presents the ratio of emissions in INTAC to those in MEIC.

430 Many discrepancies between MEIC and INTAC arise from the integration of regional emission inventories. As presented in
431 Fig. 5b, notable disparities are observed in the YRD and PRD region. Estimates for NO_x emissions in the YRD region are
432 approximately 88% of those derived from the MEIC model. This highlights an enhanced precision attributable to reliable
433 assessments of denitrification efficiency in power plants and the measured NO_x emission factors for both power plants and
434 boilers within the integrated YRD inventory, as supported by previous research studies (Zhao et al., 2018). INTAC's estimates
435 for NMVOC emissions from the YRD region are 26% lower than estimates in MEIC. The overestimation in MEIC mainly
436 results from the uncertainties of solvent use source, particularly coating and printing and dyeing processes. The integrated
437 YRD emission inventory employs more accurate calculation parameters, such as statistical data from local city yearbooks,
438 industry association reports, and apparent consumption of solvents. Furthermore, the speciation profiles of NMVOC are
439 localized and corrected based on the literature research and measurements. In the PRD region, The NO_x emissions from INTAC
440 are 41% higher than MEIC estimates, with non-road sources and non-metallic mineral products contributing 45% and 40% to
441 this difference, respectively. The PRD inventory employs a detailed calculation approach for shipping emissions based on AIS
442 data, in contrast to the simplified approach for inland waterway sources in MEIC. The NO_x emissions from industrial processes
443 of brick and flat glass manufacturing are not considered in MEIC, which is a deficiency that is addressed in the integrated PRD
444 inventory. INTAC's NMVOC emissions are approximately 59% of those from MEIC. The disparity is particularly notable in
445 industrial and solvent use sources, contributing 49% and 35%, respectively, to the observed difference. In INTAC, nearly half
446 of the VOC emission factors for industrial solvent sources are based on local measurements, and a preference for raw material-
447 based calculations over product-based ones reduces uncertainty in the estimation. For significant VOC-emitting sources like
448 cleaning solvents, MEIC employs an emission factor of 1000 g/kg, whereas the PRD inventory uses 850 g/kg. In the case of
449 oil refineries, the emission factors are 2.76 g/kg for MEIC and 1.82 g/kg for the PRD inventory.

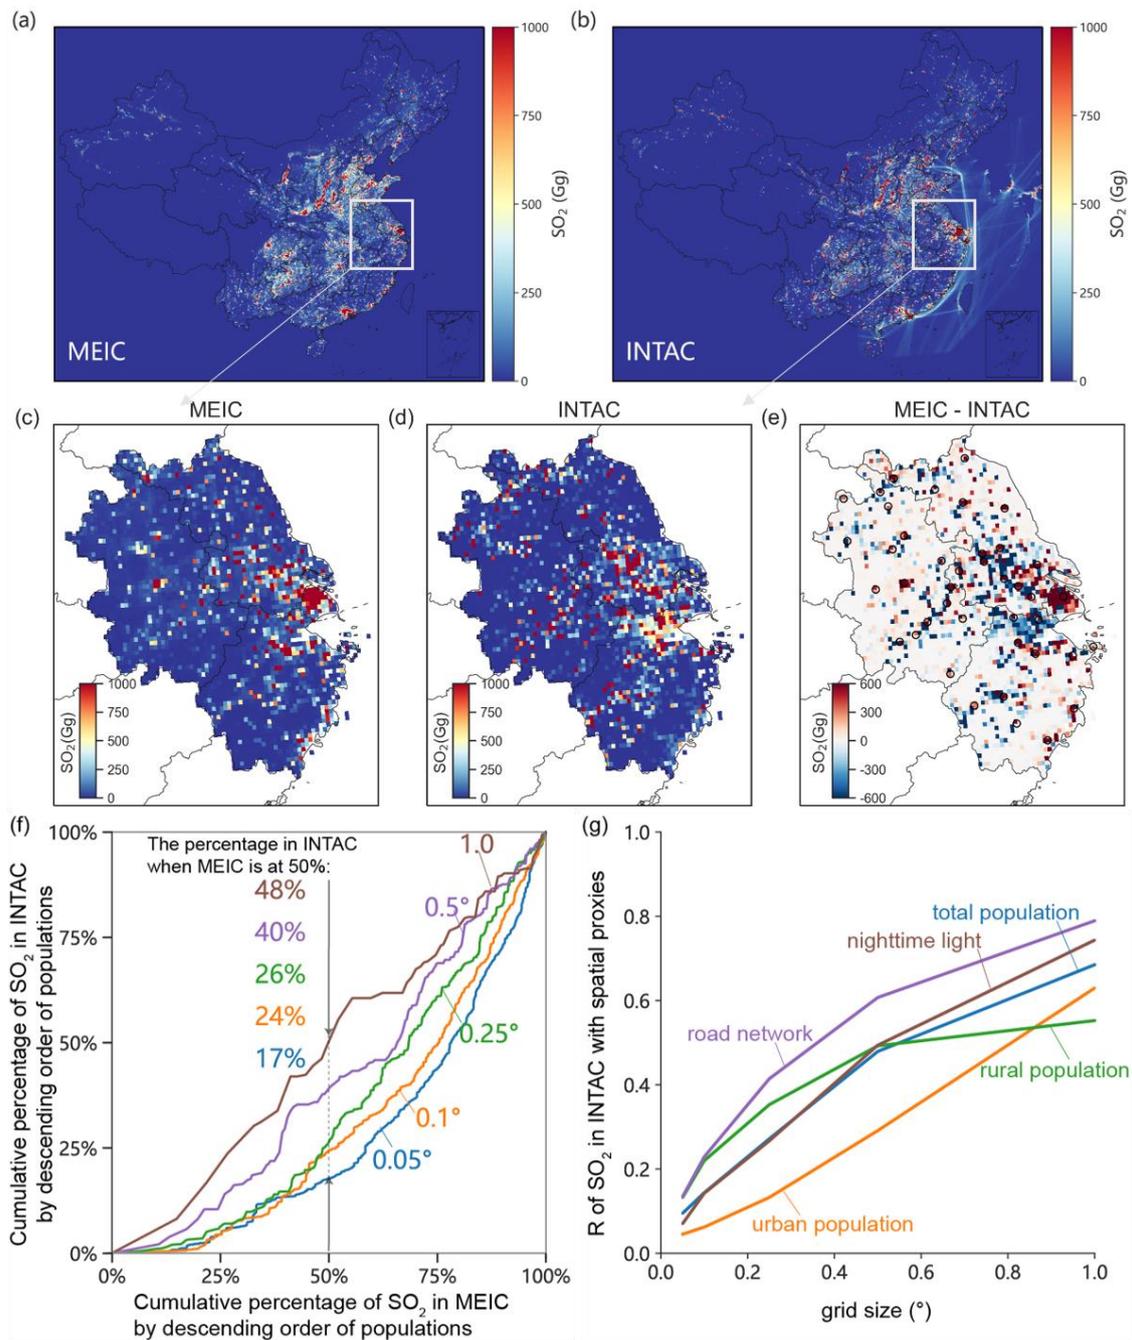

450 **3.2.2 Impact of point source contributions**

451 The most accurate method for obtaining emissions at finer-scale grids relies on spatial allocation based on precise geographical
452 coordinates. In MEIC, the majority of emission sources are represented as area sources and distributed onto grids using spatial
453 proxies such as urban population, except for power plants. In contrast, the increased proportion of industrial point source
454 emissions in INTAC significantly constrains the uncertainties associated with spatial proxies. Figure 6 shows the inter-
455 comparisons of percentage of point, on-road, and area source emissions between the INTAC and MEIC. Air pollutants,
456 especially those dominated by industrial combustion sources like SO₂, NO_x, PM₁₀, and PM_{2.5}, exhibit a significantly higher
457 proportion of point source emissions within INTAC compared to MEIC. In MEIC, the proportion of point source emissions
458 for SO₂, PM₁₀, NO_x, and PM_{2.5} is 17%, 9%, 19%, and 7%, respectively. However, in the INTAC inventory, these percentages
459 substantially increase to 66%, 54%, 52%, and 48%, respectively, indicating a more accurate representation of spatial patterns.
460 For other species with emissions mainly from area sources (e.g., residential and transportation), there are limited improvements
461 in the proportion of point source emissions in INTAC.

462 **Figure 6: Inter-comparisons of percentage of point, on-road, and area source emissions between the INTAC inventory and MEIC.**

463 To further assess the impact arising from point sources, Figure 7 takes SO₂ and YRD region as an example to compare the
 464 spatial emission patterns between INTAC and MEIC. Figures 7c–e reveal that MEIC tends to overestimate emissions in urban
 465 centers and underestimate emissions in rural areas compared to INTAC. Amid economic growth and rapid urbanization,
 466 MEIC’s use of urban population as a proxy for spatial allocation becomes impractical as many factories relocate from city
 467 centers to rural areas. **To elucidate the difference between population-based and point-source-based allocation methods in
 468 emissions mapping, we present the cumulative percentage of SO₂ emissions in MEIC and INTAC based on descending
 469 population orders in Fig. 7f. We use the grid groups where densely populated areas contribute 50% of SO₂ emissions in MEIC
 470 as an example, comparing them with the cumulative percentage in INTAC across various grid sizes. The results indicate that
 471 at a resolution of 0.05 °, INTAC only accounts for 17% of the emissions, while it reaches to 48% as the grid size increases to
 472 1.0 °. This suggests that at a fine grid scale, MEIC tends to allocate more emissions to densely populated urban areas, while
 473 INTAC allocates a larger proportion to suburban and rural areas, aligning better with the real-world emission spatial patterns.
 474 This mitigation of bias through INTAC is especially notable at finer resolutions. The close cumulative percentage at 1.0 ° in
 475 the two inventories can be attributed to the fact that urban and suburban areas often fall within the same grid, leading to a
 476 decreasing enhancement in spatial accuracy achieved by INTAC. Figure 7g further presents the correlation between the spatial
 477 patterns of SO₂ emissions in INTAC and various spatial proxies. At a resolution of 1.0 °, the correlation coefficients between
 478 emission distributions and factors (i.e., road networks, nighttime lights, total population, urban population, and rural population)
 479 fall within the range of 0.55 to 0.79. Nevertheless, at a resolution of 0.05 °, the correlation coefficients range from 0.05 to 0.13.
 480 This indicates that at higher spatial resolutions, INTAC substantially reduces the bias introduced by spatial proxies in MEIC.**

481 **Figure 7: Spatial pattern analysis of emissions in the INTAC inventory, using SO₂ emissions as an example.** (a) and (b) display the
 482 spatial distributions of SO₂ emissions in MEIC and INTAC, respectively. MEIC emissions have been downscaled from 0.25 degrees to 0.1
 483 degrees for comparison. To compare MEIC and INTAC in details, a zoom-in is applied to the YRD region. (c), (d), and (e) show spatial
 484 distributions of SO₂ emissions in MEIC, INTAC and their difference. Circles in (e) represent the center of a city. (f) compares cumulative
 485 percentage of SO₂ emissions in the INTAC inventory with those in MEIC across different spatial resolutions. The gridded SO₂ emissions,
 486 ranging from resolutions of 0.05° to 1.0°, are cumulated in descending order of populations. The percentage annotations in different colors
 487 indicate the level of accumulated SO₂ emissions in INTAC at various spatial resolutions when SO₂ emissions in MEIC reach 50%

488 **accumulation.** (g) shows correlation coefficient between SO₂ emissions in the INTAC inventory and multiple spatial proxies at different grid
489 sizes.

490 3.3 Improvements on air quality modelling by INTAC

491 3.3.1 Overall performance in key regions

492 We conduct simulations using the WRF-CMAQ model driven by INTAC and MEIC separately to evaluate the improvements
493 in modeled air pollutant concentrations. Table 4 evaluates the simulated emissions in 74 major cities (**locations depicted in Fig.**
494 **S2**) against in-situ observations, **with corresponding scatter plots shown in Fig. S3**. The INTAC demonstrates an improved
495 agreement between modeled concentrations and ground-level observations, which benefits from the integrated high resolution
496 inventories. Compared to MEIC, INTAC leads to a decline in the mean bias of simulated major pollutant concentrations by 2–
497 14 µg/m³, a reduction in the root mean square error by 4–19 µg/m³, and a decrease in the normalized mean error by 4–71%.
498 This finding indicates that INTAC produces a more accurate characterization of emissions in China overall. Furthermore,
499 given that atmospheric pollution monitoring stations are mainly located in urban areas in China, the observed differences
500 suggest that the INTAC can mitigate the overestimation of major pollutant concentrations in urban centers. As discussed in
501 Sect. 3.2.2, MEIC overestimates emissions in urban areas and underestimates them in rural and suburban areas, consequently
502 introducing uncertainties into air quality modeling. The improved accuracy in spatial distributions within INTAC significantly
503 contributes to enhancing the overall accuracy of air pollutant modeling.

504 **Table 4: The discrepancies between simulated SO₂, NO₂ and PM_{2.5} concentrations and observed values for 74 major cities at a**
505 **resolution of 12 km, using MEIC and INTAC as emission inputs.** The statistical metrics used for comparison include R, MB, and RMSE.
506 The bold font represents the difference of modeling performance between INTAC and MEIC.

Pollutants	Inventory	MB (µg/m ³)	RMSE (µg/m ³)	NME (%)
SO ₂	INTAC	11	30	92
	MEIC	25	49	163
	Difference	-14	-19	-71
NO ₂	INTAC	7	22	43
	MEIC	18	31	60
	Difference	-11	-9	-17
PM _{2.5}	INTAC	6	35	46
	MEIC	8	39	50
	Difference	-2	-4	-4

507 Figure 8 further compares the overall simulation performance between INTAC and MEIC in three key regions (BTH, YRD,
508 and PRD), **with corresponding scatter plots shown from Fig. S4 to S6**. Regarding PM_{2.5} and its precursors, MEIC shows a
509 considerable mean bias of up to 36 µg/m³ and a root mean square error of up to 59 µg/m³ in key regions. In contrast, INTAC

510 demonstrates the maximum MB values of 15 $\mu\text{g}/\text{m}^3$ and RMSE values of 40 $\mu\text{g}/\text{m}^3$. The correlation coefficients between
 511 simulated and observed concentrations of the three air pollutants are generally lower in MEIC compared to those in INTAC.
 512 The modeling performance driven by INTAC, particularly for short-lived pollutants, experiences significant improvement due
 513 to their strong correlation with spatial distributions of emission sources. Nonetheless, discrepancies between modeled and
 514 observed surface concentrations still exist because of uncertainties from meteorological, physical, and chemical processes
 515 within chemical transport models. Moreover, emission sources such as residential, transportation, agriculture in INTAC are
 516 treated as nonpoint sources, and their allocation to grids using spatial proxies can introduce biases to air quality modeling. It
 517 is noteworthy that simulated ammonium concentrations by INTAC agree better with ground measurements than MEIC (Table
 518 S3). While NH_4^+ concentrations are influenced by secondary chemical reactions, the improved model performance still reflects
 519 the benefits from the integration of PKU- NH_3 .

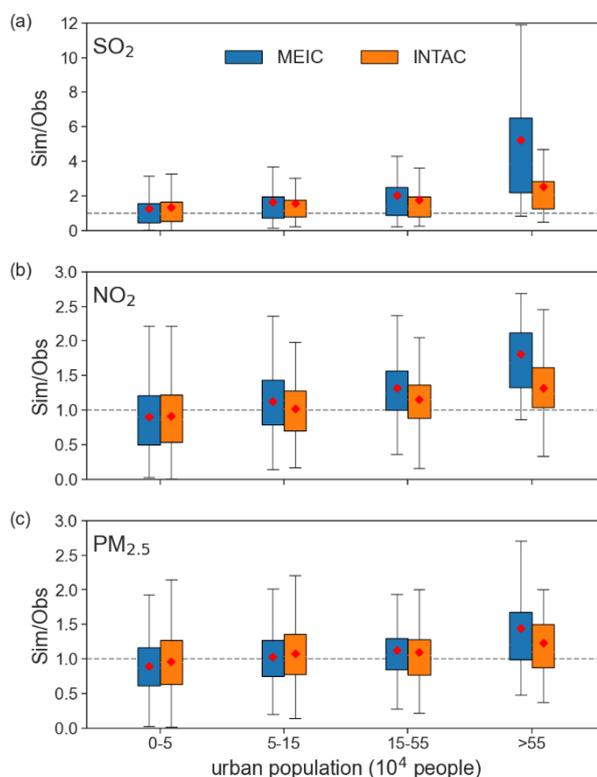

520 **Figure 8: The Comparison of modeling performance across key regions (i.e., BTH, YRD, PRD) when using MEIC and INTAC as**
 521 **emission inputs, respectively.** The statistical metrics used for comparison include R, MB, and RMSE. The regions under comparison
 522 comprise the BTH, YRD, and PRD.

523 3.3.2 Improvements across different spatial resolutions

524 To provide a more in-depth assessment of improved spatial patterns in INTAC, Figure 9 categorizes grid cells into different
 525 bins based on their urban population and calculates the ratio of simulated pollutant concentrations to ground observations for
 526 both INTAC and MEIC in each category. The results demonstrate that as urban population increases, the enhanced model
 527 performance of INTAC over MEIC for SO₂, NO₂ and PM_{2.5} becomes more evident. Specifically, when the urban population
 528 is less than 50,000, both INTAC and MEIC exhibit a median range of simulated-to-observed concentration ratios close to 1.
 529 However, as the urban population exceeds 550,000, the average range for MEIC widens to 1.4–5.2, whereas it remains within
 530 the range of 0.9–1.0 for INTAC. This indicates a significant improvement in mitigating the overestimation of emissions in
 531 densely populated areas by INTAC. This indicates that the overestimation of emissions in densely populated areas, caused by
 532 proxy-based methods in MEIC, introduces uncertainties into chemical transport models. The incorporation of the industrial

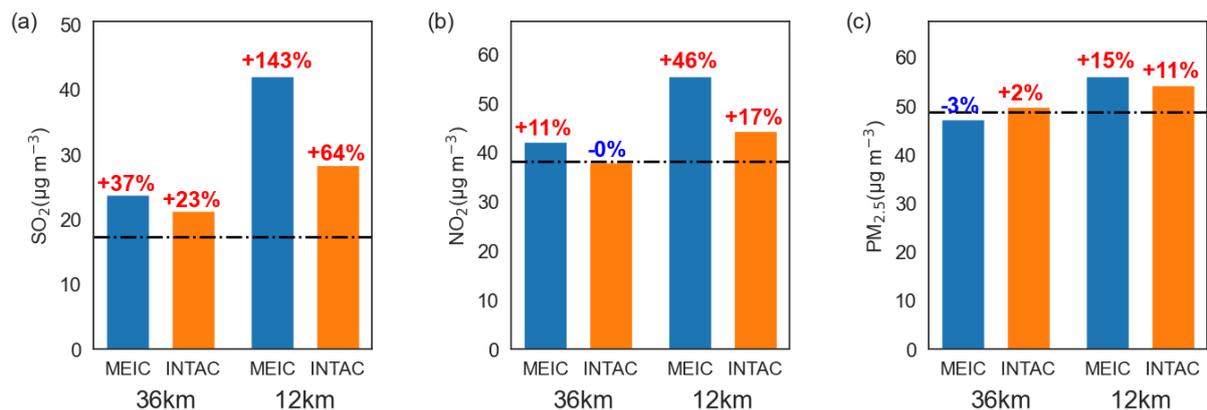

533 point source emission inventory for China, along with the YRD and PRD emission inventory significantly increases point
534 source shares in INTAC, and thus producing better spatial representations for real-world emission distributions and smaller
535 simulated deviations.

536 Model performance differences between MEIC and INTAC are influenced by grid size. Figure 10 presents the comparison
537 between modeled SO_2 , NO_2 and $\text{PM}_{2.5}$ concentrations against ground observations for 74 major cities at resolutions of 36 and
538 12 km. "Increasing spatial resolution does not lead to a reduction in simulation errors, especially for MEIC. As the horizontal
539 resolution increases from 36 km to 12 km, the mean biases of simulated SO_2 , NO_2 , and $\text{PM}_{2.5}$ concentrations using MEIC show
540 an increase from 37% to 143%, 11% to 46%, and -3% to 15%, respectively, when compared to in-situ observations. In contrast,
541 the simulation results using INTAC exhibit better agreement with ground observations, with mean biases for SO_2 , NO_2 , and
542 $\text{PM}_{2.5}$ increasing from 23% to 64%, -0% to 17%, and 2% to 11%, respectively. This is due to the fact that the deviations in
543 finer grid cells, whether overestimated or underestimated, tend to cancel out at a coarse spatial resolution. The decoupling
544 between emission spatial distributions with proxies at finer grids leads to more noticeable biases in air quality modeling.
545 Therefore, the findings suggest that the INTAC developed in this study can effectively constrain uncertainties in emissions
546 and the modeling bias, especially at fine spatial scales. The improvement will help tackle emerging challenges in high-
547 resolution air quality modeling in China.

548 **Figure 9: Comparisons of modeling performance between INTAC and MEIC in different ranges of urban population.** The 12 km
549 grids are categorized to different bins according to the urban population residing within each grid. The ratio of simulated pollutant

550 concentrations (Sim) to observed concentrations (Obs) for major pollutants (SO₂, NO₂, and PM_{2.5}) are calculated. The boxplot presents the
 551 upper quartile, median (red dot), and lower quartile of the ratios.

552 **Figure 10: The comparison of modeled air pollutant concentrations and ground observations for 74 cities at 36 and 12 km resolutions,**
 553 **using MEIC and INTAC as emission inputs, respectively.** The black dashed line represents the observational mean, and the annotations
 554 above the bar charts indicate the mean biases between simulated concentrations and the corresponding observed value.

555 4 Discussion

556 Qualitative or quantitative uncertainty assessment is a necessary element of a complete inventory for policy or scientific
 557 purposes. Approaches such as error propagation and Monte Carlo simulation are commonly used for quantitative uncertainty
 558 analysis in China's emission inventory (Lu et al., 2011; Streets et al., 2003; Zhao et al., 2011; Zhao et al., 2017b). However,
 559 this study uses an integrated method rather than a unified framework to compile a comprehensive high resolution emission
 560 inventory for China. Collecting only emission quantities from the seven inventories without detailed calculation parameters
 561 makes it challenging to assess the overall uncertainties of INTAC here. We have summarized the estimated uncertainty range
 562 for components of INTAC in Table 5, where such information is available. Although the uncertainties might be reported for a
 563 year other than 2017, they still provide a rough representation of the uncertainty range in major air pollutant emission estimates
 564 within INTAC. Species such as SO₂ and NO_x exhibit relatively low uncertainties, benefiting from well-established estimates
 565 for large-scale combustion sources. The considerable uncertainties observed in BC and OC emissions may be attributed to
 566 inaccuracies in the emission factors of the residential sector. Further details regarding the uncertainties of each component
 567 inventory can be found in corresponding literature (An et al., 2021; Huang et al., 2021; Kang et al., 2016; Liu et al., 2016b;
 568 Yin et al., 2019; Zhao et al., 2011).

569 The uncertainties of INTAC also arise from the integrated process: (1) The emission source categories are based on the MEIC
 570 model, and sectors in other inventories need to be mapped to the 88 standard sectors first. Due to limited foundational
 571 information for an aggregated sector's disaggregation, this process may introduce biases for those who initially provide coarser
 572 source categories. For example, if an inventory only offers one aggregated sector for power, which needs to be broken down
 573 into four subsectors (i.e., production of power, supply of power, production of industrial heat power and production of

574 residential heat power). We use the energy consumption for corresponding sectors from the statistical yearbook as a reference
575 basis for this allocation, which is a relatively reliable method despite potential deviations. (2) To generate speciated VOC
576 species, sectoral NMVOC emissions in each inventory need to be matched to corresponding source profiles from the MEIC
577 model. Discrepancies in emission source mapping can impact the outcomes, which will be overcome by gathering more
578 detailed sectoral information for each inventory or directly collecting speciated species in future studies. (3) The INTAC is
579 made publicly available at a monthly scale, given that the majority of its components are gathered on a monthly or annual
580 scale. The temporal disaggregation to finer resolutions for modeling is achieved using empirically selected weighting factors
581 in the MEIC model. However, it is noteworthy that the parameters employed for allocating emissions to daily or hourly scales
582 remain fixed and do not vary over time or region, introducing additional uncertainties. In the future, we plan to incorporate
583 more advanced data or method (e.g., real-time emission measurements) to enhance temporal accuracy at finer scales, as
584 indicated in the previous work for the power sector (Wu et al., 2022). (4) The border issue is inevitable when emissions for the
585 same species in two adjacent cities are derived from different inventories. A typical example is the cities located at the boundary
586 of the YRD or the PRD regions. In the INTAC, we downscale all emissions to 1 km before spatial-temporal coupling process,
587 thereby mitigating this uncertainty to some extent.

588 **Table 5: Uncertainties in the inventory components of INTAC, contingent upon the availability of such information (Unit: %).**

Emission inventory	Reporting year	SO₂	NO_x	CO	NMVOC	NH₃	PM₁₀	PM_{2.5}	BC	OC	References
PKU-NH ₃	2012					-26– 25					(Kang et al., 2016)
The shipping emission inventory for East Asia	2013	±4	±4	±5	±4			±4	±4	±4	(Liu et al., 2016b)
The open biomass burning emission inventory for China	2003– 2017	-67– 67	-78– 98	-54– 56		-44– 89	-74– 84	-65– 65	-75– 100	-74– 81	(Yin et al., 2019)
The PRD emission inventory	2017	-17– 20	-25– 28	-30– 39	-34–50	-50– 86	-45– 60	-43– 62	-53– 116	-54– 160	(Huang et al., 2021)
The YRD air pollutant emission inventory	2017	-29– 36	-28– 33	-42– 75	-44–68	-58– 117	-36– 62	-30– 46			(An et al., 2021)
	2005	-14– 13	-13– 37				-14– 45	-17– 54	-25– 136	-40– 121	(Zhao et al., 2011)

589 The INTAC for 2017 is subject to some limitations: (1) The integrated method yields emissions data across various sectors
590 from different datasets for the same city and species, or emissions in different species from different datasets for the same city
591 and sector. The utilization of species ratios requires careful consideration in these cases. (2) **Limited resources present a**
592 **substantial challenge in gathering emission inventories over extended time series from diverse research institutions within the**
593 **scope of this study. Consequently, we exclusively present the INTAC for the year 2017, with the possibility of extension to**
594 **other years in subsequent research.**

595 **5 Data Availability**

596 Data described in this manuscript can be accessed at Zenodo under <https://doi.org/10.5281/zenodo.10459198> (Wu et al., 2024)
597 and <http://meicmodel.org.cn/intac>.

598 **6 Concluding remarks**

599 **Compiling a comprehensive bottom-up emission inventory for China that encompasses both extensive coverage and high**
600 **resolution poses a significant challenge. In this work, we construct a 0.1 °resolution integrated inventory for 2017 through the**
601 **fusion of multi-source emission inventories. An integration model has been developed to effectively couple heterogeneous**
602 **emission datasets, aimed at generating a standardized data cube with consistent sectors, species, and spatial-temporal resolution.**
603 **The INTAC is created through source mapping, species mapping, temporal disaggregation, spatial allocation and spatial-**
604 **temporal coupling. Six representative emission inventories focusing on national and regional scales, as well as key species and**
605 **sources in China are merged with MEIC. This integration harnesses the strengths of each inventory, resulting in an improved**
606 **depiction of emission totals and spatial distribution patterns for China.**

607 **We find that the total emissions of SO₂, NO_x, CO, NMVOC, NH₃, PM₁₀, PM_{2.5}, BC, and OC in INTAC for 2017 are 12.3, 24.5,**
608 **141.0, 27.9, 9.2, 11.1, 8.4, 1.3 and 2.2 Tg, respectively. Industrial production serves as the main source of various atmospheric**
609 **pollutants. Residential sources contribute over 40% to CO, BC and OC emissions. Apart from agricultural sources, which**
610 **account for 83% of NH₃ emissions, the contributions from various minor emission sources cannot be overlooked. This study**
611 **emphasizes the significance of shipping emissions, particularly in contributing to SO₂ (13%) and NO_x (13%). Fossil fuel**
612 **combustion dominates the emissions of PM₁₀, PM_{2.5}, CO, BC, SO₂, and NO_x, ranging from 38% to 80%. The enhancement in**
613 **emission estimates for China in INTAC is demonstrated by the comparison with MEIC. For instance, the incorporation of**
614 **numerous point sources has notably addressed MEIC's tendency to overestimate emissions in urban centers, particularly at**
615 **higher spatial resolutions. In comparison to MEIC, INTAC exhibits a mean bias reduction in simulated concentrations of major**
616 **pollutants against ground observations across 74 cities, ranging from 2–14 µg/m³. The improvement in model performance**
617 **achieved by INTAC is particularly noticeable at finer spatial resolutions.**

618 Our study offers an efficient framework for creating highly-resolved emission inventory on a large scale. This approach
619 integrates advantages from previous studies and holds the potential to support policymakers in making well-informed decisions
620 for improving air quality. In the future, we anticipate the ongoing incorporation of additional emission datasets to offer a more
621 reliable representation of emissions in China over extended time periods.

622 **Supplement**

623 The supplement related to this article has six figures and three tables.

624 **Author contributions**

625 Nana Wu, Guannan Geng and Qiang Zhang designed the study. Nana Wu developed the INTAC emission inventory and
626 conducted chemical transport modeling. Junyu Zheng, Yu Song, Huan Liu, Yu Zhao, Ying Zhou and Qinren Shi provided the
627 emission inventories for the integration. Ruochong Xu helped with the data analysis. Shigan Liu compiled the chemical
628 transport model. Xiaodong Liu contributed to the design of computer programmes for the integration model. The manuscript
629 was written by Nana Wu and Guannan Geng, and it was revised and discussed by all coauthors.

630 **Competing interests**

631 The authors declare that they have no conflict of interest.

632 **Acknowledgements**

633 This work was supported by the National Natural Science Foundation of China (Grant No. 92044303), the National Key R&D
634 program of China (Grant No. 2022YFC3700605), and the Major Project of High Resolution Earth Observation System (Grant
635 No. 30-Y60B01-9003-22/23). We thank Zhijiong Huang, Junchi Wang, Mingxu Liu, Wenling Liao, Chen Gu for their
636 contributions to the handling and transfer of the emission inventories for the integration.
