**Abstract.** We present top-down global gridded emissions of NO<sub>x</sub> for the year 2022. This dataset is constructed from retrievals of tropospheric vertical column densities of NO<sub>2</sub> by the TROPOMI spaceborne instrument associated with winds and atmospheric composition data from ECMWF reanalyses, using an improved version of a mass-balance atmospheric inversion. The emissions are provided with a spatial resolution of 0.0625°×0.0625° and deliver a detailed overview of the distribution of emissions. They allow the identification of intense area sources and isolated emitters, and the quantification of their associated emissions. At global level, the emissions obtained are consistent with the EDGARv6.1 bottom-up inventory, although there are differences at regional level, particularly in emerging countries and countries with low observation densities. The three largest emitting countries, China, the United States and India, are 11, 16 and 6% lower than EDGAR estimates. Uncertainties remain high, and a quantitative analysis of emissions over several averaging periods indicates that averaging emissions uniformly across the year may be sufficient to obtain estimates consistent with annual averages, in regions of the world with high retrieval densities. This dataset is designed to be updated with a low latency to help policymakers monitor emissions and implement energy savings and clean air quality policies. The data can be accessed at <https://doi.org/10.5281/zenodo.13957837> as monthly files (Rey-Pommier et al., 2024).

## 1 Introduction

Air pollution is one of the leading causes of premature death in the world. Public health policies, implemented at the scale of countries, regions or cities, often aim to reduce the exposure to several pollutants, such as nitrogen oxides (NO<sub>x</sub> = NO+NO<sub>2</sub>). Such mitigation plans therefore require a precise knowledge of the emitters, as well as a monitoring of their emission levels over time. Data on NO<sub>x</sub> emissions is therefore fundamental for monitoring the implementation of air quality policies. Besides, because NO<sub>x</sub> is mainly produced during the combustion of carbon fuels at high temperatures, such data can also be a tool to measure progress towards carbon neutrality. Gridded emissions with high spatial and temporal resolution are therefore of great scientific and political value. Many of such datasets are emission inventories, i.e. bottom-up models in which emissions are calculated on the basis of known sectoral activities and allocated in time and space, combined with specific emission factors by sector and, possibly, by country. These inventories provide valuable information on long-term trends and large-scale emission budgets, but they suffer from several weaknesses. They hardly represent daily or weekly variations, their activity data may be outdated, and some sources may be misallocated or unknown, which is common in many developing countries. Besides, uncertainties surrounding rapidly changing emissions factors and the generally low temporal resolution of activity data limits, in certain circumstances, the realism of such bottom-up inventories. Finally, they have a data lag of at least one year, which limits their potential as monitoring tools.

In this context, increasing efforts have been made to overcome the weaknesses of the inventories in order to obtain independent emission datasets that are homogeneous from one country to another. Such datasets are of the top-down type: they use direct observations of pollution and result from the inversion of an atmospheric chemistry-transport model (CTM) in which these atmospheric observations are assimilated. The observation data may be in-situ measurements or satellite retrievals.

44 In previous studies, we used a method for detecting and quantifying  $\text{NO}_x$  emissions from daily observations of  $\text{NO}_2$   
45 columns by the TROPOMI instrument, onboard the Sentinel 5P instrument. This method, developed for the countries  
46 of the Eastern Mediterranean and Middle East region, is based on a two-dimensional simplification of atmospheric  
47 chemistry and transport, and does not require the direct use of a full 3D chemistry-transport model. Here, we extend  
48 the emissions domain to the whole world for the year 2022, and provide a dataset of averaged  $\text{NO}_x$  emissions at  
49 a resolution of  $0.0625^\circ \times 0.0625^\circ$ . We analyse the results by pinpointing emitters and distinguishing between point  
50 sources, generally corresponding to isolated industrial facilities, and diffuse/area sources, generally corresponding to  
51 megacities. We also compare the results with the bottom-up inventory EDGARv6.1 and assess their reliability using  
52 different average horizons.

53 This article is structured as follows: Section 2 details the method used throughout this study, its improvements  
54 and simplifications since its previous uses, and the input data in its implementation. Section 3 presents the global  
55  $\text{NO}_x$  emissions dataset and analyses the different types of emitters. It also compares the results obtained with the  
56 EDGARv6.1 bottom-up inventory, and analyses different time horizons for averaging daily emissions in order to obtain  
57 representative results. Section 4 analyses the applicability limits of the method and highlights sources of uncertainty.

## 58 2 Methods

### 59 2.1 Input data

#### 60 2.1.1 TROPOMI $\text{NO}_2$ column densities

61  $\text{NO}_2$  can be observed from space with satellite instruments based on its strong absorption features in the 400–465 nm  
62 wavelength region (Vandaele et al., 1998). By comparing observed spectra with a reference spectrum, the amount of  
63  $\text{NO}_2$  in a portion of the atmosphere between the instrument and the surface can be derived. The Tropospheric Mon-  
64 itoring Instrument (TROPOMI), onboard the European Space Agency's (ESA) Sentinel-5 Precursor (S-5P) satellite,  
65 is one of those instruments. This instrument has a large swath width ( $\sim 2600$  km), combined with the 15-day orbit  
66 cycle of the satellite, leading to a revisit time of one day for every point of the Earth in absence of clouds. Moreover,  
67 these daily measurements are always collected during the middle of the day, the satellite crossing the sunlit equator at  
68 around 13:30 local time (LT). The high spatial resolution of the instrument ( $3.5 \times 5.5$  km<sup>2</sup> since 6 August 2019) allows  
69 observing fine-scale structures of  $\text{NO}_2$  pollution, such as hotspots within medium-size cities or plumes from power  
70 plants and industrial facilities. Tropospheric vertical column densities (VCDs, or simply "columns") are provided  
71 after retrieval of total slant column densities using the Differential Optical Absorption Spectroscopy method (Platt  
72 et al., 2008). VCDs represent the integrated number of  $\text{NO}_2$  molecules per surface unit between the surface and the  
73 tropopause at the corresponding vertical. An algorithm also supplies an air mass factor, which is the ratio between  
74 slant and vertical column densities. This factor is derived from the knowledge of many physical quantities such as the  
75 vertical distribution of the absorber but also the viewing angle and the albedo of the observed surface. It comprises a  
76 significant part of the uncertainty in  $\text{NO}_2$  measurements (Boersma et al., 2004; Lorente et al., 2019), which becomes  
77 non-negligible in a polluted atmosphere. Each TROPOMI retrieval is also associated with a quality assurance value  
78  $q_a$ , which ranges from 0 (no data) to 1 (high-quality data). We selected  $\text{NO}_2$  retrievals with  $q_a$  values greater than  
79  $q_{a,\text{lim}} = 0.75$ , which correspond to clear-sky conditions (Eskes et al., 2022). Here, we use TROPOMI  $\text{NO}_2$  retrievals  
80 in 2022 (OFFL product using processor version 2.5.0, product version 2.3.1 and 2.4.0 before and after November 2022  
81 respectively). To limit effects due to product of processor version changes, other years are not studied.

#### 82 2.1.2 Meteorological and air composition fields

83 Horizontal wind is taken from the ERA5 data archive, provided by the European Centre for Medium-Range Weather  
84 Forecasts (ECMWF). Both components have a horizontal resolution of  $0.25^\circ \times 0.25^\circ$  gridded on 37 vertical pressure levels  
85 (Hersbach et al., 2020). ECMWF also produces a reanalysis for air composition, under the Copernicus Atmospheric  
86 Monitoring Service (CAMS). It provides analyses and forecasts for reactive gases, greenhouse gases and aerosols.  
87 These parameters are gridded on 25 vertical pressure levels with a horizontal resolution of  $0.4^\circ \times 0.4^\circ$  and a temporal  
88 resolution of 3 hours (Huijnen et al., 2016). Here, ground concentrations of  $\text{NO}_2$ , NO, OH, as well as temperature,  
89 are taken from CAMS to represent chemical processes in our model.

#### 90 2.1.3 Elevation data

91 For computing altitude gradients, we use the Global Multi-resolution Terrain Elevation Data (GMTED2010, Danielson  
92 and Gesch (2011)). Elevation data is regridded on the TROPOMI grid, before calculation of the corresponding gradient

93 to derive a corrective "topography-wind" value that is detailed in Section 2.2.2.

## 94 2.2 The mass-balance inversion

### 95 2.2.1 Main principle

96 The flux-divergence method is a mass-balance inversion model calculating the emissions of a given trace gas from  
97 observations of the corresponding vertical tropospheric columns, which is particularly well suited to data with high  
98 spatial resolution. In the case of  $\text{NO}_2$ , this approach was pioneered by Beirle et al. (2019). It has subsequently been  
99 implemented differently by other researchers, in different circumstances under simplified forms or, on the contrary,  
100 more complex ones (Lama et al., 2020; Rey-Pommier et al., 2022; de Foy and Schauer, 2022; Sun, 2022). The flux-  
101 divergence method is based on the conservation of mass principle, which makes it possible to calculate emission  
102 densities at the pixel scale as a function of a transport term and a sink term. By noting  $C$  the local concentration of  
103  $\text{NO}_2$  and  $\mathbf{w} = (u, v, w)$  the mean wind at the time of measurement, the corresponding emissions  $E_C$  are expressed as:

$$E_C = \frac{\partial C}{\partial t} + \text{div}(C\mathbf{w}) + S_C \quad (1)$$

104 Here  $S_C$  is the sink term expressing the loss of  $\text{NO}_2$  due to chemical reactions. Assuming that the vertical variations  
105 in concentration are small compared with the horizontal variations, and considering that most  $\text{NO}_2$  remains confined  
106 close to the ground, the previous equation can be rewritten in terms of tropospheric columns  $\Omega$ , which enables, in  
107 steady state, the computation of emissions per surface area  $E$ , as:

$$E = \frac{\partial(\Omega u)}{\partial x} + \frac{\partial(\Omega v)}{\partial y} + S_\Omega \quad (2)$$

108  $S_\Omega$  is the sink term expressed by surface unit.  $D = \frac{\partial(\Omega u)}{\partial x} + \frac{\partial(\Omega v)}{\partial y}$  is the horizontal advection (transport) term. The  
109 assumption of a stationary state and a pollution concentration close to the ground means that the temporal and vertical  
110 dimensions of the problem can be ignored, resulting in a purely horizontal calculation of emissions. The corresponding  
111 reduction in complexity means that inversions can be performed very quickly compared with the conventional use  
112 of full-fledged 3D CTMs and without *a priori* knowledge on emissions. On the downside, such simplifications are  
113 accompanied by uncertainties, the main sources of which being uncertainties on the input tropospheric columns, wind  
114 direction and atmospheric composition.

115 Finally, we convert the  $\text{NO}_2$  production into  $\text{NO}_x$  emissions. Performing this conversion is accounting for the  
116 portion of  $\text{NO}_x$ , mainly emitted as  $\text{NO}$ , which is not converted into  $\text{NO}_2$  by reaction with ozone. The reformation  
117 of  $\text{NO}$  by the photolysis of  $\text{NO}_2$  during the day leads to an equilibrium between the two compounds. The ratio  
118  $\mathcal{L} = [\text{NO}_x]/[\text{NO}_2]$  which usually varies between 1.2 and 1.4, depending on local conditions.  $\text{NO}_x$  emissions are  
119 therefore calculated as:

$$E_{\text{NO}_x} = \mathcal{L}E \quad (3)$$

120 In most urbanized areas, daytime  $\text{NO}$  concentrations frequently exceed 20 ppb. Under such conditions, this ratio is  
121 stabilized in a few minutes (Graedel et al., 1976; Seinfeld and Pandis, 2006). As this time is shorter than the inter-mesh  
122 transport timescale, the impact of stabilization time on the overall emission composition can be justifiably ignored.  
123 However, this assumption breaks down near emission sources, where the stationary hypothesis may not be applicable,  
124 and the value of  $\mathcal{L}$  could be significantly higher than 1.4. The implications of this neglect will be discussed in Section  
125 4.1.

### 126 2.2.2 Refined version

127 In order to consider only anthropogenic pollution located close to the ground, it is necessary to remove any signal of  
128 natural emissions from the tropospheric columns provided by TROPOMI. In the absence of anthropogenic sources,  
129 the  $\text{NO}_2$  columns that are observed constitute a tropospheric background  $\Omega_b$ . At the global scale, this background is  
130 mostly due to soil emissions in the lower troposphere (Yienger and Levy, 1995; Hoelzemann et al., 2004). In the upper  
131 troposphere,  $\text{NO}_2$  sources include lightning, convective injection and downwelling from the stratosphere (Ehhalt et al.,  
132 1992). We remove that background by calculating the 1st tercile in a 200 pixel  $\times$  430 pixel zone around each pixel  
133 (along  $\times$  across track, i.e. approx. 700 km  $\times$  2360 km). We assume that this zone is sufficiently large whatever the  
134 considered pixel so that this tercile corresponds to the typical local value for this background. We then subtract this  
135 background to the calculated tropospheric column densities and use the resulting lower tropospheric vertical density

136  $\Omega' = \Omega - \Omega_b$  in the flux divergence method. Such assumption can be challenged above macro-regions for which soil  
137 emissions and wildfires result in high  $\text{NO}_2$  values observed by TROPOMI (those emissions are therefore considered  
138 abusively as anthropogenic sources). This can also happen around shipping lanes where exhaust particles increase the  
139 likelihood of thunderstorms (Thornton et al., 2017). The neglect of such effects is highlighted in Section 4.1.

140 We represent the sink term  $S_\Omega$  by considering only the chemical loss of  $\text{NO}_2$  due to its reaction with the hydroxyl  
141 radical (OH). This reaction follows a first-order kinetics, and the sink term can be expressed as  $S_\Omega = k_{\text{OH}+\text{NO}_2}[\text{OH}]$   
142 with  $k_{\text{OH}+\text{NO}_2}$  the reaction rate whose value is given by Burkholder et al. (2020). This is equivalent to compute a  
143 mixed lifetime  $\tau = 1/(k_{\text{OH}+\text{NO}_2}[\text{OH}])$ , which generally ranges between 1 and 12h. In many studies, this quantity is  
144 kept uniform and constant in the use of the flux-divergence method (Beirle et al., 2019; de Foy and Schauer, 2022).  
145 Here, a singularity of our version of the flux-divergence method is to account for the temporal variability of OH, which  
146 is primarily driven by the amount of UV radiation from the stratosphere, but also for its spatial variability, since OH  
147 can also be influenced by  $\text{NO}_x$  through a non-linear relationship (Valin et al., 2011). In this respect, our sink term  
148 is heavily reliant on the  $\text{NO}_x$  sources accounted for in CAMS data. Neglecting a source, or mis-estimating the order  
149 of magnitude of its  $\text{NO}_x$  emissions, therefore results in a wrong OH field whose bias depends on the amplitude of the  
150 neglect. Similarly, the coarse resolution in CAMS data ( $0.4^\circ \times 0.4^\circ$ ) can fail to represent pollution gradients downwind  
151 different sources, leading to a wrong estimation of the real OH budget. We expect these effects to be minor compared  
152 to those that would result in representing a constant lifetime for  $\text{NO}_2$  which oversimplifies and misrepresents temporal  
153 and spatial dynamics by representing all situations the same way, whether they represent emitters or not.

154 Additionally, systematic artifacts concerning advection processes were reported over regions with complex topog-  
155 raphies, particularly when high tropospheric vertical column densities are observed over mountainous regions.  
156 These high values can hinder the identification and quantification of point sources, possibly due to inaccurate mean  
157 wind fields over mountains. A study by Sun (2022) shows that these patterns can also be caused by 3D transport  
158 effects which have been ignored in the simplified 2D approach which has been described so far. A "topography-wind"  
159  $V$  term can be introduced in Equation 3 in order to correct for this effect using ground wind  $\mathbf{w}_g$ , the topography  
160 gradient  $\nabla z_0$ , and an inverse scale height  $X_e$  as follows:

$$V = X_e \Omega' \mathbf{w}_g \cdot \nabla z_0 \quad (4)$$

161 Here, we choose a uniform and constant value of  $X_e = 0.3 \text{ km}^{-1}$ . This value corresponds to the mean inverse scale  
162 used by Sun (2022) who allowed for a variability for  $X_e$  by fitting its value using observational data through linear  
163 regressions. While we acknowledge the fact that choosing a single value for  $X_e$  is a simplification, we note that  
164 performing the fit of its value would require an arbitrary selection of the cells used for that fit. We therefore compute  
165 the following equation to estimate  $\text{NO}_x$  emissions:

$$E_{\text{NO}_x} = \mathcal{L} \left( \frac{\partial(\Omega u)}{\partial x} + \frac{\partial(\Omega v)}{\partial y} + k_{\text{OH}+\text{NO}_2}[\text{OH}] + X_e \Omega' \mathbf{w}_g \cdot \nabla z_0 \right) \quad (5)$$

166 Following de Foy and Schauer (2022), we perform the calculation of derivatives directly on the original TROPOMI grid  
167 (along-track and across-track) to better handle pixels with low-quality or no data, resulting in lower discontinuities in  
168 the calculated transport term. To do so, we re-grid the wind field on the TROPOMI grid and linearly interpolate the  
169 estimates at the satellite timestamp. We do the same for all other parameters that are concerned for the calculation of  
170 the sink term (concentrations of OH, NO and  $\text{NO}_2$ , and temperature). Emissions are thus calculated on the TROPOMI  
171 grid and are then re-gridded on a regular north-south/east-west grid with a  $0.0625^\circ \times 0.0625^\circ$  resolution.

172 Finally, the accuracy of TROPOMI retrievals can be compromised by challenges in estimating the air mass factor  
173 or local effects, particularly in specific vertical distribution scenarios (Griffin et al., 2019; Lorente et al., 2019; Judd  
174 et al., 2020). The latest versions of TROPOMI (v2.x) showed VCD values higher than those of earlier versions (v1.x),  
175 with biases up to 40%, depending on pollution levels and seasonal variations (Van Geffen et al., 2022). Additionally, the  
176 chemistry-transport model TM5, which is integrated into the operational TROPOMI product, tends to underestimate  
177 pollution near the ground, while overestimating  $\text{NO}_2$  concentrations at higher altitudes over the sea (Latsch et al.,  
178 2023; Rieß et al., 2023). To compensate for such effects, studies like Goldberg et al. (2022) or Beirle et al. (2023)  
179 corrected the used VCDs by changing the corresponding vertical sensitivity over emitters. In this study, we do not  
180 perform such adjustment, while recognizing it could constitute a further step in the improvement of our dataset. On  
181 Figure 1, we sum up the functioning of our method.

Figure 1: General overview of the mass-balance inversion.

## 182 2.3 EDGAR bottom-up inventory

183 Many high-resolution datasets for air quality exist at global (Benkovitz et al., 1996; Granier et al., 2019) or regional  
 184 scale (Kuenen et al., 2022; He, 2012). Here we compare our averaged emissions for the year 2022 to NO<sub>x</sub> emissions  
 185 provided by The Emissions Database for Global Atmospheric Research (EDGARv6.1) for 2018. It is a global inventory  
 186 providing 0.1°×0.1° gridded emissions of greenhouse gases and air pollutants at the monthly scale, covering different  
 187 sectors (Crippa et al., 2020). It is based on activity data of different nature (population, industrial processes, energy  
 188 production, fossil fuel extraction, agricultural outputs, etc.) derived from the International Energy Agency (IEA) and  
 189 the Food and Agriculture Organization (FAO), and the emission factors corresponding to each of the covered sectors.  
 190 National and regional information on technology mix data provide a better characterization of these emission factors.  
 191 End-of-pipe measurements are also used for correcting purposes. The version 6.1 of the inventory covers the years  
 192 1970-2018.

## 193 3 Technical validation

### 194 3.1 Spatial distribution of the global NO<sub>x</sub> emissions

195 The global map of the averaged NO<sub>x</sub> emissions for 2022 is shown on Figure 2. Emissions are represented as density,  
 196 i.e. by surface unit. The map is characterized by significant regional differences. The highest values are concentrated  
 197 in developing areas such as south-eastern China, India and the Middle East. High values are also found in Europe,  
 198 Russia and the United States, where they correspond to megacities and industrial areas. Transport emissions can also  
 199 be highlighted where they provide the highest share of emissions, i.e. on highways and shipping lanes which appear  
 200 in various regions. South America, Oceania and Sub-Saharan Africa display low or zero emissions except in a small  
 201 number of cities and industrial sites. Wildfires, which are frequent in rainforests and savannas (Mebust and Cohen,  
 202 2013; Castellanos et al., 2014; Osohou et al., 2019; Opacka et al., 2022), display quasi-zero emissions in Amazonia  
 203 and low emissions in the Congo basin. Figure 3 zooms over seven macro-regions that cover most of the emitters over  
 204 land and sea.

205 Generally speaking, the maps highlights the industrialized areas, revealing the world's main megacities where  
 206 several sources of emissions (traffic, power, residential) are mixed. Some industrial facilities and large power plants  
 207 also appear. Emissions are correctly resolved in most regions of the world. The observed spread of emissions over  
 208 two to three pixels (i.e. about 12 to 20 km) further away from the exact location of the corresponding emitters is  
 209 due to the turbulent spread of emissions, which is not considered in our method. Finally, we note that emissions in  
 210 mid- and high-latitude regions (beyond about 40° from the Equator) seem to be noisy, due to an averaging over a  
 211 smaller number of clear-sky days throughout the year. On average, countries such as Egypt, Niger and Saudi Arabia  
 212 are observed more than 90% of the time with a quality flag higher than  $q_{a,lim} = 0.75$ , while Ireland, Canada and  
 213 Finland are observed less than 30% of the time. This uneven sampling is also present in tropical regions where rainfall

214 is frequent, as there is no measurement during cloudy scenes. Countries like Gabon, Indonesia or Peru are seen on  
215 average less than 40% of the time with quality flags higher than the threshold. In some cases, this low density of  
216 observations prevents emissions from intense sources from being quantified correctly at the monthly scale, as it is  
217 discussed in Section 3.4.

Figure 2: TROPOMI-derived mean daytime  $\text{NO}_x$  emission rates in 2022 estimated with the flux-divergence method. The seven frames correspond to macro-regions whose emissions are specifically shown in Figure 3.

218 The statistical distribution of emissions is shown in Figure 4. Four different regimes of emissions can be distinguished  
219 in the red curve (note the log-log scale):

- 220 • Very low values of emission densities (less than  $\sim 0.02 \text{ Pmolecules.cm}^{-2}.\text{h}^{-1}$ ), in practice at places where there  
221 are almost no emissions in reality. Note that, as the calculated fluxes represent averaged emissions, such pixels  
222 can also represent places where high emissions occurred, but only during a small portion of the year, as it is the  
223 case in regions where wildfires frequently happen.
- 224 • Residual emission densities (between  $\sim 0.02 \text{ Pmolecules.cm}^{-2}.\text{h}^{-1}$  and  $\sim 0.2 \text{ Pmolecules.cm}^{-2}.\text{h}^{-1}$ ), for which it  
225 is difficult to determine the corresponding source.
- 226 • Low emission densities (between  $\sim 0.2$  and  $\sim 2 \text{ Pmolecules.cm}^{-2}.\text{h}^{-1}$ ), generally high enough to be associated  
227 with an emitter, but too low for a reliable quantification to be possible unless heavy averaging. The upper limit  
228 corresponds approximately to the emission densities observed on smaller power plants.
- 229 • High emission densities (higher than  $2 \text{ Pmolecules.cm}^{-2}.\text{h}^{-1}$ ), where the signal-to-noise ratio is high enough to  
230 quantify emissions when enough observations are averaged.

231 Figure 4 also shows negative values (blue curve), even though negative emissions are physically impossible.  
232 They appear in practice because the transport term, which includes a derivative, can be negative. In calculated  
233 emission densities, negative pixels of low absolute value are as numerous as positive pixels of the same amplitude;  
234 they correspond to numerical noise and are found in pollution-free zones where the sink term is virtually zero. Higher  
235 values for negative pixels are less frequent: we count about 4 times less pixels with emission densities lower than  $-0.2$   
236  $\text{Pmolecules.cm}^{-2}.\text{h}^{-1}$  than pixels with emission densities higher than  $0.2 \text{ Pmolecules.cm}^{-2}.\text{h}^{-1}$  (yellow and red parts  
237 of the graph in Figure 4). The locations where such high values are observed for negative pixels correspond to areas  
238 close to anthropogenic sources of  $\text{NO}_x$ , but in situations for which the absolute transport term has been overestimated  
239 or the sink term has been underestimated. Such negative emissions are limited to rare cases, such as Tehran, which  
240 will be discussed in Section 4.2.

Figure 3: TROPOMI-derived mean daytime  $\text{NO}_x$  emission rates in 2022 estimated with the flux-divergence method for North America, South America, Sub-Saharan Africa, Europe and North Africa, East Asia, Oceania, Middle East and Central Asia.

Figure 4: Distribution of positive and negative TROPOMI-inferred  $\text{NO}_x$  emissions for year 2022. Four regimes can be distinguished (the values defining the thresholds between these regimes are given as order of magnitudes).

### 241 3.2 Diffuse sources and point sources

242 The assimilation of high-resolution observations with the flux-divergence method holds a significant potential for  
243 pinpointing emissions at small scale. As a consequence, it reveals the difference between sources that emit pollutants  
244 from a localized area, called point sources, from diffuse sources emitting pollutants over a wider area, such as sprawling  
245 urban regions like megacities. While the extent of the observed  $\text{NO}_2$  pollution created by a point source is primarily  
246 determined by advection and turbulent mixing, the spread of the pollution for a diffuse source is above all determined  
247 by the spatial extent of the source itself. Point sources are therefore characterized by a dominance of the transport  
248 term, while diffuse sources (the term "area sources" is also used) exhibit a balance or dominance of the sink term  
249 (Beirle et al., 2019). Within the flux-divergence method, these two types of sources can be identified differently, since  
250 the main sources of uncertainty come from wind angle in the case of a point source while they come from the OH  
251 concentration explaining the sink term for a diffuse source. Because this distinction remains qualitative, to classify a  
252 detected source as one or the other type, arbitrary thresholds must be defined, concerning the number of pixels above  
253 a certain value of emissions, or the share of the transport term within the emissions in Equation 5. Here, we catalog all  
254 sources in the averaged emissions map for 2022. Firstly, we define a source as a cluster of at least 3 contiguous pixels  
255 above the value of  $2 \text{ Pmolecules.cm}^{-2}.\text{h}^{-1}$ . We then classify these sources as "point" or "diffuse" according to the  
256 number of pixels in the detected cluster: point sources being the clusters comprising 3 to 9 pixels, and diffuse sources  
257 those with more than 10 pixels. We detected 456 point sources and 330 diffuse sources, whose locations are displayed  
258 on Figure 5. The detailed distribution is given in Supplementary Materials and in Rey-Pommier et al. (2024).

Figure 5: Location of different point sources in blue (between 3 and 9 contiguous pixels above  $2 \text{ Pmolecules.cm}^{-2}.\text{h}^{-1}$ ) and diffuse sources in red (more than 10 contiguous pixels) for 2022.

### 259 3.2.1 Diffuse sources

260 Most point sources correspond to facilities such as power stations, cement kilns or mining sites. They can also  
261 correspond to concentrated urban areas. Conversely, almost all diffuse sources correspond to urban areas of megacities,  
262 whether they comprise industrial facilities within their extent or not. Exceptions concern mega-emitters like the Medupi  
263 and Matimba power plants in South Africa, mentioned in various articles (Reuter et al., 2019; Hakkarainen et al.,  
264 2021; Cusworth et al., 2023) or the Ain Sokhna industrial area in Egypt, already mentioned in Rey-Pommier et al.  
265 (2022). In both cases, such groups of industrial facilities exhibit particularly high emissions over more than 10 pixels  
266 and are detected as diffuse sources. Figure 6 displays the emissions of diffuse sources corresponding to megacities:  
267 Baghdad ( $32.9 \text{ t.h}^{-1}$ , 198 pixels), Istanbul ( $16.3 \text{ t.h}^{-1}$ , 132 pixels), Mexico City ( $17.4 \text{ t.h}^{-1}$ , 111 pixels), Moscow ( $20.4$   
268  $\text{t.h}^{-1}$ , 180 pixels), Riyadh ( $33.1 \text{ t.h}^{-1}$ , 172 pixels) and Shanghai ( $102.0 \text{ t.h}^{-1}$ , 837 pixels). Table 1 shows the 20 diffuse  
269 sources with the highest emissions.

Figure 6: Map of mean daytime TROPOMI-inferred  $\text{NO}_x$  emissions for 2022 for six megacities (diffuse sources), clockwise: Baghdad, Istanbul, Moscow, Shanghai, Riyadh, and Mexico City. The approximate boundaries of the cities are denoted with dashed lines and the location of power plants and cement plants are denoted with circles and squares respectively, except for Shanghai (unavailable data).

270 These six diffuse sources differ greatly from one another: Baghdad, Mexico City and Riyadh are very dense and  
 271 isolated, allowing their emissions to stand out from the rest of the hotspots, while Moscow and Istanbul are less  
 272 dense, resulting in lower emission densities. The Shanghai urban area has a large spatial extent, and the associated  
 273 cluster extends over an area much wider than the city limits. Finally, it should be noted that Moscow and Shanghai  
 274 experience many cloudy days, resulting in a fairly low level of averaging, leading to numerical noise that is visible  
 275 on the maps. Our averaging also explains the absence of high annual emissions due to wildfires in our analysis.  
 276 At a lower temporal scale however, wildfire emissions display an annual variability without significant outliers. The  
 277 example of the rainforest in the Congo basin is studied in the Supplementary Materials, with emissions higher than  
 278 the 2 Pmolecules.cm<sup>-2</sup>.h<sup>-1</sup> threshold during summer (JJA).

Number of pixels in cluster	Latitude (°N)	Longitude (°E)	Mean emission density (Pmolecules.cm <sup>-2</sup> .h <sup>-1</sup> )	Output (t.h <sup>-1</sup> )	Emitter
2818	37.527	116.010	2.827	235.03	Beijing urban area, China
837	31.283	120.352	3.834	102.01	Shanghai urban area, China
439	35.549	51.329	7.089	94.19	Tehran urban area, Iran
552	-26.406	28.739	4.266	78.45	Gauteng coal region, South Africa
425	22.798	113.630	3.721	54.22	Shenzen & Hong-Kong urban area, China
361	29.653	31.126	4.127	48.16	Cairo & Beni Suef urban area, Egypt
303	29.582	47.874	4.555	44.64	Kuwait City urban area, Kuwait
172	24.649	46.797	5.695	33.12	Riyadh urban area, Saudi Arabia
198	32.771	44.298	5.319	32.94	Baghdad urban area, Iraq
274	41.174	123.033	4.286	32.88	Anshan urban area, China
353	39.338	110.656	2.986	30.32	Ordos mining region, China
224	37.162	126.874	4.312	28.63	Seoul urban area, South Korea

Table 1: List and location of the 20 diffuse sources with highest TROPOMI-inferred NO<sub>x</sub> emissions, and corresponding size of the cluster and main sector responsible for the emissions.

### 279 3.2.2 Point sources

280 With a manual verification of the 456 detected point sources, we identify 61 outliers, 30 of which being points in  
 281 places totally empty from any anthropogenic activity, and 31 points in areas with anthropogenic activity but without  
 282 significant source (no facility of significant size). Most of these outliers are located in high-latitude regions, with 34 of  
 283 them being located north to the 50°N parallel.

284 Because a threshold has been introduced in the classification of emitters, sources classified as "point sources"  
 285 are isolated from other emitters, and their emissions constitute a peak in the displayed map. With a threshold  
 286 set at 2 Pmolecules.cm<sup>-2</sup>.h<sup>-1</sup>, the corresponding signal-to-noise is generally high enough to perform a peak-fitting  
 287 around the source. Since the observed spread of the emissions around the source is given by turbulent diffusion, we  
 288 try to fit a 2D-Gaussian function on the detected point sources over a zone of 14 × 14 pixels around the detected  
 289 maximum emission density within the corresponding cluster. Three examples are shown for the city of Medina, Saudi  
 290 Arabia, the Shar Industrial zone, Oman and the Western Mountain power plant, Libya on Figure 7. Note that these  
 291 locations correspond to point sources well-isolated from other industrial activities, in countries with frequent cloud-free  
 292 conditions that allowed an averaging over a high number of days in 2022.

293 We acknowledge the fact that the value of 2 Pmolecules.cm<sup>-2</sup>.h<sup>-1</sup> to mark the limit between high and low  
 294 emissions is arbitrary, as other values for this threshold could be used. For instance, the Beijing cluster, identified on  
 295 Table 1, with a size of 2818 pixels respectively, is broke down into 31 smaller clusters (12 diffuse sources and 19 point  
 296 sources) when changing the threshold from 2 Pmolecules.cm<sup>-2</sup>.h<sup>-1</sup> to 3 Pmolecules.cm<sup>-2</sup>.h<sup>-1</sup>. These new clusters  
 297 represent better urban sprawling around the various megacities and industrial facilities in Eastern China. However, in  
 298 the same regions, three point sources disappear when performing this threshold change. Such differences are displayed  
 299 in the Supplementary Materials. To determine the sensitivity of the point source and diffuse source detection and  
 300 classification method, we carry out the detection by changing this threshold from 2 Pmolecules.cm<sup>-2</sup>.h<sup>-1</sup> to 3 and 4  
 301 Pmolecules.cm<sup>-2</sup>.h<sup>-1</sup>. The point sources and diffuse sources are identified, and a fit with a 2D-Gaussian is carried

302 out on point sources to estimate better emissions by accounting for the Gaussian nature of turbulent diffusion around  
 303 the source. We then count the number of point sources with a fit of correct quality (with a correlation coefficient  $R^2$   
 304 higher than 0.4). The results are shown in Table 2 for the different thresholds, and we compare the countries with the  
 305 most point sources. Note that among the 61 outliers identified in the detected point sources with the threshold of 2  
 306  $\text{Pmolecules.cm}^{-2}.\text{h}^{-1}$ , only 10 reached a value of  $R^2$  higher than 0.4.

Figure 7: Calculated mean daytime  $\text{NO}_x$  emissions in 2022 for point sources (left) and fitted emissions using a 2D-Gaussian function (right) for the city of Medina, Saudi Arabia (a), the Sohar Industrial Zone, Oman (b) and the Western Mountain power plant, Libya (c).

Threshold value	2 $\text{Pmolecules.cm}^{-2}.\text{h}^{-1}$	3 $\text{Pmolecules.cm}^{-2}.\text{h}^{-1}$	4 $\text{Pmolecules.cm}^{-2}.\text{h}^{-1}$
Number of point sources	456	303	172
Point sources with $R^2 > 0.4$	237	189	114
China	24	27	18
India	37	33	22
Russia	23	18	12
United States	18	6	3
Türkiye	7	6	1
Iran	7	9	9
Saudi Arabia	5	5	5
Japan	2	5	4
Egypt	3	2	4
Germany	6	3	1
Iraq	5	5	2
Mexico	7	5	3
Algeria	5	2	0
Pakistan	5	1	2

Table 2: Analysis of the number of point sources detected as a function of the threshold applied for cluster detection, and the number of point sources whose fit with a 2D-Gaussian was of acceptable quality ( $R^2 > 0.4$ ). Countries with at least 5 point sources with one of the thresholds are displayed.

307 As seen with the example of Beijing, moving to a higher threshold can reduce the number of point sources by not  
308 including some emitters with lower emissions, but it can also increase the number of detected point sources by  
309 reducing the number of pixels corresponding to the cluster and moving certain emitters from the "diffuse source"  
310 category to the "point source" category. For example, with a limit of  $2 \text{ Pmolecules.cm}^{-2}.\text{h}^{-1}$ , the group of the Ras  
311 Laffan power stations in Qatar does not appear as a point source because its emissions are associated to a greater  
312 cluster corresponding to a diffuse source which includes the nearby Doha megacity. Conversely, with limits of 3 or  
313  $4 \text{ Pmolecules.cm}^{-2}.\text{h}^{-1}$ , these power plants appear as a point source, and a good quality Gaussian fit provides their  
314 total emissions of  $1.69 \text{ t.h}^{-1}$ , close to the value of  $1.86 \text{ t.h}^{-1}$  reported for the four-year average between 2019 and 2022  
315 in Rey-Pommier et al. (2023). Finally, it should be noted that lowering the threshold to  $1 \text{ Pmolecules.cm}^{-2}.\text{h}^{-1}$  also  
316 reduces the number of diffuse sources because several nearby urban areas become linked by residual emission zones  
317 into a single, larger, diffuse source. Conversely, lowering the threshold detects a very large number of source points,  
318 but many of these additional points are outliers. In the rest of the study, we therefore choose to keep the lowest  
319 value of the threshold, i.e.  $2 \text{ Pmolecules.cm}^{-2}.\text{h}^{-1}$ , to optimise the number of correct emitters we work with. These  
320 emitters account for a total output of  $2,388 \text{ t.h}^{-1}$  ( $370 \text{ t.h}^{-1}$  for point sources and  $2018 \text{ t.h}^{-1}$  for diffuse sources).  
321 This represents about 17% of all emissions with densities higher than  $0.2 \text{ Pmolecules.cm}^{-2}.\text{h}^{-1}$  (with a total output  
322 of  $14,335 \text{ t.h}^{-1}$ ). As urban areas with more than 1 million inhabitants gather around 16% of the global population  
323 (Zimmer et al., 2023), this share of emissions from point and diffuse sources seems consistent with the detection limit of  
324 the flux-divergence method using TROPOMI retrievals, as urban areas lower than 1 million inhabitants are generally  
325 not detected as diffuse sources here.

326 The full list of the 456 point sources and 330 diffuse sources are given in Supplementary Materials. This list can  
327 be compared with the catalog provided by Beirle et al. (2023). Of the 237 point sources for which the Gaussian fit  
328 is of correct quality (with  $R^2 > 0.4$ ), 144 also appear in their catalog. For these points, we generally obtain higher  
329 emissions (with a median of  $409 \text{ t.h}^{-1}$  and an average of  $479 \text{ t.h}^{-1}$  in our case, whereas they have a median of  $296 \text{ t.h}^{-1}$   
330 and an average of  $344 \text{ t.h}^{-1}$ ). The two datasets have no particular reason to exhibit any clear correlation because they  
331 concern different years, and because while their approach focused on monthly averages, ours presents annual averages.  
332 For example, a site designated as a point source by Beirle et al. (2023) might not be detected if averaged over a whole  
333 year, especially if it stays inactive during certain periods. For instance, their catalog shows 187 occurrences where the  
334 signal of  $\text{NO}_x$  emissions was significant for 6 months out of 12, and 348 occurrences for 5 months.

### 335 3.3 National and regional outputs and comparison with bottom-up emissions

336 We perform an analysis of emissions at the scale of countries by comparing them to the  $\text{NO}_x$  emissions provided by  
337 EDGARv6.1 for 2018. For our TROPOMI-inferred emissions, we calculate the total mean  $\text{NO}_x$  output, representing  
338 daytime emissions for 2022, for each country using country masks at the  $0.0625^\circ \times 0.0625^\circ$  resolution. To avoid any  
339 over-estimation of the total output due to a very high number of pixels with very low emissions, we exclude from  
340 the calculation pixels with emission densities below  $0.2 \text{ Pmolecules.cm}^{-2}.\text{h}^{-1}$ . For emissions in EDGARv6.1, we sum  
341 the gridded emissions, representing monthly averages in 2018, for all sectors covered by the inventory and calculate  
342 the average flux for the year 2018. The output for each country is calculated using country masks at the  $0.1^\circ \times 0.1^\circ$   
343 resolution. In both cases, we include pixels that directly touch coastlines because marine regions close to the shore  
344 see anthropogenic emissions spread due to turbulent diffusion. This can result in over-estimating total emissions for  
345 smaller countries, especially those with low emission densities. In order not to account for such outliers, we exclude  
346 countries with a population lower than 300,000 inhabitants or with a size lower than  $1,000 \text{ km}^2$  from our analysis. This  
347 concerns many insular countries in the Caribbean and the Pacific, as well as micro-states like Andorra or Singapore.  
348 Figure 8 shows the country-wise comparison, covering 164 countries, and Table 3 provides a comparison at the scale  
349 of eight different macro-regions: Europe, North America and the Caribbean, South America, Middle East and North  
350 Africa, Former USSR countries, Oceania, Sub-Saharan Africa and the rest of Asia.

351 TROPOMI-inferred emissions are generally close to EDGAR estimates for high income level countries or countries  
352 with a majority of sources located in areas with high observation densities. This is the case for the three largest emitting  
353 countries, China, the United States and India, with TROPOMI-inferred emissions 11, 16 and 6% lower than EDGAR  
354 estimates respectively. These three countries account for 44% of global emissions. However, for the fourth highest  
355 emitting country, Russia, we estimate emissions 79% higher than EDGAR. We interpret this discrepancy as due to the  
356 low density of observations there, which leads to errors in calculating emissions over a large area. This is consistent  
357 with the large discrepancies found for many countries that also have low observation densities. The other countries  
358 for which the difference between our emissions and the EDGAR estimates is significant are low-income countries.  
359 It is possible that the sources there are small and difficult to detect with our method; it is also possible that the  
360 corresponding EDGAR estimates are imprecise, due to the incomplete or outdated nature of the reported sources in

361 these countries. The macro-regions with the highest discrepancies are thus Sub-Saharan Africa and the former USSR.

Figure 8: Comparison between TROPOMI-inferred daytime  $\text{NO}_x$  emissions for 2022 and mean emissions from EDGARv6.1 in 2018 for all countries, classified by macro-regions.

362 At the global scale, our TROPOMI-inferred daytime emissions for all considered countries (i.e., excluding emissions  
 363 which take place at sea and in smaller countries) reach a total value of  $11,209 \text{ t.h}^{-1}$ . This value is consistent with  
 364 that of EDGAR at  $12,243 \text{ t.h}^{-1}$ , i.e around 107 Mt per year, close to the value of 123 Mt calculated by Stocker (2014)  
 365 for global anthropogenic emissions in 2000 (which include shipping and aircraft emissions). We should however note  
 366 that our TROPOMI-inferred emissions only represent daytime emissions taken around 13:30 LT, which are generally  
 367 lower during mid-day than other times of the day, where pollution peaks in the early morning and late afternoon are  
 368 reported for most traffic in many cities and for power generation (Menut et al., 2012). Conversely, emissions during  
 369 daytime are generally much higher than nighttime emissions.

Region	TROPOMI 2022 ( $\text{t.h}^{-1}$ )	EDGAR 2018 ( $\text{t.h}^{-1}$ )	Relative bias VS EDGAR (weighted average)	Mean absolute error VS EDGAR (unweighted average)
Subsaharan Africa	656	702	-6.5 %	90.2%
Rest of Asia	4424	5482	-19.3 %	49.3%
Europe	842	1092	-22.9 %	38.7%
Middle East & North Africa	1509	1125	34.2 %	49.0%
North America & the Caribbean	1729	1944	-11.0 %	48.9%
Oceania	104	282	-63.2 %	52.6%
South America	512	762	-32.8 %	53.4%
Former USSR	1433	856	67.6 %	74.8%
<b>Total</b>	<b>11209</b>	<b>12243</b>	<b>-8.4 %</b>	<b>60.6%</b>

Table 3: Comparison between TROPOMI-inferred daytime  $\text{NO}_x$  emissions for 2022 and mean emissions from EDGARv6.1 in 2018 for macro-regions. For each macro-region, the relative bias between total TROPOMI-inferred emissions and total EDGAR emissions is calculated. The mean absolute bias for all countries of these macro-regions is also calculated.

### 370 3.4 Temporal distribution and averaging size

371 The results presented so far concerned daytime emissions averaged on the entire year 2022 (at around 13:30 local  
 372 time for each pixel). They therefore show a certain potential for mapping the sources of pollution, quantifying the

373 corresponding emissions and characterising their type (by size and country or region). Several studies have shown the  
374 possibility to characterise a weekly cycle of  $\text{NO}_x$  emissions (Stavrakou et al., 2020; Rey-Pommier et al., 2022). The use  
375 of geostationary satellites, such as the Geostationary Environment Monitoring Spectrometer (GEMS) in East Asia  
376 (Kim et al., 2020), the Tropospheric Emissions Monitoring of Pollution (TEMPO) in North America (Zoogman et al.,  
377 2017) and Sentinel-4 (launch planned in September 2024) in Europe (Gulde et al., 2017), could also prove promising  
378 for characterising the daily cycle of emissions, which would significantly improve forecasting capabilities. In our case,  
379 TROPOMI can only monitor pollution on a daily basis provided that retrievals are of high quality, and the analyses  
380 presented so far could theoretically be carried out at this temporal resolution. In practice however, the high sensitivity  
381 of the method to wind direction and the low signal-to-noise ratio around sources at high latitudes leads to daily  
382 emission maps that are very noisy in most cases, making it difficult to monitor activity at this temporal resolution.  
383 Averaging is therefore required to limit noise effects and limit the uncertainties associated to emission estimates. Here,  
384 we try to evaluate what level of averaging is necessary to limit noise effects and allow a monitoring of emissions. To  
385 this end, we consider the average daily emissions obtained for 2022 (i.e. over a maximum of 52 weeks) to be the most  
386 accurate estimate of daytime emissions. We compare this maximum averaging value with averages based on a smaller  
387 number of estimates. We compare the emissions of various emitters, calculated with an averaging period of 12, 24, 36  
388 and 48 weeks. Figure 9 shows the results for diffuse sources, which are all urban areas, but with different latitudes,  
389 populations, levels of development and energy mixes: Ankara (Turkey), Cape Town (South Africa), Madrid (Spain),  
390 Portland (United States), Chaguanas (Trinidad and Tobago), Saint Petersburg (Russia), Manila (Philippines) and  
391 Muscat (Oman). Figure 10 shows the results for the source points, which are industrial facilities in Egypt, Australia,  
392 Mexico, Chile, India and Germany. The sources were chosen for their relative isolation from other sources. Calculated  
393 emissions correspond to the sum of pixels around the source with densities greater than  $2 \text{ Pmolecules.cm}^{-2}.\text{h}^{-1}$ . There  
394 are two pitfalls to be avoided in this comparison:

- 395 - The first pitfall would be not to account for the seasonal cycle of emissions, which is very pronounced in some  
396 cases, and to compare chronological averages. For example, comparing the first 12 weeks of the year with the  
397 first 24 weeks of the same year would not make sense in terms of the difference with emissions averaged over  
398 the whole year, because in the first case, emissions would essentially be calculated in boreal winter, whereas in  
399 the second case, emissions would be included during spring and summer. To avoid this seasonal bias, emissions  
400 averaged over 12 weeks correspond to an average over the first week of each of the 12 months of 2022, and  
401 emissions averaged over 24 weeks correspond to the first two weeks of these same 12 months, and so on.
- 402 - The second pitfall would be not to account for the weekly cycle of emissions.  $\text{NO}_x$  emissions are generally lower  
403 at weekends due to a reduction in human activity in most areas (i.e. on Saturday and Sunday, or Friday and  
404 Saturday in most Arabian and North-African countries). It is therefore necessary to ensure that the proportion of  
405 weekend days and weekdays in each of the averages calculated remains the same, hence the interest in averaging  
406 by weeks (these proportions are therefore  $2/7$  and  $5/7$  respectively). We also carry out a final set of averaging  
407 over 24 days, i.e. 2 days per month. Since the seasonal effect (first pitfall) is generally stronger than the weekly  
408 bias (second pitfall), we therefore choose to retain the principle of selecting the same number of days in each  
409 month, even if it means making comparisons between averages where the weekend and weekday rates differ by  
410  $2/7$  and  $5/7$ . This last averaging set will be indicated as "irregular".

Figure 9:  $\text{NO}_x$  emissions for 8 different urban areas (diffuse sources), averaged over a period of 24, 84, 168, 252 and 336 days, evenly distributed throughout the year. The proportion of weekend days and weekdays is identical in all the averaging sets except the first one of 24 days.

Figure 10:  $\text{NO}_x$  emissions for 8 different industrial facilities (diffuse sources), averaged over a period of 24, 84, 168, 252 and 336 days, evenly distributed throughout the year. The proportion of weekend days and weekdays is identical in all the averaging sets except for the first set of 24 days.

411 In the case of urban areas, the different averages uniformly distributed over time show a similarity in the emissions  
412 calculated over the time horizons for Ankara, Muscat, Cape Town, and, to a certain extent, Madrid. For these cities,  
413 the low cloud cover allows a high density of observations and optimal averaging. The 84-day averaging, and to some  
414 extent the 24-day irregular averaging, seems sufficient for monitoring emissions. This is not the case for the other  
415 urban areas studied, for which the observation density is lower, such as Manila, Saint Petersburg and, to a certain  
416 extent, Chaguanas. For these cities, emissions monitoring with averaging below 168 days (or even 252 days in the case  
417 of Saint Petersburg) is therefore limited by noise effects. In the case of the studied point sources, similar emissions  
418 are observed after an 84-day averaging. In some cases, a 24-day averaging is also sufficient, while in others it is not.  
419 The representativeness of emissions on such a low level of averaging should be considered with caution, as emissions  
420 from industrial plants are always more irregular than those from cities, with the exception of power stations used for  
421 baseload electricity generation. The averages over 84 days presented here represent emissions that include several days  
422 of activity and several moments of inactivity.

423 Overall, this analysis seems to indicate that tracking emissions from source points or diffuse sources using the  
424 flux-divergence method requires an averaging effort to limit the noise obtained in the daily emissions. This averaging  
425 effort, which increases with the density of observations, is of about a month in countries with frequent high-quality  
426 observations, but of about a quarter in regions with low observation densities, such as tropical regions and high-latitude  
427 regions.

## 428 4 Uncertainties and assessment of results

### 429 4.1 Model uncertainties

430 Our top-down emissions are calculated here using a flux-divergence model, based on a simplified calculation of a  
431 transport term, a sink term and a conversion factor from  $\text{NO}_2$  to  $\text{NO}_x$ . This simplicity reduces the computation time  
432 to calculate emissions and the dependence on external datasets, at the cost of increased model uncertainties. Here,  
433 although a "topography-wind" term has been introduced in this article to refine the transport term, the sink term  
434 remains simple and only represents the reaction between  $\text{NO}_2$  and OH. While this reaction is the first contributor  
435 of  $\text{NO}_x$  loss, other sinks may be significant. For instance, organic peroxy radicals can oxidise  $\text{NO}_x$  to form peroxy  
436 nitrates, making the corresponding sink important in the presence of VOCs (Stavrakou et al., 2013), especially in  
437 biomass fires. In different conditions, the formation of peroxyacetyl nitrate from  $\text{NO}_2$  (Moxim et al., 1996), can also  
438 contribute to a significant share of the  $\text{NO}_x$  loss.

439 Another model uncertainty comes from the calculation of the conversion of  $\text{NO}_2$  production to total  $\text{NO}_x$ . The  
440 majority of  $\text{NO}_x$  is emitted in the form of NO, which is not observed from space. A common assumption is that NO  
441 is rapidly transformed into  $\text{NO}_2$  through its reaction with ozone, reaching a stationary state within a few minutes.  
442 Numerous studies (Beirle et al., 2019; de Foy and Schauer, 2022) assumed a photostationary state in typical urban  
443 conditions and used a ratio of 1.32 based on Seinfeld and Pandis (2006). Here, the values of this ratio calculated  
444 from CAMS data did not differ much from this value. However, the photostationary state is a hypothesis which is  
445 potentially not verified on the scale of a  $\text{NO}_x$  source like a power plant stack. Li et al. (2023b) calculated values of

446 this conversion ratio correlated with the combustion temperature and energy efficiency for sources in China that are  
447 highly intensive in energy such as power plants, and found a median value of 3.3. Biases in the calculation of the  
448  $\text{NO}_x:\text{NO}_2$  ratio can also arise in highly polluted environments, in which the Leighton relationship used to calculate  
449 this ratio is no longer valid. In particular, OH can also react with VOCs and form oxygenated VOCs. Further studies  
450 estimating this ratio at various spatial and temporal scales would thus provide a better implementation of our model.

## 451 4.2 Data uncertainties

452 The  $\text{NO}_2$  column densities are the main input quantity in our estimation of  $\text{NO}_x$  emissions, making the its calculation  
453 within the TROPOMI product the first element to examine when considering the data uncertainties in our estimates.  
454 Columns are calculated from measurements of solar backscattered radiation and comparison with a specific UV-Visible  
455 band using the Differential Optical Absorption Spectroscopy method, before being assimilated to derive a tropospheric  
456 vertical component. The corresponding uncertainty under polluted conditions is dominated by the sensitivity of  
457 satellite observations to air masses near the ground, and is expressed through the calculation of the tropospheric air-  
458 mass factor (AMF). To assess the significance of such effects, vertical profiles within the TROPOMI product can be  
459 replaced by any other profile information, resulting in a new retrieved tropospheric  $\text{NO}_2$  column. Douros et al. (2023)  
460 replaced the *a priori* TROPOMI OFFL  $\text{NO}_2$  profile by high-resolution air quality forecasts for Europe. As compared  
461 to the standard TROPOMI  $\text{NO}_2$  data, this new product was found to be biased-low by 5% to 12% for most European  
462 cities. The air mass factor (AMF) itself can be replaced: for instance, Lama et al. (2022) re-calculated the AMF  
463 by replacing the tropospheric AMF of the original TROPOMI OFFL product by an AMF taken from WRF-Chem  
464 simulations. Similarly, Beirle et al. (2023) re-calculated the AMF above different emitters from the corresponding  
465 averaging kernel based on a peak profile at plume height to better reflect the distribution of  $\text{NO}_2$  close to ground,  
466 which resulted in an AMF correction of about 1.61. Here, we did not perform any of such corrections, and we consider  
467 a relative uncertainty for the column of 30% (Boersma et al., 2004), consistent with S-5P validation activities which  
468 indicate that TROPOMI tropospheric  $\text{NO}_2$  columns are systematically biased low by about 30%–50% over cities  
469 (Verhoelst et al., 2021). Such a bias seems to run counter to our comparison with the catalog by (Beirle et al., 2023),  
470 for which this change in sensitivity was performed but leading to emissions generally lower than ours. A more detailed  
471 analysis of the concerned emitters seems necessary to better understand the parameters that have the largest impact  
472 on the vertical sensitivity of TROPOMI retrievals and our inversion model.

473 Other data uncertainties can arise from other parameters that play a crucial role in the estimation of advection  
474 and chemistry effects. An accurate representation of the wind is critical to estimate the transport term correctly.  
475 For a given plume, the poor representation of wind speed leads to an under-or over-estimation of transport, but the  
476 correct orientation of positive and negative values around the source remains. However, an incorrect representation  
477 of the wind direction, such as a non-alignment with the main direction of the plume, fails to represent a correct  
478 orientation of positive and negative values. The estimation of the transport term significantly thus relies heavily on  
479 the representation of the wind angle. Higher errors are therefore expected to be high in regions having winds that  
480 vary rapidly in time, or regions with complex horizontal wind variations, such as mountainous regions. In particular,  
481 situations where sub-grid scale-phenomena occur, not accounted for in ERA5 wind fields, might display even higher  
482 errors in the estimation of transported  $\text{NO}_x$ . For instance, Tehran, Iran, has an extremely complex topography,  
483 and in the calculated emissions, the transport term is particularly high compared with the sink term, with high and  
484 unrealistic negative values on large scales around the Tochal mountain immediately to the north of the city. Other  
485 megacities such as Seoul, South Korea, Jeddah, Saudi Arabia, Chittagong, Bangladesh, also exhibit unrealistically  
486 high values for the transport term. Such errors in the estimation of emission can also come from a wrong estimation  
487 of the air composition when calculating the sink term. The  $\text{NO}_2$  lifetime relies heavily on the representation of the  
488 OH concentration field, which varies with  $\text{NO}_x$  itself through a non-linear mechanism. An incorrect representation  
489 of the sink term can occur at the scale of a plume by not capturing this relationship due to an incorrect knowledge  
490 of emitters on the ground. This can also be due to the  $0.4^\circ \times 0.4^\circ$  resolution of CAMS that do not always capture  
491 the  $\text{NO}_2$  gradients adequately in plumes near a known emitter (Valin et al., 2011; Li et al., 2023a). For the OH  
492 concentration, a relative uncertainty of 30% has been used (Huijnen et al., 2019), representing the largest component  
493 of absolute uncertainty apart from the vertical columns. Large errors in the annual cycle of OH, and therefore in the  
494 sink term, can thus be expected. As a consequence, a wrong estimation of wind angle and OH concentration can lead  
495 to unrealistically high emissions, or even negative emissions.

## 496 5 Conclusion

497 In this study, we present a global quantification of NO<sub>x</sub> emissions by performing a mass-balance inversion based on  
498 the flux-divergence method, based. This approach offers a rapid alternative to traditional 3D inversion methods using  
499 Chemical Transport Models. The foundation of this method lies in the observation of tropospheric vertical column  
500 densities of NO<sub>2</sub> provided by TROPOMI. Our methodology incorporates several components in the calculation of  
501 emissions: a transport term driven by horizontal wind, a sink term largely driven by OH concentrations, and a  
502 topography-wind correction term. The emissions calculated represent mean daytime fluxes for the year 2022, allowing  
503 us to map emissions on a global scale. The results highlight that the primary sources of NO<sub>x</sub> emissions are industrialized  
504 and developing countries. Our emission estimates are consistent with global estimates, as well as the EDGARv6.1  
505 inventory, though notable discrepancies are observed at the national level, particularly in former USSR countries  
506 and sub-Saharan Africa. Besides, we performed a pinpointing of emitters by distinguishing between diffuse sources,  
507 typically large metropolitan areas with extensive spatial distribution (456 identified emitters), and point sources,  
508 generally isolated industrial facilities with emissions that often exhibit a Gaussian spread. 456 diffuse sources and 330  
509 point sources are identified. Significant uncertainties remain, especially in regions where OH is not the only source of  
510 NO<sub>x</sub> removal, regions where wind representation is inaccurate, and regions where TROPOMI data exhibit substantial  
511 biases. Nonetheless, our work demonstrates the feasibility of annual NO<sub>x</sub> emission monitoring with reduced latency  
512 and fewer mis-allocation issues compared to traditional inventories. Our approach enables the monitoring of emissions  
513 at the monthly scale in regions with high observation densities, that usually correspond to dry, mid-latitude countries.  
514 Conversely, the effect of numerical noise, combined with low-observation densities, restricts such monitoring to a higher  
515 averaging period of up to months, generally in tropical and high-latitude regions. Efforts should be made to further  
516 develop this method to provide a near-real time monitoring tool a higher temporal resolution for these regions. The  
517 results of this study were obtained from the calculation of daily NO<sub>x</sub> emissions in 2022 and their annual average.

## 518 6 Data availability

519 The monthly NO<sub>x</sub> emission maps can be accessed at <https://doi.org/10.5281/zenodo.13957837> (Rey-Pommier  
520 et al., 2024). Data is made available as emission grid maps as .nc files with emissions expressed in petamolecules per  
521 square centimetre per hour (Pmolecules.cm<sup>-2</sup>.h<sup>-1</sup>). The lists of diffuse and point sources are also provided.

522 **Author contributions.** AR analysed the data, prepared the main software code and wrote the paper. AH improved  
523 some aspects of the code and prepared the code for Gaussian fitting. FC, PC, TC, JK and JS contributed to the  
524 improvement of the method and the interpretation of the results. All the authors read and agreed on the published  
525 version of the paper.

526 **Financial support.** This study has been funded by the European Union's Horizon 2020 research and innovation  
527 programme under grant agreement no. 856612 (EMME-CARE) and partially under grant agreement no. 958927  
528 (Prototype System for a Copernicus CO<sub>2</sub> Service (CoCO<sub>2</sub>)).

529 **Competing interests.** The authors declare no competing interests.

530 **Ethical Approval.** Not applicable.

531 **Consent to Participate.** Not applicable.

532 **Consent to Publish.** Not applicable.
