**Abstract.** Fires are a significant disturbance in Earth's systems. Smoke aerosols emitted from fires can cause environmental degradation and climatic perturbations, leading to exacerbated air pollution and posing hazards to public health. However, research on the climatic and health impacts of fire emissions is severely limited by the scarcity of air pollution data directly attributed to these emissions. Here, we develop a global daily fire-sourced  $\text{PM}_{2.5}$  concentration ( $[\text{PM}_{2.5}]$ ) dataset at a spatial resolution of  $0.25^\circ$  for the period 2000-2023, using the GEOS-Chem chemical transport model driven with two fire emission inventories, the Global Fire Emissions Database version 4.1 with small fires (GFED4.1s) and the Quick Fire Emission Dataset version 2.5r1 (QFED2.5). Simulated all-source  $[\text{PM}_{2.5}]$  are bias-corrected using a machine learning algorithm, which incorporates ground observations from over 9000 monitoring sites worldwide. Then the simulated ratios between fire- and all-source  $[\text{PM}_{2.5}]$  at individual grids are applied to derive fire-sourced  $[\text{PM}_{2.5}]$ . Globally, the average fire-sourced  $[\text{PM}_{2.5}]$  is estimated to be  $1.94 \mu\text{g m}^{-3}$  with GFED4.1s and  $3.74 \mu\text{g m}^{-3}$  with QFED2.5. Both datasets show consistent spatial distributions with regional hotspots in central Africa and widespread decreasing trends over most areas. While the mean levels of fire-sourced  $[\text{PM}_{2.5}]$  are much larger at low latitudes, fire episodes at the boreal regions can cause comparable  $\text{PM}_{2.5}$  levels as in the tropics. This dataset serves as a valuable tool for exploring the impacts of fire-related air pollutants on climate, ecosystems, and public health, enabling accurate assessments and supports for decision-making in environmental management and policy.

## 1 Introduction

Atmospheric particulate matter, typically  $PM_{2.5}$  with aerodynamic diameter less than  $2.5\ \mu m$ , poses  
 40 significant impacts on air quality, climate system, and public health (Salana et al., 2024; Xie et al.,  
 2024; Gu et al., 2021). These fine particles originate from a variety of sources, among which the biomass  
 burning from both natural wildfires and anthropogenic activities makes substantial contributions (Burke  
 et al., 2023; Connolly et al., 2024; Atuyambe et al., 2024). The fire  $PM_{2.5}$  is particularly toxic due to its  
 chemical composition and smaller size compared to urban-derived  $PM_{2.5}$  (Aguilera et al., 2021). Exposure  
 45 to elevated fire  $PM_{2.5}$  has been observed to increase the mortality rates for various diseases, particularly  
 cardiovascular and respiratory ailments (Chen et al., 2021). Additionally, the increased temperatures  
 associated with wildfire emissions promote the likelihood of adverse health effects (Xu et al., 2020).  
 Furthermore, the heterogeneous distribution of fire  $PM_{2.5}$  concentrations ( $[PM_{2.5}]$ ) poses much larger  
 population exposure for low-income countries (Xu et al., 2023). Over the past a few decades, the  
 50 frequency and magnitude of wildfire occurrences have escalated due to climate change and extreme  
 weather events (Ward et al., 2012; Melia et al., 2022; Zhu et al., 2021; Hu et al., 2024b). Hence, a  
 comprehensive examination of the trends and influencing factors related to fire  $PM_{2.5}$  is important for the  
 development of effective environmental protection and health policies.

Currently, two principal approaches are used for estimating fire  $[PM_{2.5}]$  on the large scale (Yue et al.,  
 55 2024). The first method derives the changes of air pollutants before and after specific fire events using  
 observational records. For example, Roberts and Wooster (2021) used Copernicus Atmosphere  
 Monitoring Service, a system integrating remote sensing and ground-based observations, to estimate that  
 fire air pollutants result in approximately 750,000 deaths annually worldwide with the highest mortality  
 rates observed in Asia and Africa. Burke et al. (2023) utilized both surface and spaceborne  $PM_{2.5}$   
 60 measurements (from 2000 to 2022) and found that wildfire smoke has stabilized or even reversed the  
 decreasing trends of  $[PM_{2.5}]$  in most U.S. states since 2016. Notably, these fire-induced increases are  
 expected to remain unregulated as the climate continues to warm. In addition to station and satellite  
 observations, numerical modelling is also a valuable tool to assess  $[PM_{2.5}]$  from fire emissions. For  
 instance, Chen et al. (2021) employed the GEOS-Chem model to estimate daily  $[PM_{2.5}]$  attributable to  
 65 wildfires and revealed that short-term exposure to fire  $PM_{2.5}$  increases mortality risks, especially the all-  
 cause, cardiovascular, and respiratory deaths. Zhang et al. (2023) utilized an advanced model to assess  
 daily  $[PM_{2.5}]$  originating from both fire and non-fire sources across various regions of the USA. Their  
 findings showed that fire smokes accounted for over 25% of the daily  $PM_{2.5}$  levels recorded in the Air  
 Quality System of Environmental Protection Agency (EPA) from 2007 to 2018, deteriorating the U.S. air  
 70 quality particularly along the Pacific coast and in the southeast.

However, there are considerable discrepancies in modelled concentrations of wildfire pollutants due  
 to variations in physicochemical processes, model resolutions, and meteorological forcings (Markakis et  
 al., 2015; Wolke et al., 2012). Moreover, differences in fire emission inventories can significantly

influence the assessment of fire air pollutants. For example, Desservettaz et al. (2022) used the chemical  
 75 transport model (CTM) GEOS-Chem and revealed that the Global Fire Emissions Database version 4  
 with small fires (GFED4s) outperformed other fire inventories in Australia. On the global scale, Pan et al.  
 (2020) used six fire emission inventories to drive GEOS-Chem model and found that simulations using  
 the Quick Fire Emission Dataset (QFED) version 2.4 yielded the closest estimate of aerosol optical depth  
 compared to both site-level and satellite-based observations during fire seasons. These studies revealed  
 80 certain discrepancies among fire inventories and suggested a need of the comparison among these  
 inventories to improve the accuracy of predicted fire air pollutants.

Due to inherent limitations in CTMs and inventories, there has been a growing utilization of machine  
 learning algorithms in recent years. These algorithms have proven effective in reducing biases in model  
 simulations, particularly in regional analysis and prediction of wildfire pollutant concentrations. For  
 85 instance, Wei et al. (2019) developed a space-time random forest (RF) algorithm that integrated satellite  
 data, ground observations, and model outputs to estimate daily  $PM_{2.5}$  and black carbon concentrations at  
 a one-kilometer resolution across the U.S. during 2000-2020.. On the global scale, Xu et al. (2023) used  
 the RF algorithm to bias-correct the GEOS-Chem output, so as to assess global daily  $[PM_{2.5}]$  generated  
 from wildfires during 2001-2019. They improved the determination coefficient of simulated  $PM_{2.5}$  from  
 90 0.22 of the original GEOS-Chem model to 0.75 with the RF adjustment. Their analyses showed that  
 approximately 2.18 billion people experienced at least one day of severe pollution per year due to fire-  
 emitted  $PM_{2.5}$ , with an average exposure of 9.9 days per person each year. However, due to the large  
 computational cost, most of these machine learning algorithms were applied at the regional scale or driven  
 with single fire inventories, which restricts their ability to accurately quantify the spatiotemporal  
 95 variability of fire air pollutants.

In this study, the GEOS-Chem model was employed to create two global datasets of fire  $[PM_{2.5}]$   
 corresponding to the GFED4.1s and QFED2.5 emission inventories. These model datasets were refined  
 using the eXtreme Gradient Boosting (XGBoost) machine learning approach in combination with  
 abundant *in situ* measurements from thousands of monitoring stations. Subsequently, two sets of daily  
 100 fire  $PM_{2.5}$  data were generated with temporal coverage from 2000 to 2023 and a fine spatial resolution of  
 $0.25^\circ \times 0.25^\circ$ . We aim to systematically compare  $[PM_{2.5}]$  across different regions, specifically focusing on  
 the variations in  $PM_{2.5}$  levels attributable to fire emissions.

## 2 Data and methods

### 2.1 Observations of surface $PM_{2.5}$ concentrations

105 We collected site-level measurements of  $[PM_{2.5}]$  from a total of ~9000 monitoring stations in the  
 world. The site number varied year by year with the maximum of 9541 in the year 2022. The data at 1822  
 sites in China for 2014-2023 were obtained from the China National Environmental Monitoring Center

(CNEMC, <http://www.cnemc.cn>). For the earlier years (2000-2013), we interpolated the data-fusion product of Tracking Air Pollution (TAP, <http://tapdata.org.cn>) (Xiao et al., 2021; Geng et al., 2021) to  
 110 1822 ground stations to align with the CNEMC data. This TAP dataset has shown a good consistency with observed Chinese PM<sub>2.5</sub> levels for 2015-2022 (Fig. S1). In the United States, PM<sub>2.5</sub> observations at 1198 sites for 2000-2023 were obtained from the Environmental Protection Agency (EPA, <https://www.epa.gov>). European PM<sub>2.5</sub> data at 1687 sites in 2013-2023 were obtained from the European Environment Agency (EEA, <https://www.eea.europa.eu/en>), with data in pre-2013 coming from the  
 115 European Monitoring and Evaluation Programme (EMEP, <https://emep.int>). PM<sub>2.5</sub> data for other countries at 4995 sites were downloaded from OpenAQ (<https://openaq.org>) and the World's Air Pollution: Real-time Air Quality Index (<https://waqi.info>), where the Air Quality Index (AQI) was converted to PM<sub>2.5</sub> following a standardized methodology. All PM<sub>2.5</sub> data, both daily and hourly, have undergone rigorous quality checks with outliers removed to ensure accuracy. Daily values were calculated from the hourly  
 120 data, and sites with fewer than 10-day data in a year were excluded from the analysis. Finally, a total of 2560645 records were compiled for the model training and validation.

## 2.2 Auxiliary data

The auxiliary data utilized in this study are detailed in Table S1. Climatic data were downloaded from the ECMWF Reanalysis v5 (ERA5, <https://www.ecmwf.int/en/forecasts/dataset/ecmwf-reanalysis-v5>)  
 125 with a spatial resolution of 0.25°×0.25° at the hourly interval. Relative humidity was calculated using surface pressure, 2-m temperature, and 2-meter dewpoint, based on the Clausius-Clapeyron equation (Pechony and Shindell, 2009). These meteorological data were aggregated to daily time scale to be consistent with PM<sub>2.5</sub> measurements. Global land cover data from 2000 to 2023 were obtained from MODIS Land Cover (<https://modis-land.gsfc.nasa.gov/landcover.html>), which classifies 17 vegetation  
 130 types according to the International Geosphere-Biosphere Programme (IGBP).

## 2.3 GEOS-Chem model simulation

We used the GEOS-Chem model (version 12.0.0, <https://geoschem.github.io>) to predict global [PM<sub>2.5</sub>] and isolate the contributions from fire emissions. The model is a global three-dimensional CTM operating  
 135 at a horizontal resolution of 2° latitude by 2.5° longitude with 47 vertical layers extending from ground level to the mesosphere (Lu et al., 2019; David et al., 2019; Yan et al., 2018). The model incorporates MERRA-2 meteorological inputs and implements a comprehensive chemical mechanism covering HOx-NOx-VOCs-O<sub>3</sub>-halogen-aerosol interactions (Mao et al., 2013). Previous studies have extensively demonstrated the effectiveness of GEOS-Chem in simulating the reasonable distribution of trace gases  
 140 and aerosols at multiple spatial and temporal scales (Breider et al., 2014; Li et al., 2019; Xu et al., 2013).

Emissions from various sources, regions, and types are processed using the Harvard–NASA Emissions Component (HEMCO) module, which operates online and allows users to specify the grid, apply scaling factors, and dynamically integrate, overlay, and update emission inventories (Keller et al., 2014). In our study, we incorporated two daily fire emission inventories within the HEMCO framework, including GFED4.1s (short as GFED thereafter) and QFED2.5 (short as QFED thereafter), both of which range from 2000 to 2023 (last modified in June 26<sup>th</sup>, 2024). All simulated PM<sub>2.5</sub> data at 2°×2.5° from GEOS-Chem were downscaled to 0.25°×0.25° using the bilinear interpolation (Wei et al., 2021). In addition, we estimated [PM<sub>2.5</sub>] unaffected by fires by disabling the biomass combustion inventories in GEOS-Chem.

## 2.4 The machine learning algorithm

We used the XGBoost machine learning algorithm to bias-correct the simulated all-source [PM<sub>2.5</sub>]. XGBoost is based on the principle of gradient tree boosting (GTB) algorithms, which combine multiple imperfect decision trees (referred to as base or weak learning trees) to create a more accurate composite decision tree (Chen and Guestrin, 2016). XGBoost is designed for efficiency and speed, capable of building trees gradually and supporting customized objective functions and evaluation metrics. These features make it particularly well-suited for various regression tasks. The primary objective of this algorithm is to minimize of loss function, enhancing the model’s predictive accuracy. Notably, XGBoost provides a robust and scalable solution that optimizes computational speed and reduces memory usage when training large sample datasets (Li et al., 2020). The formula for prediction is defined as follows:

$$\hat{Y} = \sum_{k=1}^K f_k(X) \quad (1)$$

where  $\hat{Y}$  is the predicted daily [PM<sub>2.5</sub>];  $X$  is the input variable related to [PM<sub>2.5</sub>], which includes simulated [PM<sub>2.5</sub>] from GEOS-Chem, meteorological fields, and land cover data (Table S1).  $K$  is the number of decision trees used in the model, and  $f_k$  denotes the tree constructed to minimize the residuals left by the  $(k-1)^{\text{th}}$  tree.

XGBoost implements early stopping strategies and regularization techniques within the objective function to effectively prevent overfitting. The  $k^{\text{th}}$  iteration of XGBoost function ( $R^k$ ) is defined as follows:

$$R^k = \sum_{i=1}^t l(y_i, \hat{y}_i^k) + \sum_{j=1}^k \Omega(f_j) \quad (2)$$

where  $t$  refers to the number of samples;  $y_i$  represents the actual value of the  $i^{\text{th}}$  sample, and  $\hat{y}_i^k$  means the predicted value of the  $i^{\text{th}}$  sample after  $k$  iterations. The function  $l(y_i, \hat{y}_i^k)$  is a differentiable loss function used to measure the discrepancy between  $y_i$  and  $\hat{y}_i^k$ . The regularization term  $\Omega(f_j)$  includes the complexity of the amount of the tree  $f_j$ , such as the number of nodes and the weights assigned to each node (Ma et al., 2020). In addition, XGBoost employs a second-order Taylor expansion for the loss

function, enhancing the precision of the model's error assessment and consequently improving the accuracy of predictions (Wong et al., 2021).

175 In this study, we used meteorological data, land cover information, and simulated all-source  $[PM_{2.5}]$  from the GEOS-Chem model (Table S1) to develop XGBoost models. These gridded input data were interpolated to monitoring sites, and the site-level  $PM_{2.5}$  measurements was used as the predictand. Due to the substantial data volume, we trained the XGBoost model on a year-by-year basis using available measurements and modeling data from the corresponding years. For each year, 80% of observational  
 180 records were randomly selected to train the XGBoost model, while the remaining 20% were used as independent samples for validations. The developed and validated machine learning models were then used to derive global gridded  $[PM_{2.5}]$ , using meteorological reanalyses, land cover data, as well as  $PM_{2.5}$  outputs from GEOS-Chem models, at the resolution of  $0.25^\circ \times 0.25^\circ$  on a daily base. We estimated fire-emitted  $[PM_{2.5}]$  by applying the simulated fire-to-all ratio of  $[PM_{2.5}]$  to the XGB-adjusted all-source  
 185  $[PM_{2.5}]$  following the same approach by Xu et al. (2023):

$$[PM_{2.5}]_{fire} = \frac{[PM_{2.5}]_{all}^{GC} - [PM_{2.5}]_{nofire}^{GC}}{[PM_{2.5}]_{all}^{GC}} \times [PM_{2.5}]_{all}^{XBG} \quad (3)$$

### 3 Results

#### 3.1 Bias-correction and validation of all-source $[PM_{2.5}]$

Figure 1 shows the locations of monitoring sites and the corresponding  $[PM_{2.5}]$  in 2022. High levels  
 190 of  $PM_{2.5}$  are observed in Asia, especially over India and East Asia, where large anthropogenic emissions locate. Predicted all-source  $[PM_{2.5}]$  by the XGBoost model, which implements GEOS-Chem simulations considering GFED fire emissions, in general captures the observed spatial pattern with the determination coefficient ( $R^2$ ) of 0.82, a root-mean-square error (RMSE) of  $9.22 \mu g m^{-3}$ , and a normalized mean bias (NMB) of 0.71%, respectively (Fig. 1b). Similarly, the XGBoost model demonstrates good performance  
 195 when applied to GEOS-Chem simulations driven with QFED inventory, as shown in Fig. S2 for the results of 2022.

Figure 2 presents the top ten most crucial features identified by the XGBoost model for predicting all-source  $[PM_{2.5}]$  using two different fire inventories in 2022. As expected, the data simulated by the GEOS-Chem model consistently rank as the most important feature. This is followed by meteorological  
 200 variables such 10-meter wind speed, surface pressure, and boundary layer height, which have a significant influence on  $[PM_{2.5}]$  variations (Wei et al., 2019). Although there are variations in the importance scores of the top ten features between the two inventories, it is evident that meteorological data has a more pronounced impact on  $[PM_{2.5}]$  compared to land use data.

Following the same protocol, we developed machine learning models using XGBoost method for  
 205 other years as well. Each year's model featured distinct parameterization schemes, and we utilized a 10-

fold cross-validation (CV) method to verify the robustness of these models. The statistical indicators, including CV score  $R^2$ , overall  $R^2$ , and RMSE for the XGBoost procedures over 24 years are displayed in Fig. 3. The  $R^2$  of CV validation remained above 0.85 throughout the study period, demonstrating that the XGBoost model effectively bias-corrected the predicted all-source  $PM_{2.5}$  with reasonable spatial coverage and temporal stability. It should be noted that the  $R^2$  gradually decreased after 2012, likely due to the rapid growth in data volume, which may have weakened the correlations (Perry and Dickson, 2018).

### 3.2 Development and validation of fire $[PM_{2.5}]$

We compare the all-source  $[PM_{2.5}]$  with ( $[PM_{2.5}]_{all}^{XBG}$ ) and without ( $[PM_{2.5}]_{all}^{GC}$ ) the XGBoost adjustment. Averaged for 24 years, the original simulations exhibit high  $[PM_{2.5}]$  in North Africa, India, and East Asia, and relatively high values in eastern U.S. and central Europe (Fig. 4a). With the bias-correction, those hotspots are either weakened or shrink (Fig. 4b). Specially,  $[PM_{2.5}]$  decreases by 28.8% in North Africa, 12.3% in India, 41.7% in East Asia, 27.5% in eastern U.S., and 35.5% in central Europe (Table 1). In contrast, the adjusted  $[PM_{2.5}]$  tends to increase over the regions with limited anthropogenic perturbations, such as boreal forest, Tibetan Plateau, Australian desert and so on (Fig. 4c). Such discrepancies suggests that the GEOS-Chem model generally underestimates pollution levels in pristine regions (Kim et al., 2015; Protonotariou et al., 2010) and overestimates them in areas with dense pollution (Lei et al., 2021). Similar changes in  $[PM_{2.5}]$  are found for the simulations using QFED (Fig. S3) fire inventories. It worths noting that changes of  $[PM_{2.5}]$  varied significantly over some regions among different fire inventories. For example, the bias-corrected  $[PM_{2.5}]$  decreases by 19.2% in India and 33.6% in eastern U.S. with QFED (Table 1), much larger than those with GFED, suggesting that differences in fire inventories result in certain discrepancies in the regional  $[PM_{2.5}]$ .

We further derive fire-sourced  $[PM_{2.5}]$  using Equation (3) and validate it for typical fire events during 2018-2022 (Fig. 5). Fire carbon emissions from GFED are used to pinpoint the accurate fire locations for these events (Table S2). The fire-affected sites are determined if their back trajectory cross the fire locations within the three days after occurrence. For example, 55 sites in Canada exhibited abrupt enhancement of  $[PM_{2.5}]$  more than 5 times above ordinary level around August 15<sup>th</sup>, 2023. The back trajectory of these sites aligned with the large fire emissions at the western coast during August 13-15 (Fig. S4). Similarly, 94 sites along the eastern coast of Australia were affected by the fire plume transport during December 8-10, 2019 (Fig. S5). Averaged for these 12 events, the correlation coefficient ( $R$ ) of  $[PM_{2.5}]$  between observations and simulations increases from  $0.16 \pm 0.37$  without fire emissions to  $0.58 \pm 0.29$  with fire emissions. The NMB is improved from  $-53.17 \pm 25.50\%$  without fire emissions to  $10.68 \pm 24.96\%$  with fire emissions during the correspondent fire periods. A similar improvement of  $[PM_{2.5}]$  is achieved with QFED emission inventory for these fire events (Fig. S6).

### 3.3 Spatiotemporal variations of fire-sourced $[PM_{2.5}]$

We examine the spatiotemporal variations of fire  $[PM_{2.5}]$  derived from the GFED inventory (Fig. 6). Averaged for 2000–2023, fire-sourced  $[PM_{2.5}]$  shows strong spatial heterogeneity with the highest concentrations in central Africa and secondary hotspots in South America, Southeast Asia, North America, and Siberia. An upward trend in fire-related  $[PM_{2.5}]$  is found in Siberia and North America, while most other regions show downward trends (Fig. 6b). Predictions using the QFED inventory indicate much higher long-term average fire-related  $[PM_{2.5}]$  compared to GFED (Table 2), particularly in the Middle East, western Siberia, and eastern South America (Fig. 6c and 6e). The decreasing trend in fire  $[PM_{2.5}]$  predicted by QFED is even more pronounced than that predicted by GFED in fire-prone regions such as western Siberia, South America, and Australia (Fig. 6d). In contrast, a positive trend is predicted by QFED in eastern China and Europe, where wildfires are typically limited due to the dense population (Bistinas et al., 2014; Knorr et al., 2014). These differences in fire-sourced  $[PM_{2.5}]$  are mainly due to the discrepancies in fire inventories. In global fire-prone regions, organic carbon (OC) emissions from fires are 51.08–65.18% lower in the GFED inventory compared to the QFED inventory (Fig. 7a). Moreover, the trends in fire emissions are generally more negative or less positive in QFED than in GFED (Fig. 7b). Globally, the average fire-sourced  $[PM_{2.5}]$  is estimated to be  $1.94 \mu\text{g m}^{-3}$  with GFED and  $3.74 \mu\text{g m}^{-3}$  with QFED (Table 2).

On the long-term mean basis, fire-related  $[PM_{2.5}]$  is significantly higher in the tropics than in boreal regions (Fig. 6), primarily due to the high fire emissions in central Africa (Fig. 7). However, during extreme events, fire-sourced  $[PM_{2.5}]$  can reach comparable levels at both low and high latitudes (Fig. 8). For instance, an unprecedented fire event over Canada in 2023 resulted in a regional hotspot exceeding  $30 \mu\text{g m}^{-3}$ , surpassing the maximum value of  $\sim 20 \mu\text{g m}^{-3}$  in central Africa. Similarly, the extreme Siberian fires in 2019 significantly elevated local  $[PM_{2.5}]$  and resulted in air pollution levels comparable to those in South America. In the vast tropical areas, fires are primarily driven by anthropogenic activities (Marques et al., 2021; Ward et al., 2018), leading to relatively stable emissions from year to year. In contrast, most biomass burning in boreal regions is caused by wildfires, which are less inhibited by human activities. These uncontrolled fire episodes, combined with the huge carbon storage in boreal forests, result in tremendous emissions in specific years, significantly affecting air quality, climate system, and ecosystem functions at high latitudes in the Northern Hemisphere. It is worth noting that fire-sourced  $[PM_{2.5}]$  shows lower extreme values in QFED (Fig. S7) compared to those in GFED (Fig. 8) over Canada, though the mean fire  $[PM_{2.5}]$  is much higher associated with the former inventory (Fig. 7).

### 4 Conclusions and discussion

We developed a global high-resolution dataset of fire-sourced  $PM_{2.5}$  concentrations for the period of 2000–2023, using a chemical transport model driven with two fire inventories. A machine learning algorithm was applied to correct biases in the simulated  $[PM_{2.5}]$  from the GEOS-Chem model, and to

enhance the spatial resolution of data product. Validations demonstrated its high accuracy in capturing all-sourced  $[PM_{2.5}]$  across more than 9000 global sites and the fire-sourced  $[PM_{2.5}]$  for typical fire events. Though with some discrepancies, fire-sourced  $[PM_{2.5}]$  from the two inventories displayed a consistent spatial pattern, with high levels of fire-related air pollution in tropics and relatively lower concentrations at middle to high latitudes. They also exhibited significant global declines in fire-sourced  $[PM_{2.5}]$  over time, with the most pronounced decreases occurring in tropical regions. In contrast, fire episodes in boreal regions led to stronger enhancement of  $[PM_{2.5}]$  compared to those in the tropics, due to the larger fuel loads of northern forests and the uncontrolled scale of fires in these areas.

Recent advancements in ground monitoring networks and satellite observation systems have led to the development of high-resolution, long-term benchmark datasets for air pollutants (Wei et al., 2023; Gui et al., 2020; Song et al., 2022; Wang et al., 2023; Xiao et al., 2022). However, these datasets typically retrieve total amount of  $PM_{2.5}$  without isolating the concentrations specifically caused by fire events. To accurately derive fire-related  $[PM_{2.5}]$ , it is crucial to firstly estimate  $PM_{2.5}$  concentrations that are unaffected by fires. Some studies have identified fire-affected sites using satellite imagery and then obtained non-fire  $PM_{2.5}$  either by taking the median  $[PM_{2.5}]$  during non-fire seasons or by using data at nearby sites outside the influence of fire plumes (Burke et al., 2023; Delp and Singer, 2020; O'Dell et al., 2019). This approach, however, depends heavily on the accuracy of high-frequency fire tracking systems to correctly identify fire periods and affected areas. Additionally, it may introduce biases due to not accounting for baseline  $[PM_{2.5}]$  differences across various locations or periods. In our study, we performed sensitivity experiments using a CTM, where fire emissions were selectively activated or deactivated. This allowed us to more accurately quantify the changes of  $[PM_{2.5}]$  attributable to fire emissions. Furthermore, we employed machine-learning adjustments to minimize biases inherent in chemical models, thereby improving the accuracy and resolution of the derived fire-related  $[PM_{2.5}]$ .

The two datasets derived from different inventories showed discrepancies in both the long-term mean and trend of fire-sourced  $[PM_{2.5}]$  (Fig. 6). In general, fire-related  $[PM_{2.5}]$  is much higher when using the QFED inventory compared to GFED, but the long-term trend is more negative with QFED. As expected, these discrepancies can be attributed to differences in the underlying fire emission inventories (Fig. 7). Further validations showed that all-source  $[PM_{2.5}]$  using GFED yielded an R value of  $0.58 \pm 0.29$  and an NMB of  $10.68 \pm 24.96\%$  averaged for the 12 fire episodes (Fig. 5). Slightly improved statistical metrics were achieved using QFED, with an R value of  $0.63 \pm 0.26$  and an NMB of  $6.56 \pm 27.61\%$  for the same events (Fig. S6). However, these differences are too minor to conclusively determine which dataset provides a better estimate of fire-sourced  $[PM_{2.5}]$ . Fire-sourced  $[PM_{2.5}]$  is generally lower in the GFED dataset compared to QFED; exceptions exist, such as the 2023 Canadian fires, in which fire-sourced  $[PM_{2.5}]$  from GFED (Fig. 8) was significantly higher than that from QFED (Fig. S7). Therefore, we recommend using fire-sourced  $[PM_{2.5}]$  from both inventories jointly to better capture the uncertainties associated with fire-related air pollutants.

There are some uncertainties and limitations in our study. First, the  $PM_{2.5}$  observations used for machine learning lack broad spatial coverage. Although we gathered data from thousands of monitoring sites worldwide, most of them are located in the middle to high latitudes of the Northern Hemisphere.  $PM_{2.5}$  records are limited in the fire-prone regions, such as central Africa, which are usually wildland areas far away from populated regions. This uneven distribution of monitoring sites may introduce some biases in the derived all-source  $[PM_{2.5}]$  estimates and the subsequent contributions by fire emissions. Second, we used only one machine learning method for data training. In the preliminary stages, we compared the effectiveness of three different machine learning approaches for correcting biases in simulated  $[PM_{2.5}]$ . We found that XGBoost algorithm outperformed the other two methods, Random Forest and Deep Neural Networks, showing better statistical metrics against observations (not shown). Although we chose XGBoost for the final analyses, further investigation into results from other machine learning algorithms is warranted to reduce uncertainties inherent in data-driven methods.

Despite the limitations mentioned, our study presents a significant advancement in the development of global daily fire-sourced  $[PM_{2.5}]$  datasets, featuring the most up-to-date, fine spatial resolution, and covering the longest time period available. By integrating a chemical model with a machine learning approach, we have effectively isolated the impact of fire emissions on ground-level  $[PM_{2.5}]$ , while also addressing and reducing modeling biases. This methodology allows for a more accurate representation of fire-related air pollution. Furthermore, we provide results derived from two different emission inventories, offering a comparison that highlights the uncertainties associated with varying emission estimates. The dataset we have constructed is not only a novel contribution to the field but also holds significant value for future research. It can serve as a critical input for studies examining the climatic, ecological, and epidemiological impacts of air pollutants from global fires. The insights gained from this dataset can inform policy decisions, improve public health strategies, and enhance our understanding of the broader environmental effects of wildfire emissions.

**Data availability.** The daily fire-sourced  $[PM_{2.5}]$  from GFED4.1s and QFED2.5 for 2018-2022 are available at <https://doi.org/10.5281/zenodo.13380164> (Hu et al., 2024a). The full dataset will be publicly available after the publication of this study.

**Author contributions.** XY conceived the study. XY, CT and YH designed the research. YH performed the model runs, completed data analysis, and wrote the draft. XY reviewed and edited the manuscript. YL, YC, RX, and YG helped with methods. All authors contributed to the discussion of the results and to the finalization of the paper.

**Financial support.** This study was jointly supported by the National Key Research and Development Program of China (no. 2023YFF0805402) and Jiangsu Funding Program for Excellent Postdoctoral Talent (no. 2023ZB113).

**Figure 1.** Observed  $\text{PM}_{2.5}$  concentrations and their comparisons with predictions made by the XGBoost model. Panel (a) presents the annual mean  $\text{PM}_{2.5}$  concentrations ( $\mu\text{g m}^{-3}$ ) at 9541 monitoring sites in 2022. Panel (b) shows daily  $\text{PM}_{2.5}$  concentrations predicted by the GEOS-Chem model, adjusted using the XGBoost approach, and compared with validation subsets of observations in 2022. The GEOS-Chem simulations incorporate emissions from both anthropogenic sources and the Global Fire Emissions Database version 4.1s. Colors in (b) represent data frequency, and the red dashed line indicates the linear regression. Validation metrics, including the sample size ( $N$ , 20% of total observational records), regression equation, determination coefficient ( $R^2$ ), root-mean-square error (RMSE), and normalized mean bias (NMB), are provided. GEOS-Chem simulations using QFED inventory for 2022 are shown in Fig. S2.

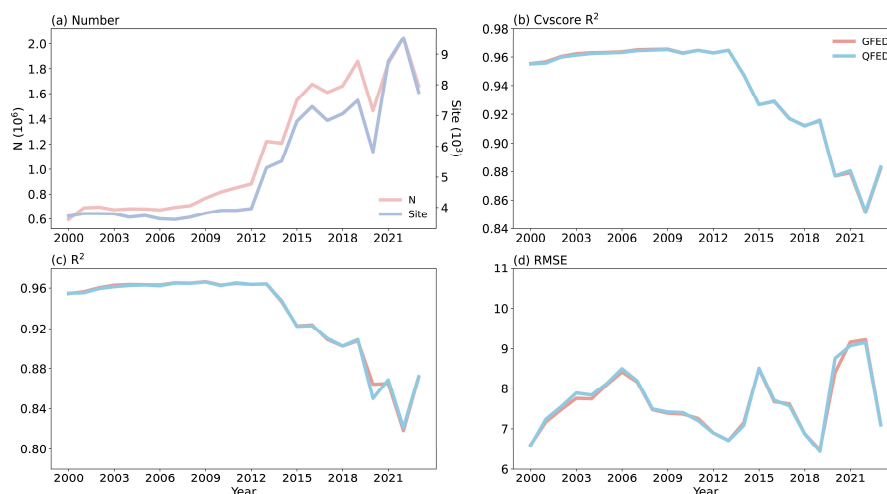

520

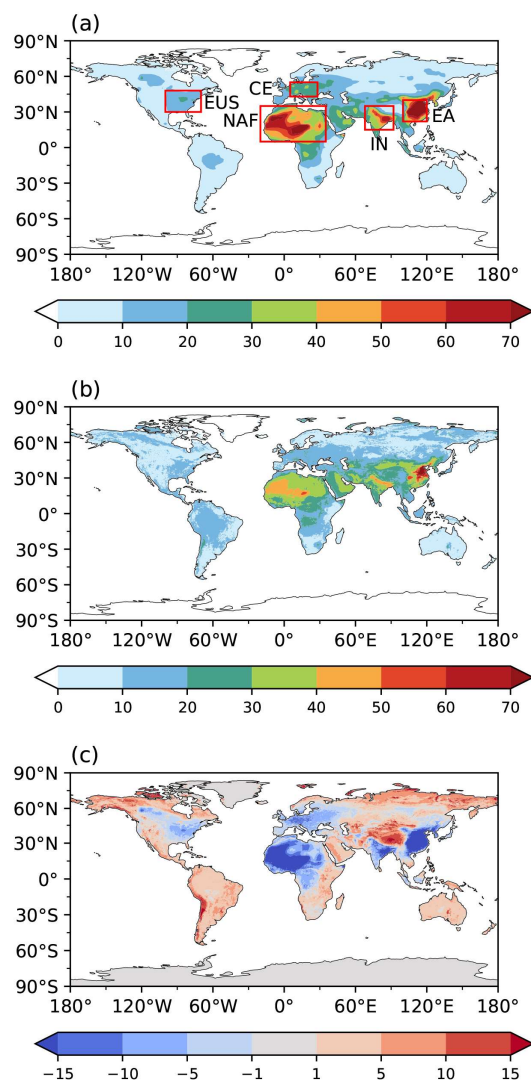

**Figure 2.** Top 10 important features measured by F-score for the machine learning model, which was trained using GEOS-Chem simulations with fire emissions from (a) GFED and (b) QFED inventories in 2022, respectively. The full name of each feature is shown in Table S1.

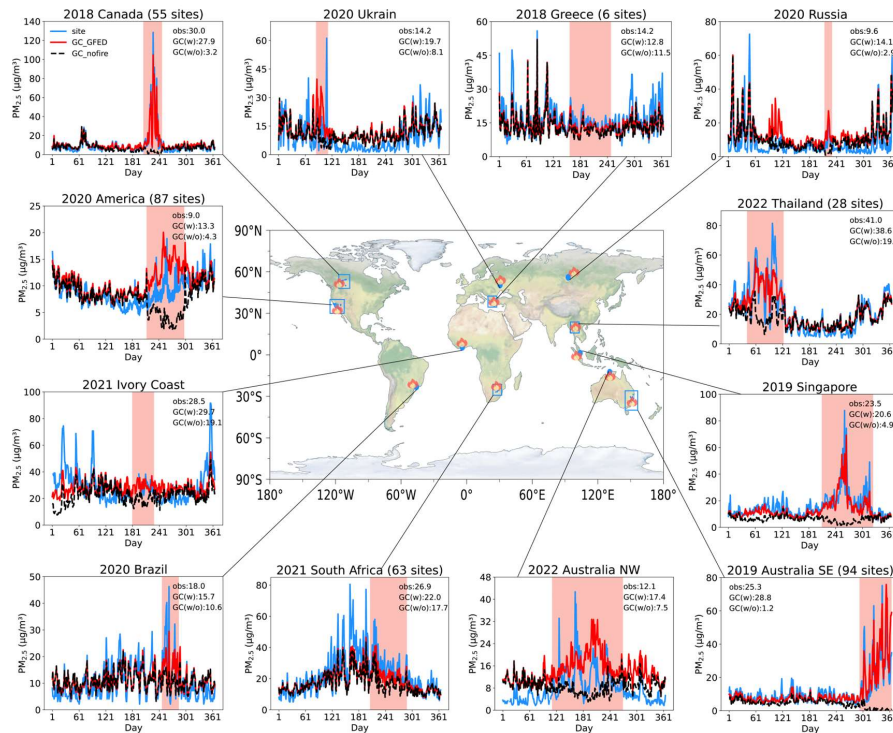

525

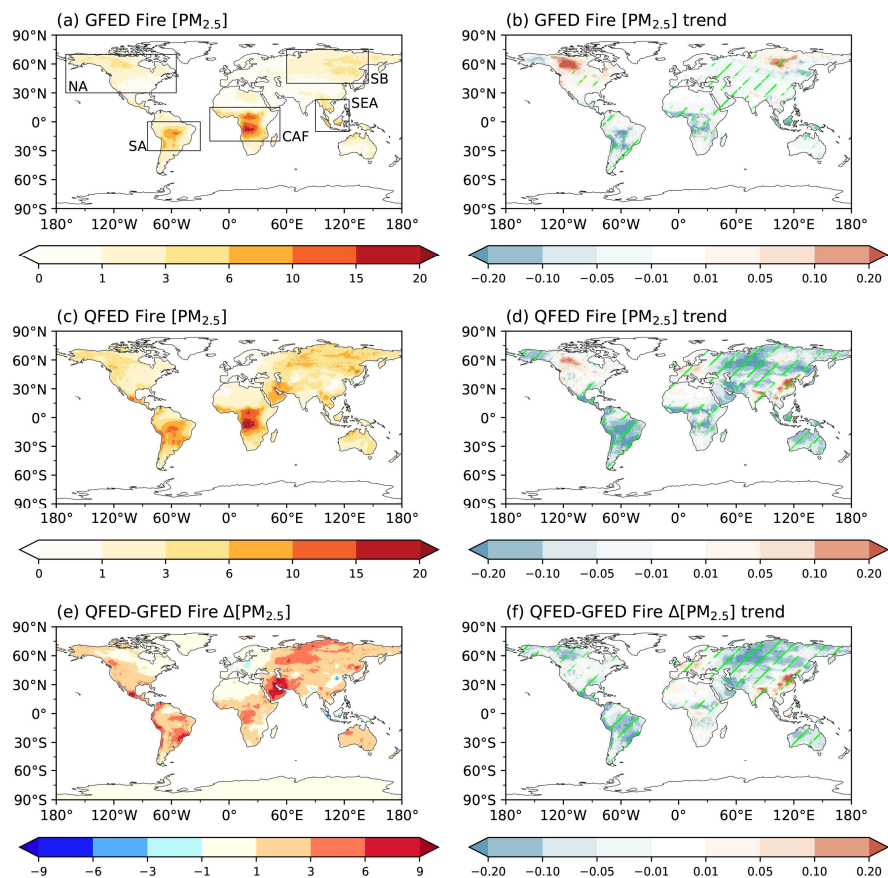

**Figure 3.** Statistical metrics of simulated  $PM_{2.5}$  concentrations ( $[PM_{2.5}]$ ) from 2000 to 2023. Panel (a) shows the total number of sites and samples (N) used for machine learning training. Panel (b) presents the 10-fold cross-validation  $R^2$  for each year, comparing simulations using different fire emission inventories, including GFED and QFED. Panels (c) and (d) display the year-to-year  $R^2$  and RMSE between observed and simulated  $[PM_{2.5}]$  using these different fire emission inventories.

**Figure 4.** Annual mean all-source  $\text{PM}_{2.5}$  for 2000-2023 from the (a) original GEOS-Chem simulations at  $0.25^\circ \times 0.25^\circ$  resolution and (b) bias-corrected simulations using the XGBoost approach at the same resolution. The difference between the original and bias-corrected  $\text{PM}_{2.5}$  is shown in (c). The simulated  $\text{PM}_{2.5}$  is derived using GFED4s fire emissions.

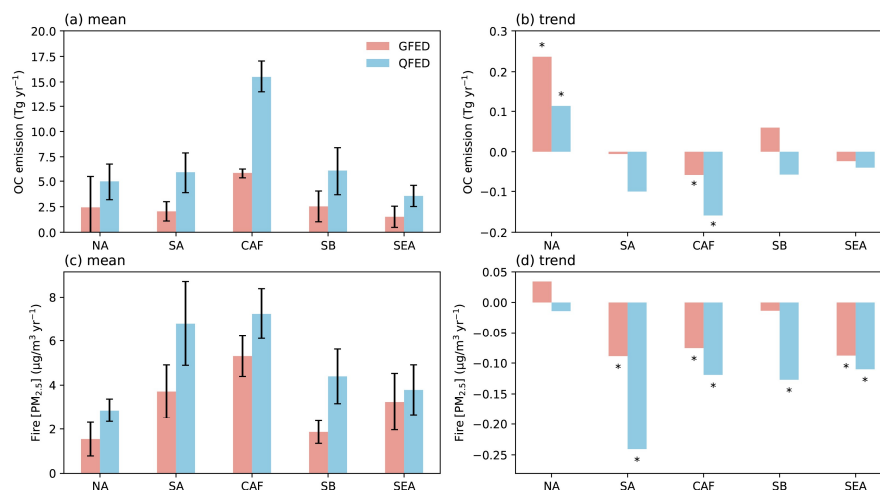

**Figure 5.** Comparisons of  $[PM_{2.5}]$  between observations (blue) and simulations with (red) and without (black) fire emissions for 12 incidences during 2018-2022. The simulations are performed using the GEOS-Chem model driven with fire emissions from the GFED inventory and bias-corrected with the XGBoost approach. Blue boxes (representing multiple sites) or points (representing single sites) on the map indicate the locations of air quality monitoring sites affected by nearby fire plumes. The sources of these fire episodes were determined using Lagrangian back-trajectory analysis as shown in Figs S4-S5. The observed and simulated  $[PM_{2.5}]$  at all sites averaged for fire periods are shown on each panel. These fire events were sourced from the Global Disaster Data Platform (<https://www.gddat.cn/newGlobalWeb>), which provides fire locations and the approximate start and end dates as shown in Table S2.

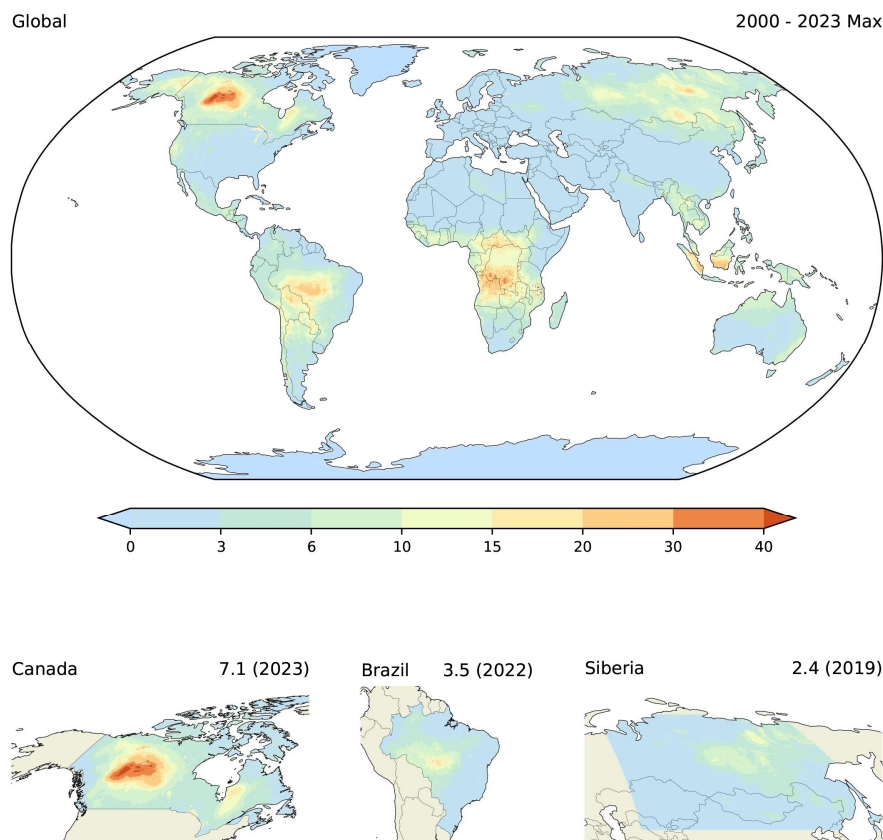

**Figure 6.** Long-term (a) mean and (b) trend of fire [PM<sub>2.5</sub>] derived using the GFED inventory for 2000-2023. The box regions in (a) indicate areas used for comparing differences between two inventories. Panels (c) and (d) display the same information as (a) and (b), but for fire [PM<sub>2.5</sub>] from QFED inventory. The differences in fire [PM<sub>2.5</sub>] ( $\Delta$ [PM<sub>2.5</sub>]) between the two inventories are presented for the long-term (e) mean and (f) trend during 2000-2023. Green slashes indicate areas with significant ( $p < 0.05$ ) changes.

555

**Figure 7.** The mean (a) and trend (b) of OC emissions in high fire-prone regions indicated by the GFED (red) and QFED (blue) inventories. Panels (c) and (d) display the fire-sourced [PM<sub>2.5</sub>] predicted using these two inventories. Errorbars represent one standard deviation for the year-to-year variations, and “\*” denotes areas with significant ( $p < 0.05$ ) trends. Domain of the labelled regions is shown on Fig. 6a.

**Figure 8.** The global maximum of fire  $[PM_{2.5}]$  ( $\mu g m^{-3}$ ) from 2000 to 2023 derived using the GFED inventory, along with fire  $[PM_{2.5}]$  during years of high wildfire emissions in various regions. For each grid on the global map, the maximum fire-sourced  $[PM_{2.5}]$  during 2000-2023 is shown. For the three regions, numbers before the parentheses represent the mean fire  $[PM_{2.5}]$  averaged for the affected countries or regions in that specific year.
