Text S1. Approach for filling the missing values in bulk density measurements

Although we filtered soil sample data from multiple databases for ensuring all contain the soil organic content observation values at multiple soil layers. The measurements of bulk density (BD) were not always available for all soil layers of the profiles considered in our study. Following the approach provided in FAO - CMCC (2017), some pedotransfer functions were adopted to estimate BD if they are missing. In particular, for layers with a SOC content lower than 12%, according to Hiederer & Köchy (2011), an exponential function was used to calculate BD for global data either in the topsoil or subsoil. For soil layers with a SOC content higher than 12%, it was used the log-transformed function. The abovementioned pedotransfer functions used depending on the SOC content and the considered soil layer to estimate BD are summarized in the following equation.

$$BD = \begin{cases} e^{(a \cdot SOC + b)} & \text{if SOC content} \leq 12\% \\ -0.285 \cdot \ln(SOC) + 1.456 & \text{if SOC content} > 12\% \text{ and soil depth} \leq 30\text{cm} \\ -0.291 \cdot \ln(SOC) + 1.389 & \text{if SOC content} > 12\% \text{ and soil depth} > 30\text{cm} \end{cases} \quad (S1)$$

where $a = -0.034$, $b = 0.100$.

Text S2. Non-extracted aboveground NPP in croplands

When calculating the aboveground NPP (ANPP) in cropland areas, a decent fraction of ANPP is removed as the harvest products, and it should be additionally considered. The way for estimating the non-extracted ANPP in croplands is as follows. We first confirmed that, in the aboveground and belowground biomass carbon maps (Spawn et al., 2020), the crop's yield and the harvest index (crop-specific) were used to estimate the maximum standing biomass of crops prior to harvest. Following the work of Spawn et al., we adopted the crop-specific harvest index provided by Wolf et al. (2015) and Spawn et al. (2020) to estimate the unharvested residue in croplands. First, we used the EARTHSTAT dataset (Monfreda et al., 2008) to extract the spatial coverage of different croplands with different crop types. Then, we considered the aboveground residue retention rate in areas with different developing levels. According to the published literature, the residue retention rates can be assumed as 30% in developing regions such as Asia and Africa (e.g., Erenstein, 2011; Jiang et al., 2012; Baudron et al., 2014), and 60% in other regions (e.g., Scarlat et al., 2010; Lokupitiya et al., 2012; Baudron et al., 2015). This way was also adopted in a previous study (Wang et al., 2016). In addition, the manure input is an extra carbon input in croplands. We used the global crop-specific nitrogen (N) fertilization dataset

from Adalibieke et al. (2023), to determine the consumption of N fertilizer input from manure application. The C:N ratio of farmyard manure provided by FAO (Roman et al., 2015) was adopted for converting the amount of N to the carbon.

For the grassland and forest areas, we acknowledge that considering the human-induced decrease (e.g. grazing, deforestation) or increase (e.g. dung excretions during grazing, afforestation) of carbon input co-exist, and the available accurate global datasets that quantify these impacts are still not well developed, so these impacts were not included in our study for the limited observations and datasets.

Text S3. Fraction of aboveground NPP transfers into topsoil

When calculating carbon input flux for topsoil, apart from belowground NPP (BNPP), the carbon input also contains a portion of carbon from surface litterfall, which should be additionally considered. Although there are no spatially-explicit values of this proportion provided directly, we found currently available datasets and literatures that help us generate estimations as follows.

It should be noted here that the organic litter on the surface was not incorporated in the soil (White, 2006), therefore, we need to know the fraction of ANPP converted into litterfall. For having a biome-specific estimation on it, we collected datasets provided by Holland et al. (2015) and Jia et al. (2016), to get a total number of 813 geo-referenced observations with the values of litterfall ($\text{kg m}^{-2} \text{yr}^{-1}$). Combining these observations with the ANPP values we processed before and the global biome map provided by (Dinerstein et al., 2017), we compiled a biome-specific estimated result of the fraction of litterfall in ANPP, which is shown in Table S5 as below. Considering the difference between tree species (needle-leaved, broadleaved, evergreen and deciduous), we further used MODIS land cover data product to divide the litterfall sample data by a more detailed classification. Table S6 shows the differences of this value in forests with different leaf types.

Then, we need to know the fraction of litterfall allocated to topsoil. Such data are very limited so that we cannot be supported to get a spatially detailed estimation. Refer to Community Land Model (CLM) (Oleson et al., 2013), also some evidences from Millennial model (Abramoff et al., 2022) and MEMS 2.0 model (Zhang et al., 2021), we adopted a value of 0.5 as the respiration fraction (rf) for litter pool as suggested from CLM that based on a model structure used in Century model (Oleson et al., 2013). Therefore, it can be considered that approximately half of litterfall released as CO_2 back to the atmosphere, thereby the left half

of it allocated into the topsoil. Finally, the fraction of ANPP that transferred as carbon input into the topsoil (denoted as fr_a), can be determined as the biome-specific value of the fraction of litterfall in ANPP multiplied by $(1 - rf)$. For subsoil, fr_a was set to be zero.

Text S4. Calculation of variable importance that contributes τ pattern

The relative importance (RI) of each covariate (the contribution of each predictor) was calculated by using permutation-based feature importance. The permutation feature importance is defined to be the decrease in the model accuracy when a single feature (covariate) value is randomly shuffled. The feature importance can be computed on a held-out validation set. This approach can avoid the problem that the feature might be given high importance on the training set but not on the held-out validation set caused by the model overfitting. The RI of a certain covariate can be calculated as follows:

$$RI_i = s - \frac{1}{K} \sum_{k=1}^K s_{k,i} \quad (S2)$$

Where RI_i is the relative importance of the i -th covariate, s is the score of model performance fitted on the original data without permutation, $s_{k,i}$ is the score of model fitted on the data with shuffled values of the i -th covariate in the k -th reputation, and K is the number of times to permute a covariate. The score of the model was set as the metric of R^2 on the withheld validation set.

The RI of each environmental covariate to the global variations of τ in top- and subsoil layers was quantified. To further reflect the difference in influences of the four variable categories on τ , we integrated the importance of variables in each category. The variable with the highest RI in each category was used to represent the importance of that category. Compared to taking the sum or mean of RI for each category, this way avoids to some extent over or underestimate of importance caused by the difference of variable importance within each category and the different number of variables included among categories. Then, the importance values of all categories were scaled to a sum of 1, and the percentage number represents the importance of each category. The same procedure of calculating variable importance was also conducted for data in different biomes (Fig. S23 and S24).

Text S5. Detecting interactive effects among climate and edaphic factors on τ

Given the potentially non-significant effects of a variable (e.g. the global impact of precipitation) on τ in a global-level linear model, it does not necessarily imply that the respective variable has no influence on τ . Instead, this lack of significance may arise from its divergent effects when interacting with other factors. This led to an interest in exploring the reasons behind such nonlinear and uncoherent driving mechanisms. Considering the extrinsic climate effects on soil carbon turnover can be interacted by regionally intrinsic soil characteristics (Doetterl et al., 2015), we used the following approach to exemplify the interactive effects of MAT and MAP on top- and subsoil τ in response to the changes of other factors (namely interactive factors).

The variables of MAP/MAT, CLAY+SILT, C:N, CEC, and soil pH were selected (according to the analytical results of variable importance) as the important interactive factors for detect nonlinear MAT/MAP effect on τ . Each selected interactive factor was divided into ten intervals by using Jenks natural breaks classification method (Jenks, 1967), and all sample data were divided into ten subsets according the intervals that their interactive factors fall into. Then, the ten partial correlation coefficients between τ and two climatic variables within all intervals were connected to generate a line chart, which reveals how effects of temperature and water availability on τ strongly interact with edaphic factors (Fig. 3).

Text S6. Local-level analysis of dominating factors

In addition to the overall importance of covariates analyzed at the global level, the local-level importance for four categories of variables was also assessed. We quantified *RI* of covariates based on the RF model trained by sample data at local scales stratified by the global terrestrial ecoregions (Dinerstein et al., 2017). The same procedure of calculating importance of variables and categories mentioned in above was conducted in each ecoregion. This approach enables the globally geographical pattern of the regional importance of covariates yield. The global maps of the dominant factors (the category of covariate) influencing τ at top- and subsoil layers were generated by interpolating results in all windows. Additionally, since the sample sizes in different windows are not same (Fig. S26), the relative density of samples in each local window was considered. We determined the relative density to be the ratio of sample points fall within each window to a number of 200 which is considered as a sufficient size. All ratio that larger than 1 were controlled to be 1, so that the relative density value is between 0 and 1. The colors represent the local importance of the four categories of covariates in the maps was adjusted to display lighter proportionally to the lower the sample density.

Supplementary Figures

Fig. S1

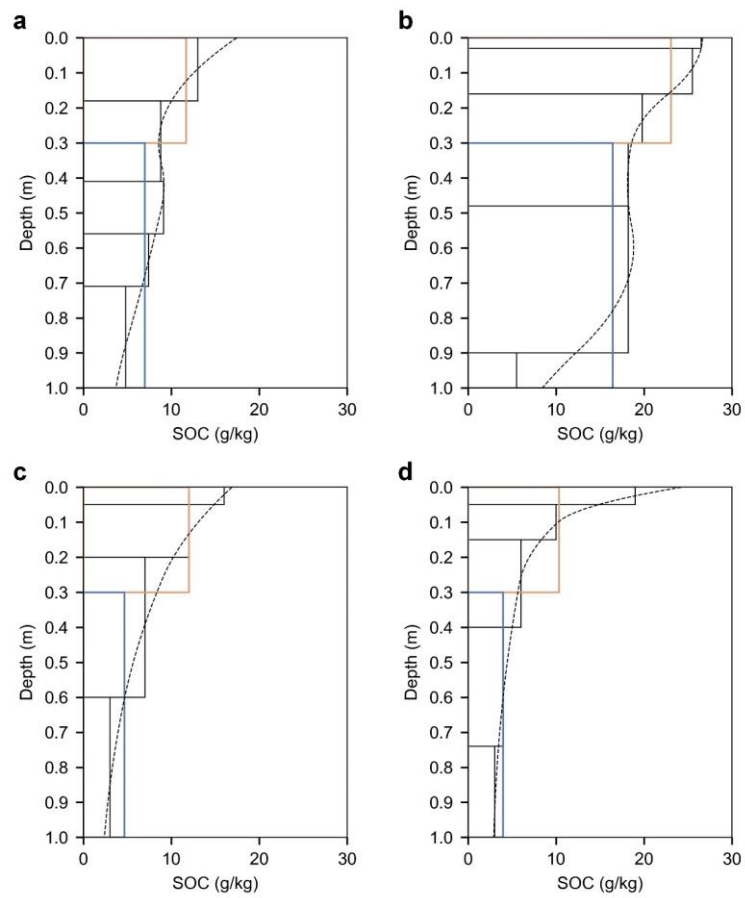

Figure S1. Examples of the fitted variation of soil organic carbon content (SOC, g kg^{-1}) with depth (m). The figure shows observed SOC values (black bars) and fitted splines (dashed lines) by using the equal-area smoothing spline algorithm referred to Bishop et al. (1999) and Malone et al. (2009) at four randomly selected sample sites. Orange and blue lines represent the estimated averages at top- (0-0.3 m) and subsoil (0.3-1 m) layers.

Fig. S2

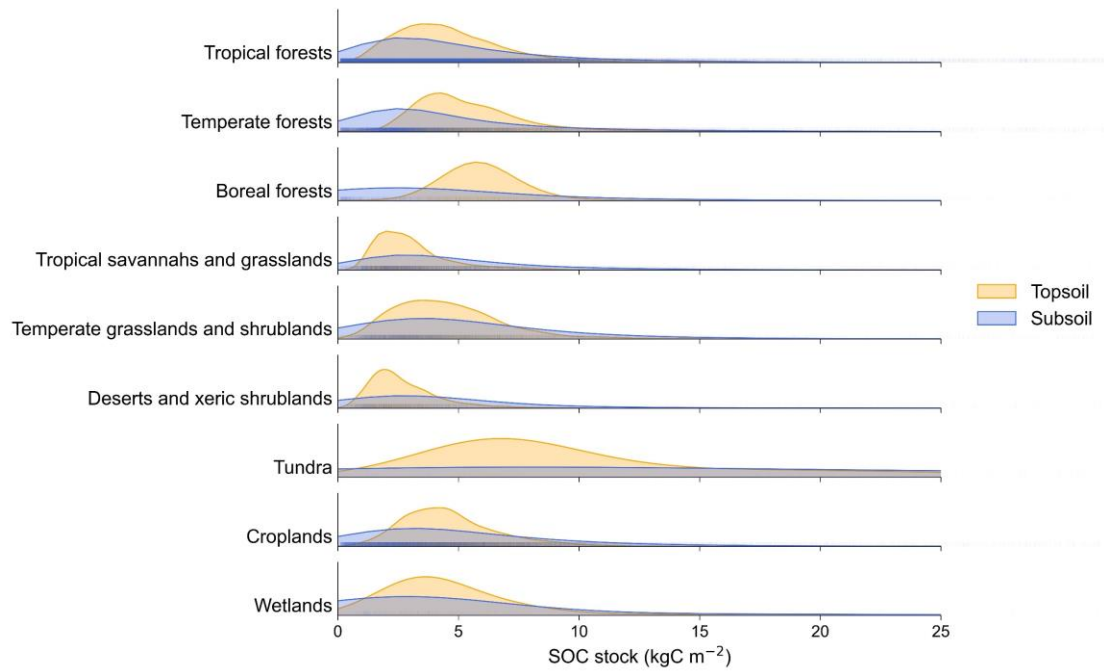

Figure S2. Kernel density estimates of soil organic carbon stock (SOCS, kgC m^{-2}) in top- and subsoil by biome, based on data aggregated by soil profile observations.

Fig. S3

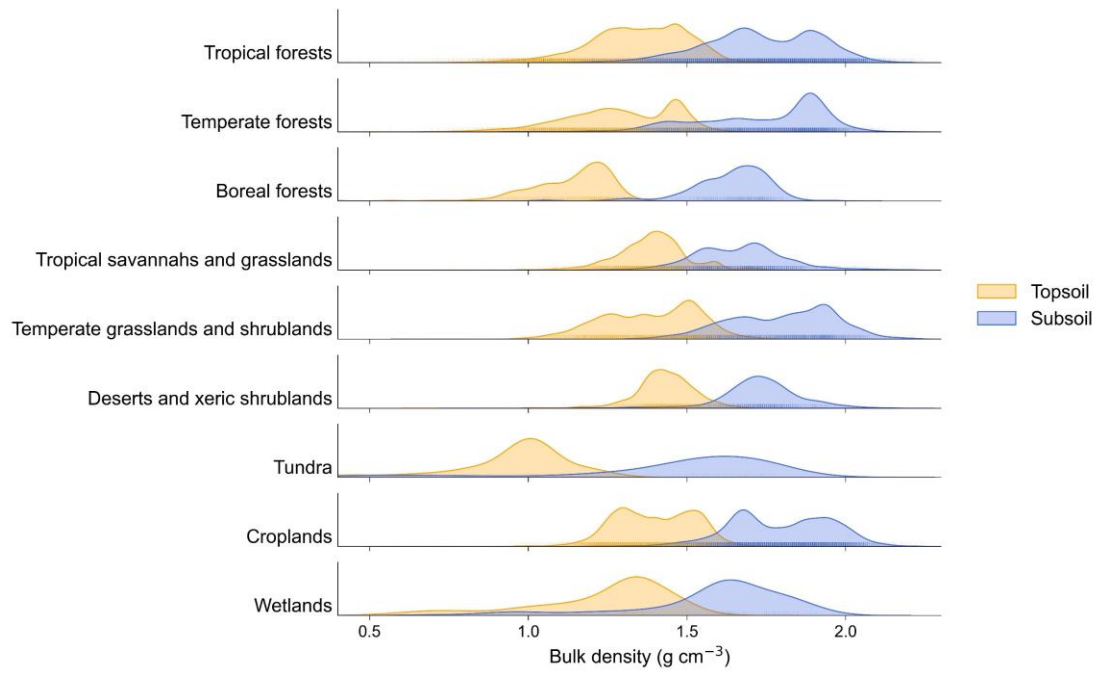

Figure S3. Kernel density estimates of bulk density (g cm⁻³) in top- and subsoil by biome, based on data aggregated by soil profile observations.

Fig. S4

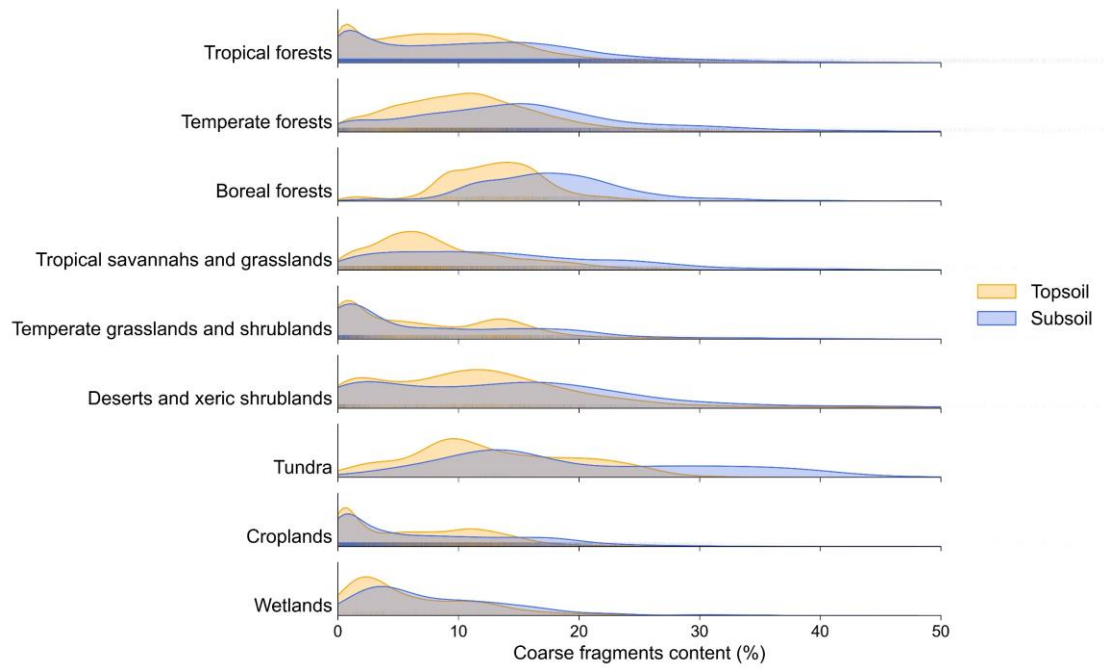

Figure S4. Kernel density estimates of coarse fragments (> 2 mm) content (%) in top- and subsoil by biome, based on data aggregated by soil profile observations.

Fig. S5

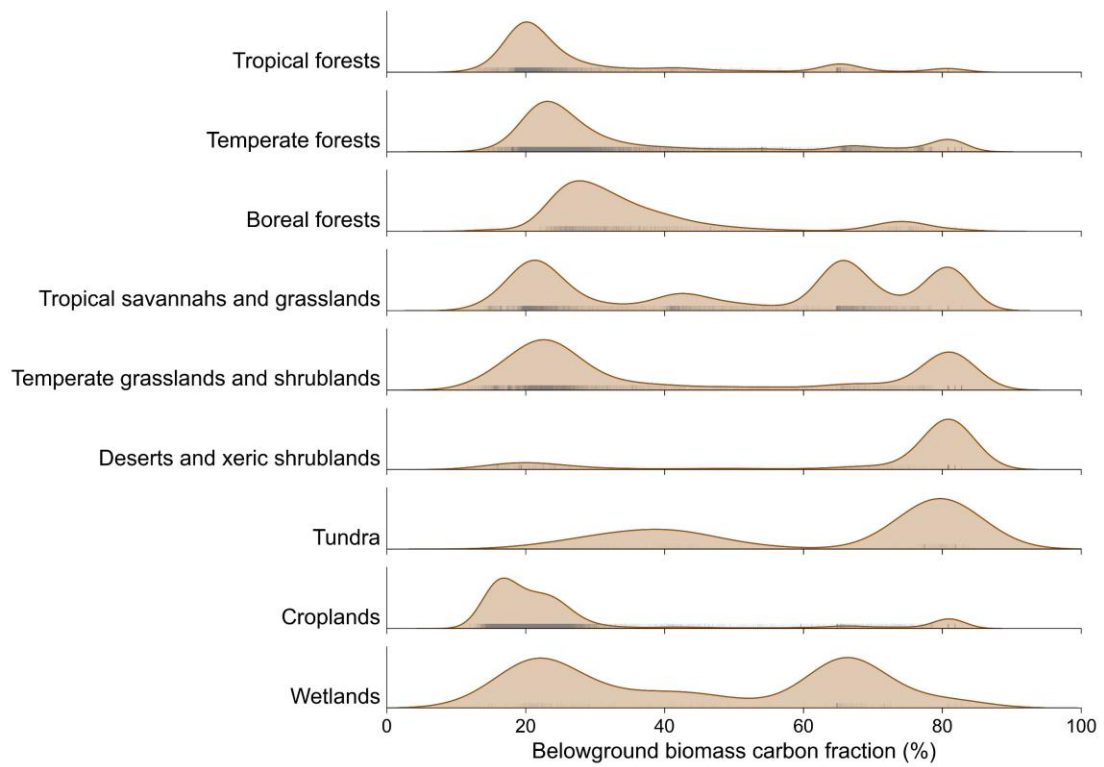

Figure S5. Kernel density estimates of belowground biomass carbon fraction (%) by biome, based on data aggregated by locations of soil profile observations. The root-to-shoot ratio at each sample location was collected from the harmonized global maps of above and belowground biomass carbon density provided by Spawn et al. (2020).

Fig. S6

Figure S6. An illustration of the root distribution estimation through the information of belowground extents from the Root Systems of Individual Plants (RSIP) and global the global root traits (GRooT) databases. The cumulative root mass fraction along the depth was estimated by using a asymptotic nonlinear model (Eq. 6) considering the maximum rooting depth (Gale and Grigal, 1987; Zeng, 2001).

Fig. S7

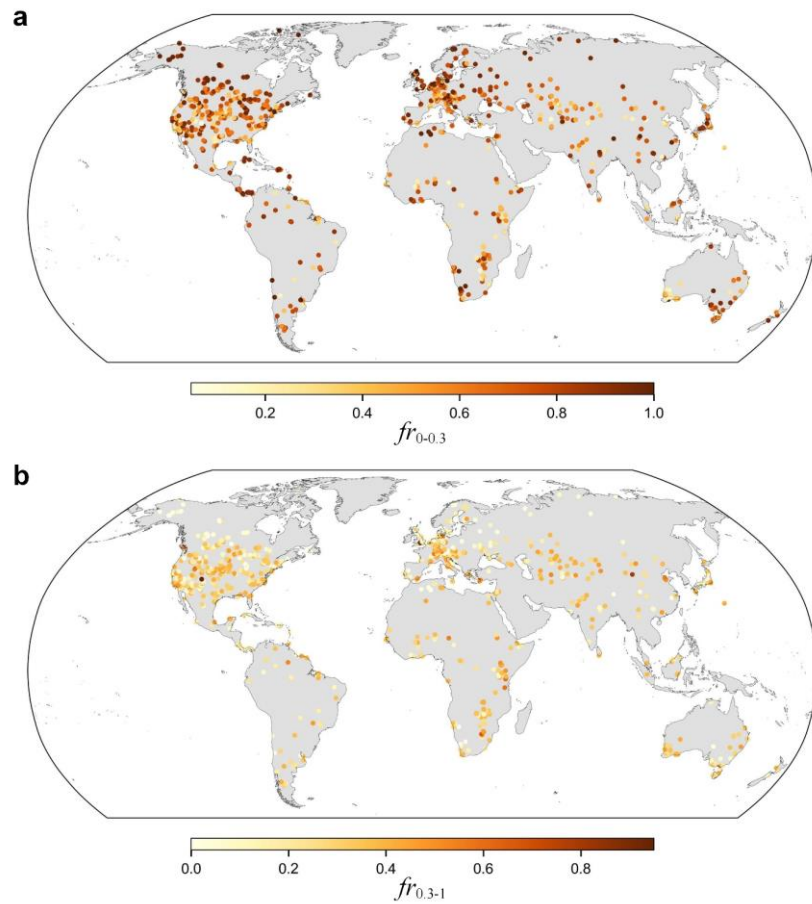

Figure S7. Global distribution of estimated fraction of root from 0 to 0.3 m (a) and from 0.3 to 1 m (b) at available root profiles and root size observations. The observations with a total number of 1,732 geo-referenced measurements were collected from the root profiles with the root distribution information provided by Schenk & Jackson, (2002), the extended Root Systems of Individual Plants (RSIP) database provided by Tumber-Dávila et al. (2022), and the global root traits (GRooT) database provided by Guerrero-Ramírez et al. (2021).

Fig. S18

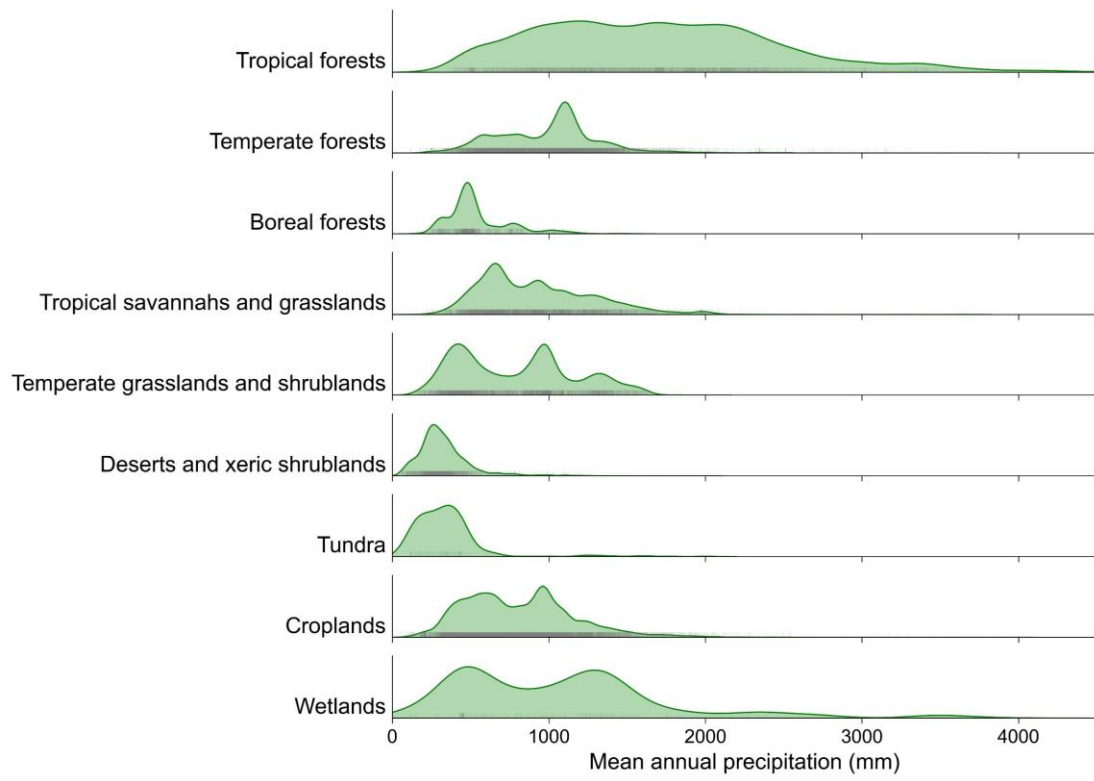

Figure S18. Kernel density estimates of mean annual precipitation (mm) by biome, based on data aggregated by locations of soil profile observations.

Fig. S19

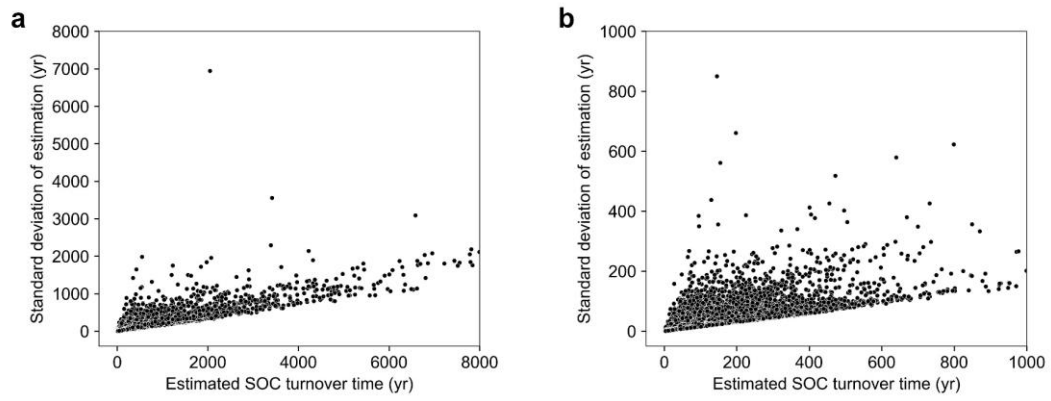

Figure S19. The relationship between the estimated values of SOC turnover time and their estimation error (standard deviation) at sample locations. The error was determined by the cumulative uncertainty of the inputs that participate in calculation of SOC turnover time according to the error propagation theory.

Fig. S20

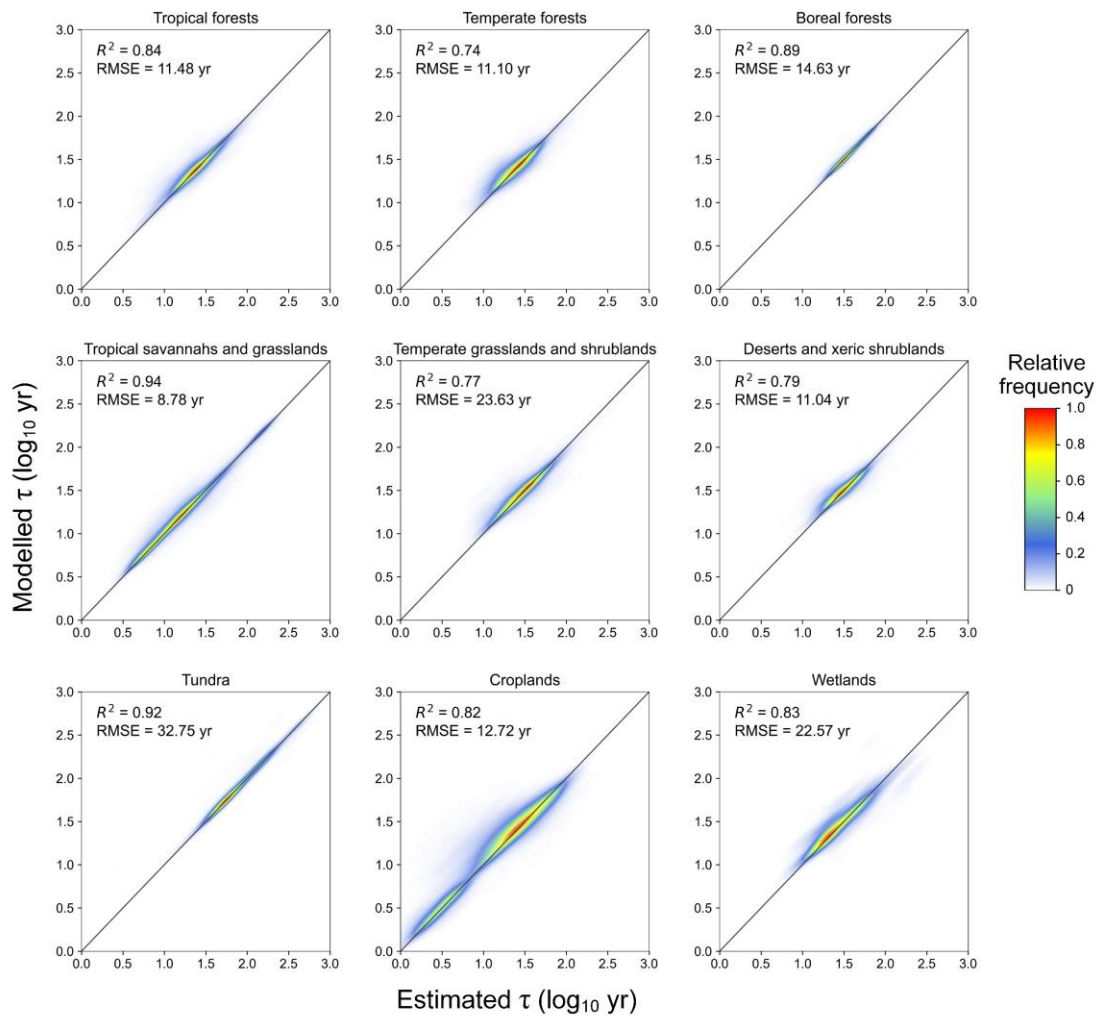

Figure S20. Plots of measured versus predicted values of SOC turnover times (τ , yr) at topsoil (0–0.3 m) layer in different biomes. R^2 values represent the coefficient of determination relative to the 1:1 line (solid diagonal lines) of the estimated τ values based on observed data and the predicted values for all validation samples using 10-fold cross-validation. Colors indicate the proportion (relative frequency) of data points at each pixel. Validation results show that biomes with a greater number of sample data generally have larger variability.

Fig. S21

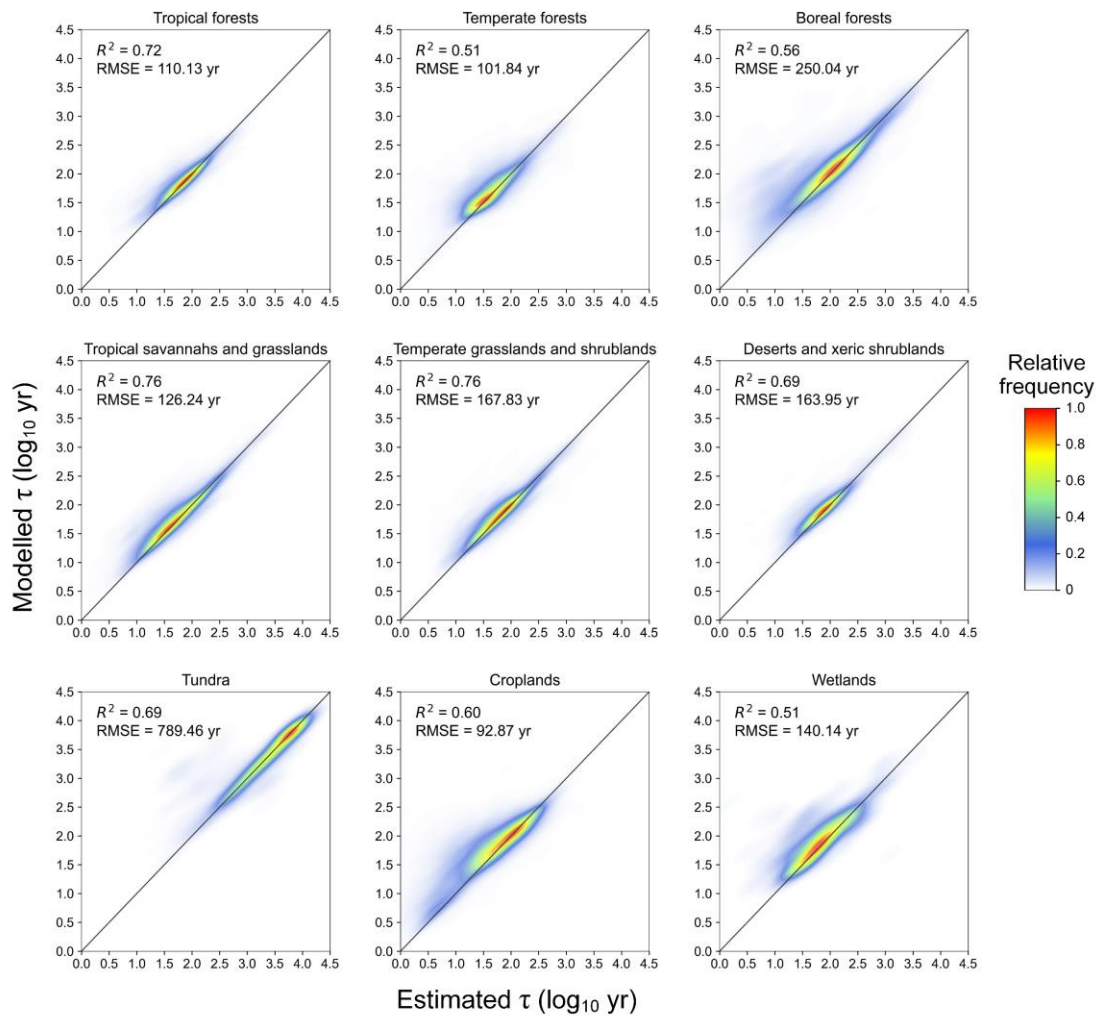

Figure S21. Plots of measured versus predicted values of SOC turnover times (τ , yr) at subsoil (0.3–1 m) layer in different biomes. R^2 values represent the coefficient of determination relative to the 1:1 line (solid diagonal lines) of the estimated τ values based on observed data and the predicted values for all validation samples using 10-fold cross-validation. Colors indicate the proportion (relative frequency) of data points at each pixel. Validation results show that biomes with a greater number of sample data generally have larger variability.

Fig. S22

Figure S22. Plots of the proportion of observed τ values at top- (a) and subsoil (b) layers in validation set falling within probability intervals (accuracy plot (Goovaerts, 2001)). The values on x -axis represent a series of symmetric p -probability intervals (PI) bounded by the $(1 - p)/2$ and $(1 + p)/2$ quantiles. The values on y -axis represent the probability that the actual target values (the observed τ values in validation set) fall into each p -PI. A correct modelling of the prediction uncertainty would entail that the proportion of validation points covered in each prediction interval approximately equals the value of that PI, for all values of p . The plotted points substantially higher than the 1:1 line suggests that the uncertainty was overestimated, and the substantially lower values indicate that it was underestimated.

Fig. S23

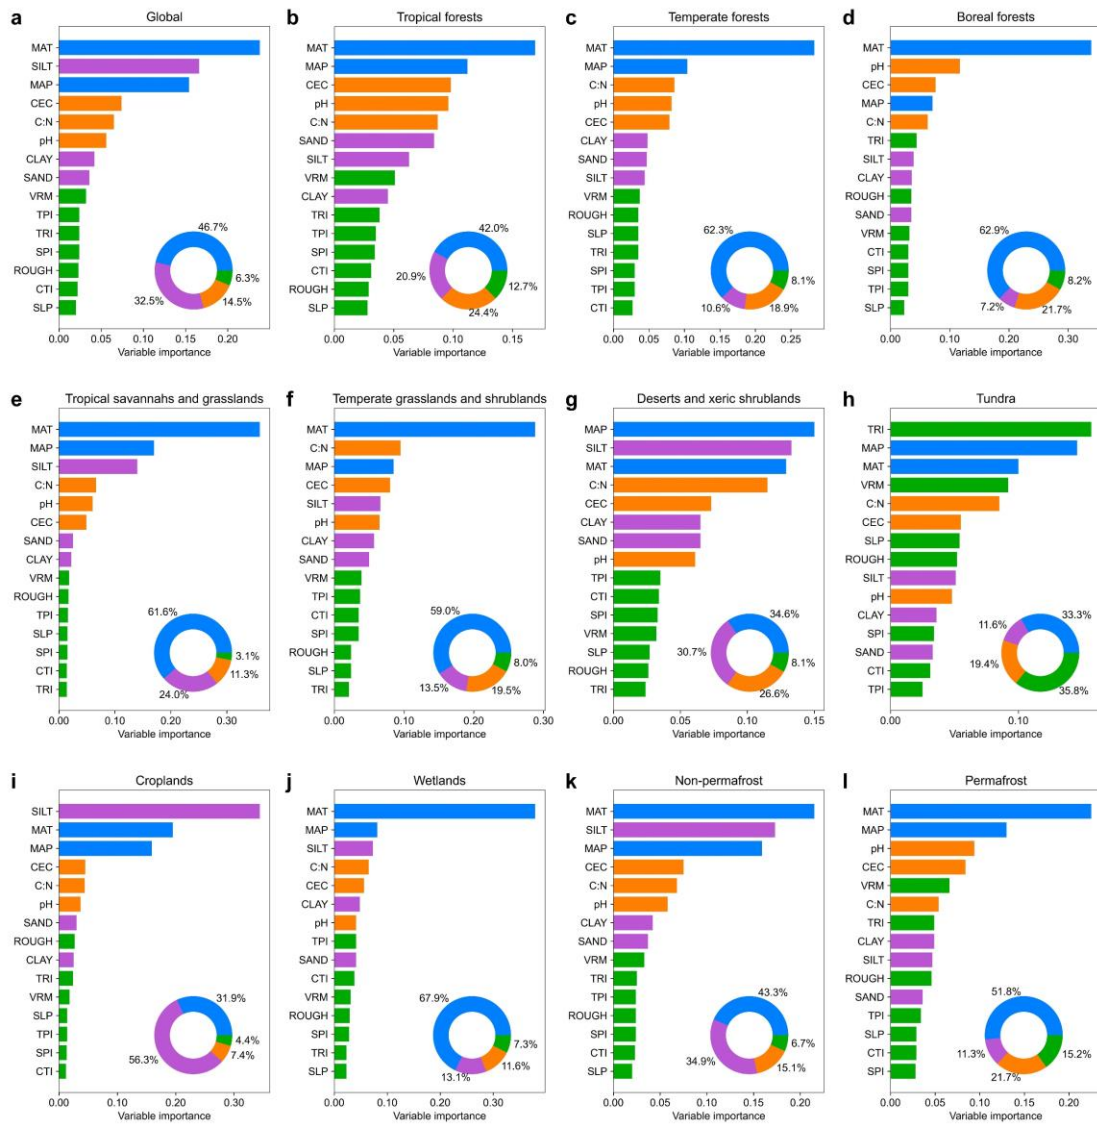

Figure S23. The influences of climate, soil physical and chemical properties, and topography factors on the topsoil organic carbon turnover time (τ). Variable importance metrics at the global scale and main biomes are calculated by using the random forest model for evaluating the effects of these environmental variables on τ at topsoil layer.

Fig. S24

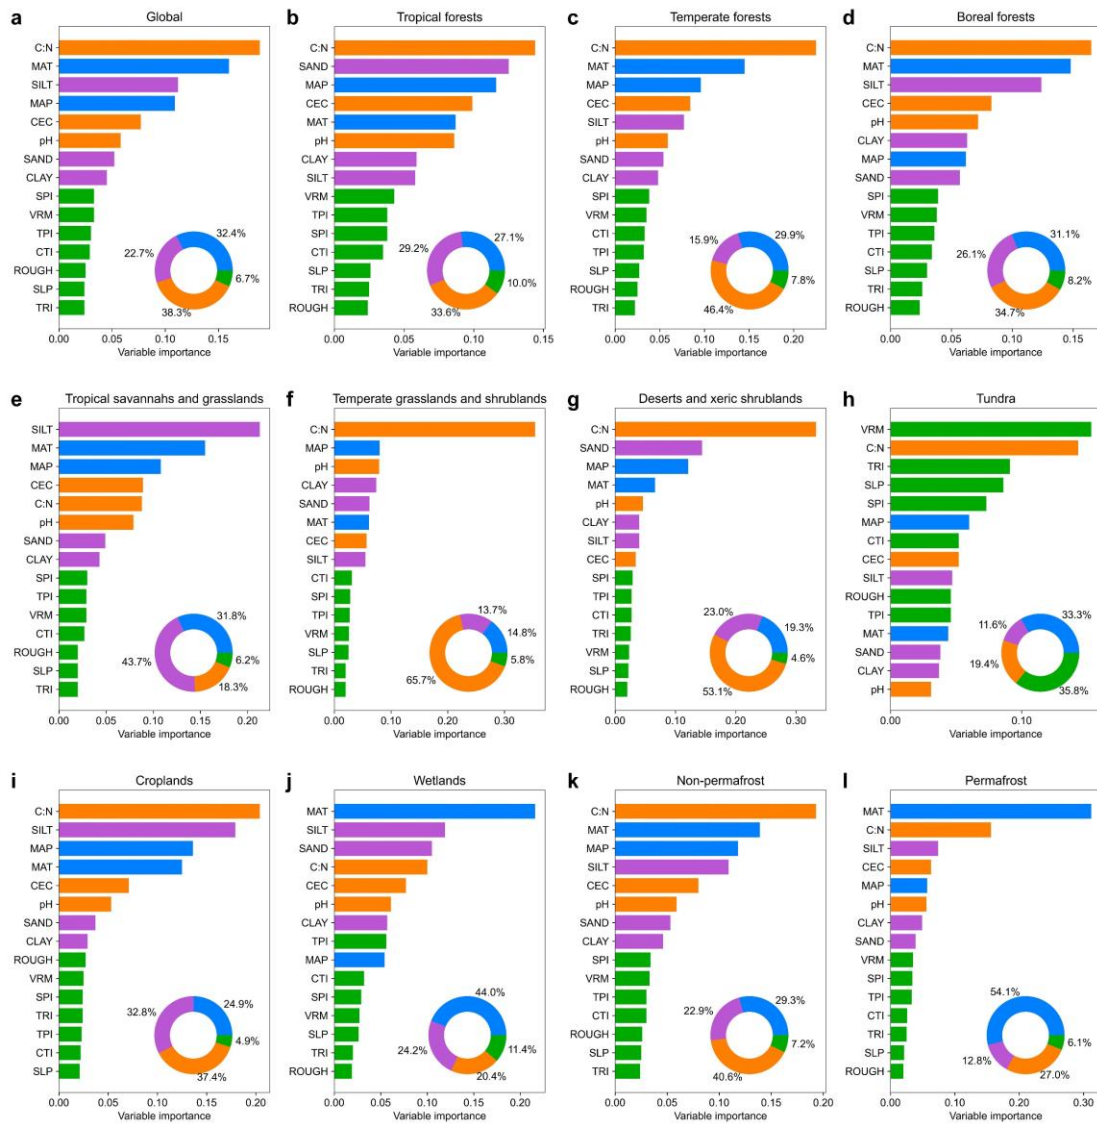

Figure S24. The influences of climate, soil physical and chemical properties, and topography factors on the subsoil organic carbon turnover time (τ). Variable importance metrics at the global scale and main biomes are calculated by using the random forest model for evaluating the effects of these environmental variables on τ at subsoil layer.

Fig. S25

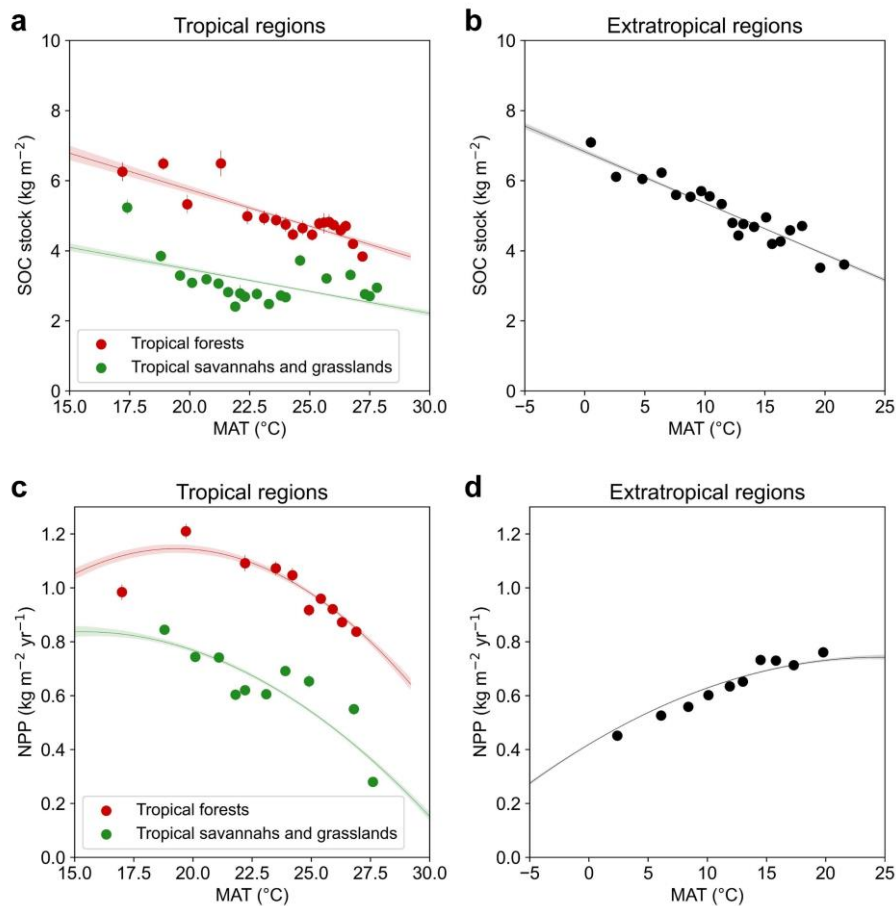

Figure S25. Relationships of SOC stock and NPP with temperature in tropical and extratropical regions. Points are the averaged SOC stock or NPP values at soil sample locations within each bin of mean annual temperature (MAT) values (MAT were divided into 20 discrete bins). Solid lines or curves (using 2nd order polynomial) represent the results of their regression fits. This reflects a uniquely tropical phenomenon contrasting to extratropical regions. The tropical plants are often near their thermal optimum for photosynthesis (related to the role of vapor pressure deficit [VPD]-induced stomatal closure), and the rising temperature can lead to higher respiration rates, thereby potentially reducing the net carbon gain in tropical ecosystems. Whereas in extratropical regions, it usually shows that temperature becomes a more critical limiting factor, with NPP generally increasing with temperature up to a certain point.

Fig. S26

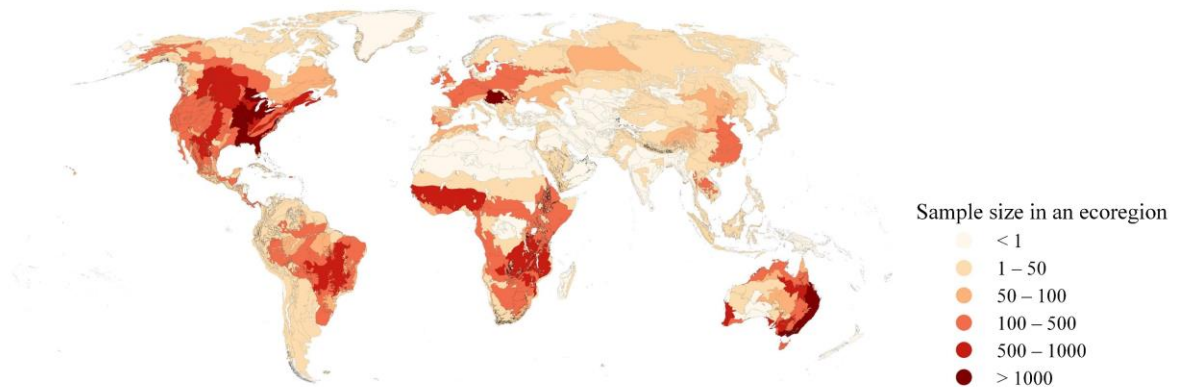

Figure S26. Sample size in each ecoregion across the globe. The global terrestrial ecoregions were classified according to the map provided by Dinerstein et al. (2017). The darkness of colors represents the number of samples fall in a certain ecoregion.

Fig. S27

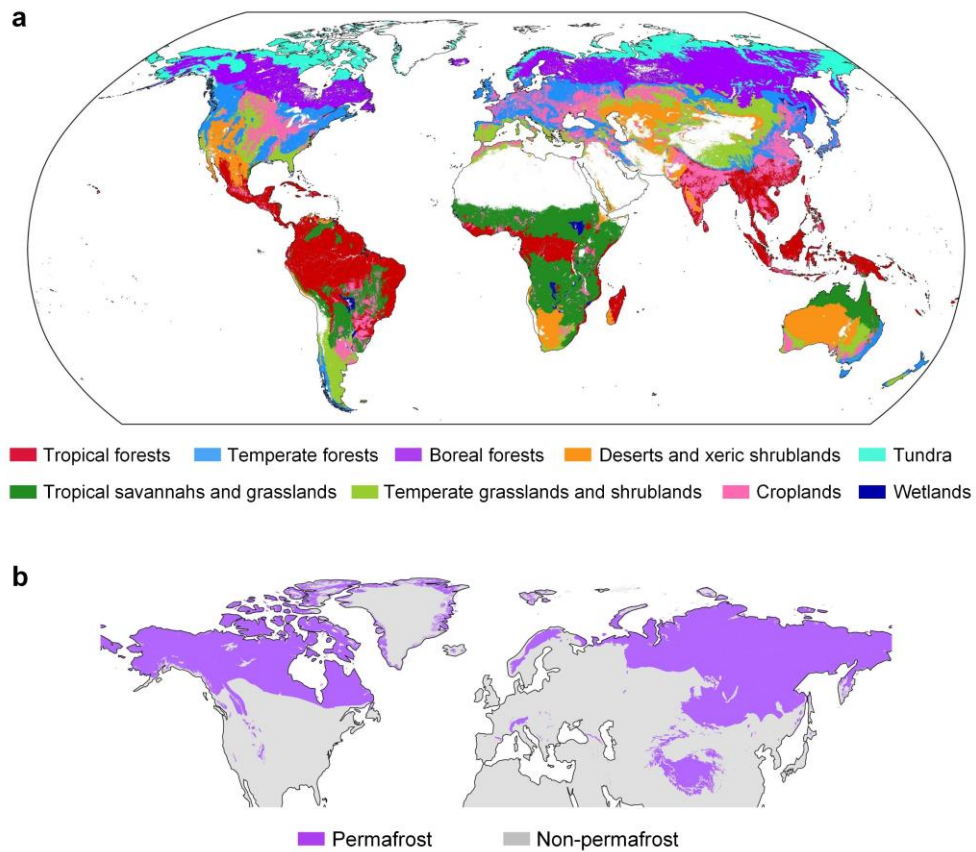

Figure S27. The global biome map used in this study. The nine biome types (a) were reclassified from the terrestrial biome map provided by Dinerstein et al. (2017). All forests, savannahs, grasslands and shrublands were reclassified according to latitude into tropical ($-23^{\circ}\text{S} \sim 23^{\circ}\text{N}$), temperate ($23^{\circ} \sim 50^{\circ}$) or boreal ($> 50^{\circ}$) categories. Cropland areas were extracted from MODIS Land Cover MCD12Q1 product (Friedl and Sulla-Menashe, 2019). Areas with low NPP (below $10 \text{ gC m}^{-2} \text{ yr}^{-1}$) were removed in this map. The global permafrost and non-permafrost areas were classified by using the Circum-Arctic permafrost and ground ice map provided by Brown et al. (2002).

Supplementary Tables

Table S1. Overview of datasets used for the calculation of SOC turnover time at sample locations.

Variable name	Description	Unit	Source
SOC	Soil organic carbon content	g kg ⁻¹	WoSIS (Batjes et al., 2020), NCSCD
BD	Bulk density	g cm ⁻³	(Hugelius et al., 2013), China soil survey (Zhang et al., 2013; Liu et al., 2022), and SoilGrids (Hengl et al., 2017; Poggio et al., 2021)
CF	Coarse fragments content	%	
NPP	Net primary production	kg m ⁻² yr ⁻¹	The MOD17A3HGF Version 6.1 product (Running and Zhao, 2019)
RSR	Root-shoot ratio	%	Harmonized global above and belowground biomass carbon density maps (Spawn et al., 2020)
$fr_{D_u-D_l}$	Fraction of root in a soil layer between upper (D_u) and lower depth (D_l)	%	Global root profile database (Schenk and Jackson, 2002), RSIP database (Tumber-Dávila et al., 2022), and GRooT database (Guerrero-Ramírez et al., 2021)

Note: WoSIS, standardized soil profile data from World Soil Information Service (WoSIS) registered in the ISRIC (World Soil Information) data repository; NCSCD, the Northern Circumpolar Soil Carbon Database. SoilGrids, the global gridded soil information that uses state-of-the-art machine learning methods to map the spatial distribution of soil properties across the globe.

Table S2. Details on four categories of environmental variables for predictive mapping of SOC turnover time (τ) and analyzing the driving mechanism of τ .

Variable category	Variable name	Code	Description	Unit	Source
Climate	Temperature	MAT	Mean annual temperature	°C	WorldClim (Fick and Hijmans, 2017)
	Precipitation	MAP	Mean annual precipitation	mm	
Soil physical property	Clay	CLAY	Proportion of clay particles (< 0.002 mm) in the fine earth fraction	g kg ⁻¹	WoSIS (Batjes et al., 2020), NCSCD (Hugelius et al., 2013), SoilGrid (Hengl et al., 2017; Poggio et al., 2021)
	Sand	SAND	Proportion of sand particles (> 0.05 mm) in the fine earth fraction	g kg ⁻¹	
	Silt	SILT	Proportion of silt particles (> 0.002 mm and < 0.05 mm) in the fine earth fraction	g kg ⁻¹	
Soil chemical property	Cation exchange capacity	CEC	Cation Exchange Capacity of the soil	cmol _c kg ⁻¹	
	C:N ratio	C:N	Organic carbon to total nitrogen ratio	-	
	pH	pH	Soil pH	-	
Topography	Elevation	ELEV	Elevation	m	GTOPO30 (Gesch et al., 1999) Geomorpho90m (Amatulli et al., 2020)
	Slope	SLP	Slope	°	
	Compound topographic index	CTI	Compound topographic index	-	
	Terrain ruggedness index	TRI	Terrain ruggedness index	-	
	Vector ruggedness measure	VRM	Vector ruggedness measure	-	
	Roughness	ROUGH	Roughness	-	
	Topographic position index	TPI	Topographic position index	-	
	Stream power index	SPI	Stream power index	-	

Note: WorldClim, a database of high spatial resolution global weather and climate data. WoSIS, the standardised soil profile data from World Soil Information Service (WoSIS) registered in the ISRIC (World Soil Information) data repository; NCSCD, the Northern Circumpolar Soil Carbon Database. SoilGrid, the global gridded soil information that uses state-of-the-art machine learning methods to map the spatial distribution of soil properties across the globe; GTOPO30, a global digital elevation model (DEM) developed by the U.S. Geological Survey's (USGS) Center for Earth Resources Observation and Science (EROS). Geomorpho90m, a global dataset comprising of different geomorphometric features derived from the high-resolution DEM.

Table S3. Differences of our data-derived SOC turnover time (τ) and τ from selected Earth system models from CMIP6. The values of τ difference report ratio of ESM-derived τ to our observation-derived τ in four statistical indices by aggregating the global estimates.

Model	τ difference				Proportion of area on global land with the τ difference less than 1
	P 2.5	Median	P 97.5	SD	
ACCESS-ESM1-5	0.09	0.42	1.80	0.47	92%
CESM2-WACCM	0.09	0.47	2.44	0.62	89%
IPSL-CM6A-LR	0.02	0.25	1.15	0.37	97%
NorESM2-LM	0.08	0.42	2.70	0.63	89%
Average	0.07	0.39	2.02	0.52	92%

Note: P 2.5, P 97.5 and SD represent the range of τ difference values between the 2.5th and 97.5th percentiles and standard deviation from the aggregation of all grid cells globally.

Table S4. Differences of our data-derived SOC turnover time (τ) and τ from selected Earth system models from CMIP6 in different biomes. The values of τ difference report ratio of ESM-derived τ to our observation-derived τ in four statistical indices by aggregating the global estimates.

Biome	τ difference			
	P 2.5	Median	P 97.5	SD
Tropical forests	0.12	0.29	0.70	0.20
Temperate forests	0.22	0.53	0.90	0.23
Boreal forests	0.15	0.54	1.71	0.61
Tropical savannahs and grasslands	0.07	0.43	0.99	0.53
Temperate grasslands and shrublands	0.20	0.50	1.32	0.43
Deserts and xeric shrublands	0.06	0.53	3.15	0.96
Tundra	0.07	0.41	2.39	0.80
Croplands	0.16	0.46	1.03	0.30
Wetlands	0.15	0.47	2.34	0.78

Note: P 2.5, P 97.5 and SD represent the range of τ difference values between the 2.5th and 97.5th percentiles and standard deviation from the aggregation of all grid cells globally.

Table S5. The estimated mean of the fraction of litterfall in ANPP for each biome.

Biome	Fraction of litterfall in ANPP
Boreal Forests/Taiga	0.59
Deserts & Xeric Shrublands	0.90
Flooded Grasslands & Savannas	0.50
Mangroves	0.50
Mediterranean Forests, Woodlands & Scrub	0.41
Montane Grasslands & Shrublands	0.71
Temperate Broadleaf & Mixed Forests	0.73
Temperate Conifer Forests	0.70
Temperate Grasslands, Savannas & Shrublands	0.65
Tropical & Subtropical Coniferous Forests	0.70
Tropical & Subtropical Dry Broadleaf Forests	0.68
Tropical & Subtropical Grasslands, Savannas & Shrublands	0.59
Tropical & Subtropical Moist Broadleaf Forests	0.65
Tundra	0.56

Table S6. The estimated mean of the fraction of litterfall in ANPP for forest areas with different leaf types.

Biome	Leaf type	Fraction of litterfall in ANPP
Temperate forests	Deciduous Broadleaf	0.70
	Evergreen Broadleaf	0.55
	Evergreen Needleleaf	0.71
Tropical forests	Deciduous Broadleaf	0.68
	Evergreen Broadleaf	0.69
	Evergreen Needleleaf	0.83
