**Abstract.** Understanding optical and radiative properties of aerosols and clouds is critical to reduce uncertainties in climate models. For over 10 years, the Observatory of Atmospheric Physics of La Réunion (OPAR, ~~21.079°S, 55.383°E~~) has been operating three active lidar instruments (named Li1200, LiO3S and LiO3T) providing time-series of vertical profiles from 3 to 45 km of the aerosol extinction and backscatter coefficients at 355 and 532 nm, as well as the linear depolarization ratio at 532 nm. This work provides a full technical description of the three systems, details about the methods chosen for the signal preprocessing and processing, and an uncertainty analysis. About 1737 night-time averaged profiles were manually screened to provide cloud-free and artifact-free profiles. Data processing consisted in Klett inversion to retrieve aerosol optical products from preprocessed files. The measurement frequency was lower during the wet season and the holiday periods. There is a good correlation between the Li1200 and LiO3S in terms of stratospheric ~~Aerosol Optical Depth (AOD)~~ at 355 nm ( $0.001-0.107$ ;  $R = 0.92 \pm 0.01$ ), and with the LiO3T in terms of Angström exponent 355/532 ( $0.079-1.288$ ;  $R = 0.90 \pm 0.13$ ). The lowest values of the averaged uncertainty of the aerosol backscatter coefficient for the three time-series are  $64.4 \pm 31.6$  % for the LiO3S,  $50.3 \pm 29.0$  % for the Li1200, and  $69.1 \pm 42.7$  % for the LiO3T. These relative uncertainties are high for the three instruments because of the very low values of extinction and backscatter coefficients for background aerosols above Maïdo observatory. Uncertainty increases due to ~~Signal to Noise Ratio (SNR)~~ decrease above 25 km for the LiO3S and Li1200, and 20 km for the LiO3T. The ~~Lidar Ratio (LR)~~ is responsible for an uncertainty increase below 18 km (10 km) for the LiO3S and Li1200 (LiO3T). The LiO3S is the most stable instrument at 355 nm due to less technical modifications and less misalignments. The Li1200 is a valuable addition to fill in the gaps in the LiO3S time-series at 355 nm or for specific case-studies about the middle and low troposphere. Data described in this work are available at <https://doi.org/10.26171/rwcm-q370> (Gantois et al., 2024).

46       Uncertainties concerning aerosol and cloud optical and radiative properties strongly affect surface climate and  
47 also the accuracy in climate models (Hansen et al., 1997; Alexander et al., 2013). Aerosols can be of multiple  
48 origins, compositions, sizes, and shapes, but can also interact at different temporal and spatial scales and be  
49 influenced by various dynamical processes. This makes their observation at the global scale and the modelling of  
50 their properties challenging. Improving our knowledge in this area implies to use different measurement techniques  
51 (in situ, active and passive remote sensing methods) synergistically and to provide continuous timeseries of high-  
52 resolution measurements in the low and middle atmosphere.

53       The Observatory of Atmospheric Physics of La Réunion (OPAR), located on Réunion Island near Madagascar,  
54 is currently equipped with more than 50 instruments distributed over three different sites: two historical coastal  
55 sites in the north, and a high-altitude site (Maïdo observatory, 2160 m asl, Baray et al., 2013), which now houses  
56 more than two-thirds of these instruments. OPAR is part of many international networks, including GAW (Global  
57 Atmospheric Watch), NDACC (Network for the Detection of Atmospheric Composition Change), SHADOZ  
58 (Southern Hemisphere Additional OZonesondes), and AERONET (Aerosol Robotic Network). Additionally, it is  
59 a part of the European research infrastructures ACTRIS (Aerosol, Clouds, and Trace Gases Research  
60 Infrastructure) and ICOS (Integrated Carbon Observing System).

61       Maïdo observatory (21.079°S, 55.383°E) is one of the very few active observational sites in the Southern  
62 Hemisphere (SH). It is **barely** influenced by anthropic aerosols. Its importance lies in the fact that the aerosol load  
63 in the atmosphere above Reunion Island is under the influence of many different sources of emission and  
64 dynamical processes responsible for short and long-range air-mass transports (Baray et al., 2013) such as biomass  
65 burning (BB) plumes (Edwards et al., 2006; Khaykin et al., 2020), which are emitted seasonally in the SH.  
66 Moreover, it is not rare for volcanic aerosols to be detected in the stratosphere above Maïdo observatory. In fact,  
67 several volcanoes are located at the same latitude (Hunga-Tonga), or in the same Hemisphere (Calbuco) as Reunion  
68 Island (Bègue et al., 2017; Khaykin et al., 2017; Tidiga et al., 2022; Baron et al., 2023; Sicard et al., 2023). The  
69 high altitude of this facility is also of great importance as it is located above the boundary layer during the night,  
70 allowing the observation of the free troposphere in a quasi-pristine environment.

71       Since its creation in 2012, the Maïdo facility has been equipped with four research lidar (light detection and  
72 ranging) instruments emitting electromagnetic radiations at different wavelengths. Three of them have been  
73 providing high resolution time series of aerosol extinction and backscatter vertical profiles in the UV (355 nm)  
74 and visible (532 nm) domains. As of today, these measurements have only been used occasionally for case studies  
75 (Bègue et al., 2017; Khaykin et al., 2017; Tidiga et al., 2022; Baron et al., 2023; Sicard et al., 2023). Full  
76 exploitation of these timeseries will enable to provide timeseries of aerosol extinction and backscatter profiles over  
77 Reunion Island. This can only be achieved after homogenizing the processing method for the three instruments.

78       This work provides a summary of the specifications of the systems and a full description of the preprocessing  
79 and processing methods used to produce different levels of the datasets for the three Maïdo lidars.

## 80 **2. Instrumental description**

81       **Table 1** is a summary of the characteristics of the three Maïdo lidars used to retrieve aerosol optical properties. A  
82 full description of each system is available in the following subsections.

86 Table 1: Systems technical features. The letters VL, L, M and H after the wavelength stand for Very Low, Low, Medium and High, respectively. Only aerosol channels are listed here.

87

88 2.1. Lidar 1200 (Li1200)

89 The Li1200 is a Rayleigh Raman lidar able to measure vertical profiles of temperature between 30 and 100 km asl  
 90 and water vapor ratio from the ground up to 18 km (Vèrèmes et al., 2019). Vertical profiles of aerosol light  
 91 extinction and backscattering can also be retrieved from the raw signals, as this instrument provides Rayleigh-Mie  
 92 scattering at 355 nm and Raman N<sub>2</sub> scattering at 387 nm. This instrument has been operating at the Maïdo facility  
 93 since 2012 and produces data since 2013.

94 (i) Actual configuration

95 The emission consists in two Nd: YAG lasers Pro-290, Quanta-Ray Pro Series, from Spectra-Physics, emitting  
 96 electromagnetic pulses at 1064 nm and 30 Hz  
 97 ([https://www.laserlabsource.com/files/pdfs/solidstatelasersource\\_com/product-](https://www.laserlabsource.com/files/pdfs/solidstatelasersource_com/product-305/Nd_Yag_Laser_Nanosecond_Laser_1064nm_1250mJ_Spectra_Physics-1462086952.pdf)  
 98 [305/Nd\\_Yag\\_Laser\\_Nanosecond\\_Laser\\_1064nm\\_1250mJ\\_Spectra\\_Physics-1462086952.pdf](https://www.laserlabsource.com/files/pdfs/solidstatelasersource_com/product-305/Nd_Yag_Laser_Nanosecond_Laser_1064nm_1250mJ_Spectra_Physics-1462086952.pdf)). The final

a supprimé: YAG Quanta Ray pro 290 lasers, from Spectra-Physics, ...

109 wavelength emitted is 355 nm, which corresponds to the third harmonic of the initial wavelength. Each pulse  
110 delivers 375 mJ in 9 ns. The optical design of this lidar is represented in **Figure 1**. The two laser beams are  
111 recombined through a polarizer cube, then sent to the telescope through a series of mirrors. It should be noted that  
112 the lasers and the telescope are not in the same room, hence the use of many mirrors. BE1 and BE2 lenses form  
113 an afocal of magnification 1.25, reducing the divergence of the beams and mixing the phases. The goal is to reduce  
114 the hot spots, especially on the very fragile optic BE3. Last, the laser beam is channeled through the center of the  
115 main telescope and magnified by a factor of 10 thanks to the afocal system BE3 and BE4. The emission and main  
116 reception are therefore static coaxial, reducing the parallax effect and the minimum overlap altitude.

117 **The reception** is made of two telescopes. The main telescope consists in a primary mirror of 1200 mm diameter  
118 (M1200), which gave its name to this instrument. A secondary mirror HM sends the beam to the detection system.  
119 The L1 lens allows the beam to converge faster, which explains the 3.6 m value of the focal length. GS1 is a glass  
120 plate that sends about 8 % of the beam on the 355 nm Very Low (355VL channel) detector. As this detector is  
121 located before the FD2 diaphragm, its field of view is the same as the one of the telescope, and it receives signal  
122 in the very near-range. A density (ND) was placed in front of this detector to avoid saturation. FD2 is a diaphragm,  
123 located at the focal plane of the telescope. Its aperture improves the geometrical factor of the telescope for the  
124 detectors following it. DM1 is a dichroic filter that reflects 355nm and allows 387nm and 407nm to pass through.  
125 GS2 is a glass plate that sends about 8% of the beam on the 355 nm Medium (355M) channel and 92% of the beam  
126 on the 355nm Hight (355H) channel. DM3 is a dichroic filter which selects the 387 nm for the Raman N2 channel.  
127 As of 2017, a second telescope, with a 200 mm M200 primary mirror and a focal length of 1 m, sends the signal  
128 to a second detection box, using an optical fiber. This detection box filters the Rayleigh and Raman signals and  
129 channels them respectively to the 355L and 387L detectors.

130 All the **detectors** are photomultiplier tubes (PMT) from Hamamatsu, reconditioned by the Licel company  
131 ([https://www.hamamatsu.com/content/dam/hamamatsu-](https://www.hamamatsu.com/content/dam/hamamatsu-photonics/sites/documents/99_SALES_LIBRARY/etd/PMT_TPMZ0002E.pdf)  
132 [photonics/sites/documents/99\\_SALES\\_LIBRARY/etd/PMT\\_TPMZ0002E.pdf](https://www.hamamatsu.com/content/dam/hamamatsu-photonics/sites/documents/99_SALES_LIBRARY/etd/PMT_TPMZ0002E.pdf)). The 355H, 355M, and 355L  
133 detectors are electronically shuttered to prevent saturation. The **acquisition** cards also come from Licel and operate  
134 in photocounting mode. There are no analog channels. Raw files follow a 1-minute integration.

135 **To summarize**, 355M and 355H channels exist since 2013, but their acquisition starts at 15 and 25 km,  
136 respectively, to avoid saturation. Hence, the 355VL and 355L channels were added in 2017 to cover the first  
137 altitude ranges below 15 km. The minimum height for 355L electronic shuttering is 450 m asl.

### 138 (ii) *Previous modifications*

139 The detection unit was modified in 2017. Before that, the detection unit containing the 355L and 387VL  
140 detectors did not exist. The M1200 mirror separation unit was modified. First, the part containing the FD1 to L3  
141 optics, as well as the 355VL detector, did not exist. And there was an optic between IF2 and DM2 that would send  
142 the visible signal to another detection unit. Indeed, originally, this lidar was supposed to operate at two emission  
143 wavelengths, 355 and 532nm. However, during installation, due to mechanical and optical problems, only the 355  
144 nm channel was retained (Dionisi et al., 2015).

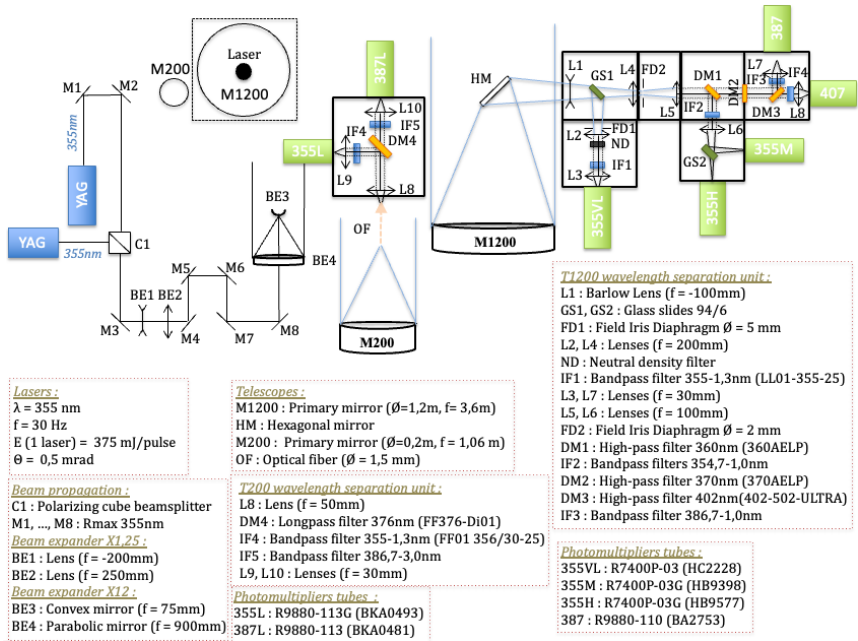

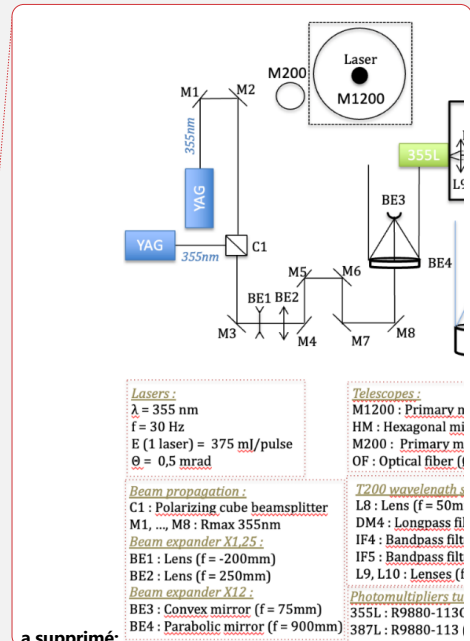

Figure 1 : Li1200 optical scheme

## 2.2. Stratospheric Ozone Lidar (LiO3S)

The Stratospheric Ozone Lidar (LiO3S) works with the Differential Absorption Lidar (DIAL) technique and provides vertical profiles of ozone ( $O_3$ ) concentration in the stratosphere, between the tropopause and about 45 km (Godin-Beekmann et al., 2003; Portafaix et al., 2003). To this end, two different wavelengths are emitted: a 308 nm signal strongly absorbed by ozone molecules and a 355 nm signal weakly absorbed by ozone molecules. Vertical profiles of aerosol light extinction and backscattering can be retrieved from the elastic scattering at 355 nm and Raman  $N_2$  scattering at 387 nm. From 2000 to 2012, the LiO3S was located at the Moufia University campsite in Saint-Denis and provided ozone vertical profiles. It was moved to the Maïdo facility in 2012 and has been measuring from this location since 2013.

### (i) Actual configuration

The emission set-up consists in two different lasers. An excimer laser IPEX-840, PulseMaster PM-800 Series excimer laser with XeCl gas from LightMachinery (<https://lightmachinery.com/lasers/excimer-lasers/ipex-800/>), emits electromagnetic pulses at 308 nm with a frequency of 40 Hz and pulse energy of 220 mJ. A Nd:YAG laser Lab-150, Quanta-Ray Lab Series from Spectra-Physics emits electromagnetic pulse at a 1064 nm with a frequency of 30 Hz ([https://www.laserlabsource.com/files/pdfs/solidstatelasersource.com/product-305/Nd\\_Yag\\_Laser\\_Nanosecond\\_Laser\\_1064nm\\_1250mJ\\_Spectra\\_Physics-1462086952.pdf](https://www.laserlabsource.com/files/pdfs/solidstatelasersource.com/product-305/Nd_Yag_Laser_Nanosecond_Laser_1064nm_1250mJ_Spectra_Physics-1462086952.pdf)). The final wavelength emitted by the Nd:YAG laser is 355 nm, corresponding to the third harmonic of the emitted wavelength. The pulse energy at this wavelength is 130 mJ. The laser beam diameter is about 10 mm, and its divergence is 0.5 mrad. The optical design of this lidar is represented in Figure 2. Again, the emission and reception

a supprimé: A Nd:YAG Lab 150 laser from Spectra-Physics emits electromagnetic pulse at a 1064 nm wavelength with a frequency of 30 Hz.

174 of this lidar are located in different rooms, explaining the use of many mirrors. The expander consists in three  
 175 lenses, BE1, BE2 and BE3, magnifying the signal by a factor 10. The final beam has a 100 mm diameter.

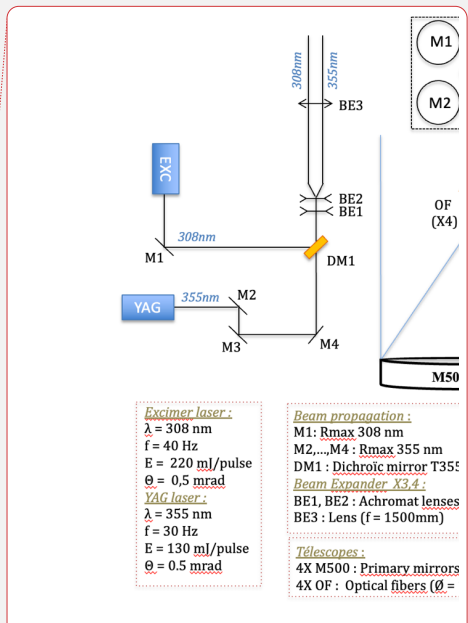

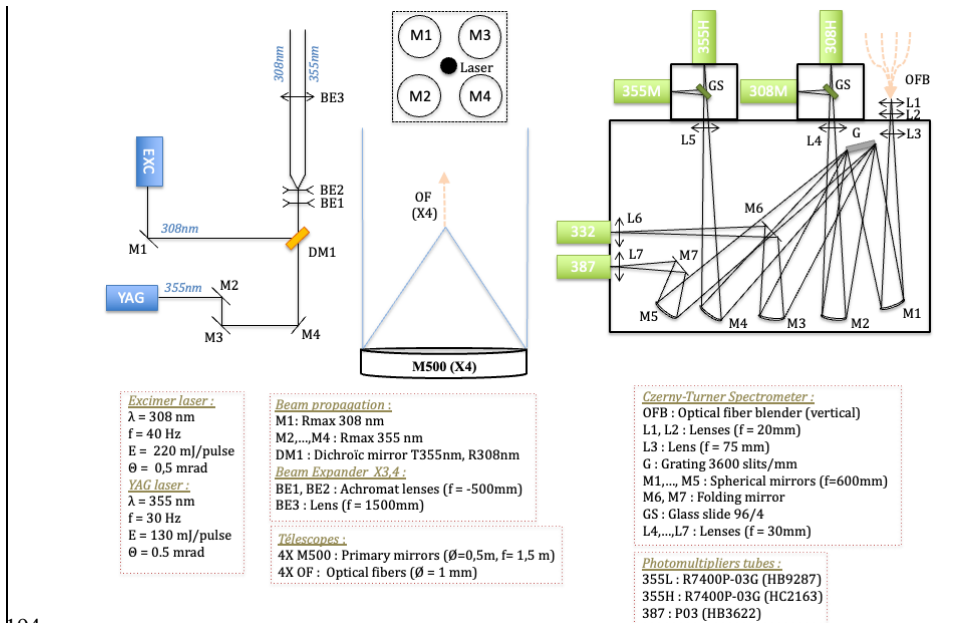

176 **The reception** is made of four 500 mm diameter telescopes. The primary mirrors are M1, M2, M3 and M4.  
 177 The signal is emitted at the center of these telescopes, and the distance between the emission and the center of each  
 178 telescope is 600 mm. At the receiving end, the signal is a focused from each telescope to a corresponding optical  
 179 fiber, which are positioned in line before entering the detection box. In this box, a diffraction grating separates the  
 180 different wavelengths. Internal mirrors allow the beam to be reflected in the detectors. Finally, a glass plate  
 181 discriminates the high and low energy channels at 355 nm.

182 **All the detectors** are photomultiplier tubes (PMT) from Hamamatsu, reconditioned by the Licel company  
 183 ([https://www.hamamatsu.com/content/dam/hamamatsu-](https://www.hamamatsu.com/content/dam/hamamatsu-photonics/sites/documents/99_SALES_LIBRARY/etd/PMT_TPMZ0002E.pdf)  
 184 [photonics/sites/documents/99\\_SALES\\_LIBRARY/etd/PMT\\_TPMZ0002E.pdf](https://www.hamamatsu.com/content/dam/hamamatsu-photonics/sites/documents/99_SALES_LIBRARY/etd/PMT_TPMZ0002E.pdf)), and the signal acquisition cards  
 185 are from Licel. The 355 nm detectors are electronically shuttered to avoid saturation. The acquisition is in  
 186 photocounting mode only for the high energy channels, and in photocounting and analog mode for the low energy  
 187 channels. Raw files follow a 1 minute integration.

188 (ii) *Previous modifications*

189 Before 2017, the electronic obturation concerned only 355H and 308H channels, and a mechanical chopper  
 190 shuttered 355M, 308M and Raman channels at the entrance of the detection box. In 2017, this chopper  
 191 malfunctioned and was replaced by electronic obturation for the 355M and 308M channel. Raman channels were  
 192 not shuttered anymore. The initial integration time was 3 minutes and was reduced to 2 and then 1 minute. During  
 193 this period, the vertical resolution was modified from 120 m to 15 m.

a supprimé:

194 **Figure 2 : LiO3S optical scheme**

198

### 199 2.3. Tropospheric Ozone Lidar (LiO3T)

200 The Tropospheric Ozone Lidar (LiO3T) also works with the DIAL technique and provides vertical profiles of  
201 ozone (O<sub>3</sub>) concentration in the troposphere, between 6 and 25 km (Dufлот et al., 2017). To this end, two different  
202 wavelengths are emitted using stimulated Raman scattering: a 289 nm signal strongly absorbed by ozone molecules  
203 and a 316 nm signal weakly absorbed by ozone molecules. Vertical profiles of aerosol light extinction and  
204 backscattering can be retrieved from the residual emission of the laser in terms of elastic scattering at 532 nm and  
205 1064 nm, and Raman N<sub>2</sub> scattering at 607 nm. From 1993 to 2012, the LiO3T was located at the Moufia University  
206 campsite in Saint-Denis and provided ozone vertical profiles. It was moved to the Maïdo facility in 2012 and has  
207 been measuring from this location since 2013. The first aerosol dedicated polarized channels were installed in  
208 2014.

#### 209 (i) Actual configuration

210 **The emission** consists in a [Nd: YAG lasers Pro-290, Quanta-Ray Pro Series, from Spectra-Physics](https://www.laserlabsource.com/files/pdfs/solidstatelaser.com/product-305/Nd_Yag_Laser_Nanosecond_Laser_1064nm_1250mJ_Spectra_Physics-1462086952.pdf), emitting  
211 initially at 1064 nm at 30 Hz ([https://www.laserlabsource.com/files/pdfs/solidstatelaser.com/product-](https://www.laserlabsource.com/files/pdfs/solidstatelaser.com/product-305/Nd_Yag_Laser_Nanosecond_Laser_1064nm_1250mJ_Spectra_Physics-1462086952.pdf)  
212 [305/Nd\\_Yag\\_Laser\\_Nanosecond\\_Laser\\_1064nm\\_1250mJ\\_Spectra\\_Physics-1462086952.pdf](https://www.laserlabsource.com/files/pdfs/solidstatelaser.com/product-305/Nd_Yag_Laser_Nanosecond_Laser_1064nm_1250mJ_Spectra_Physics-1462086952.pdf)). While the fourth  
213 harmonic (266 nm) is used to retrieve tropospheric ozone profiles (through its passage in a Raman cell generating  
214 289 and 316 nm pulses), we use the second harmonic (532 nm) to retrieve aerosol light extinction and  
215 backscattering. Each pulse at 532 nm provides an energy of 250 mJ. The laser beam diameter is of about 10 mm,  
216 and its divergence is about 0.5 mrad. The optical design of this lidar for aerosol measurements is represented in  
217 **Figure 3**. Again, the emission and reception of this lidar are located in different rooms, explaining the use of many  
218 mirrors. The lenses, BE1, BE2 and BE3, magnify the signal by a 15 factor. The final emitted beam diameter is 100  
219 mm.

220 **The reception** is made of two telescopes: one for the Rayleigh and Raman channels (532, 607 and 1064 nm,  
221 respectively), and the other for the polarized channels at 532 nm. The first telescope (M500) consists in a 500 mm  
222 diameter primary mirror. An optical fiber located at its focal point, conducts the signal to the detection box.  
223 Dichroic filters separate the 532, 607 and 1064 nm wavelengths. The second telescope consists in a 200 mm  
224 diameter primary mirror immediately followed by a polarizing cube. An optical fiber leads the polarized and cross-  
225 polarized beams to interference filters and to the detectors.

226 **All the detectors** are [photomultiplier tubes \(PMT\) from Hamamatsu, reconditioned by the Licel company](https://www.hamamatsu.com/content/dam/hamamatsu-photonics/sites/documents/99_SALES_LIBRARY/etd/PMT_TPMZ0002E.pdf)  
227 ([https://www.hamamatsu.com/content/dam/hamamatsu-](https://www.hamamatsu.com/content/dam/hamamatsu-photonics/sites/documents/99_SALES_LIBRARY/etd/PMT_TPMZ0002E.pdf)  
228 [photonics/sites/documents/99\\_SALES\\_LIBRARY/etd/PMT\\_TPMZ0002E.pdf](https://www.hamamatsu.com/content/dam/hamamatsu-photonics/sites/documents/99_SALES_LIBRARY/etd/PMT_TPMZ0002E.pdf)), except for the 1064 nm detector,  
229 which is an avalanche diode with a 3 mm diameter sensor ([https://www.hamamatsu.com/content/dam/hamamatsu-](https://www.hamamatsu.com/content/dam/hamamatsu-photonics/sites/documents/99_SALES_LIBRARY/ssd/si_apd_kapd0001e.pdf)  
230 [photonics/sites/documents/99\\_SALES\\_LIBRARY/ssd/si\\_apd\\_kapd0001e.pdf](https://www.hamamatsu.com/content/dam/hamamatsu-photonics/sites/documents/99_SALES_LIBRARY/ssd/si_apd_kapd0001e.pdf)). The 532 high energy channel  
231 (532H) detector is the only one electronically shuttered. All the **acquisition** cards are from Licel. The acquisition  
232 of the 532 nm polarized channel as well as the 607 nm channel are in photocounting mode. The acquisition of the  
233 532H channel is in photocounting and analog modes, and the acquisition of the 1064nm channel is only in analog  
234 mode. Raw files follow a 2-minute integration.

a supprimé: Quanta Ray Pro 290 laser from Spectra-Physics ...

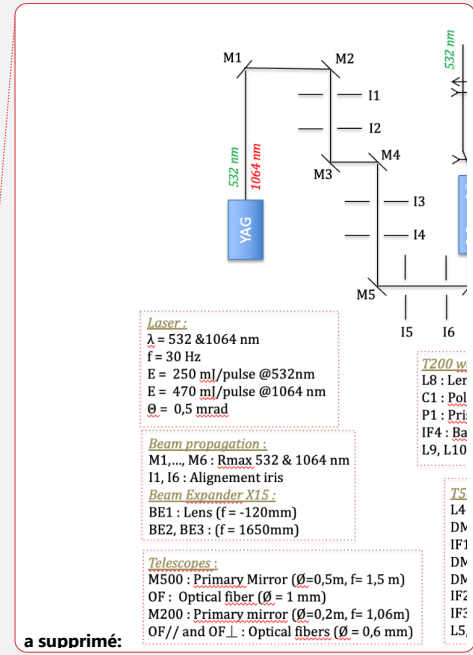

a supprimé: .

a supprimé: All the detectors are PMT from Hamamatsu,

240 In 2014, the 200 mm telescope (M200) and the T200 wavelength separation unit were installed, allowing for the  
 241 first aerosol measurements with polarized channels. In 2017, one of the four 500 mm telescopes initially dedicated  
 242 to ozone measurements was used for aerosol measurements. A second detection box was added, enabling the 607  
 243 nm and 1064 nm channels acquisition.

244 **Figure 3 : LiO3T optical scheme**

245 **a supprimé:**

246 **3. Routine measurements**

247 The Maïdo lidars are research instruments that require manual handling and a constant human presence while  
 248 operating. Maïdo observatory is a high-altitude facility (2160 m asl) and is located above the boundary layer in the  
 249 free troposphere during the night. Acquisitions are only made during the night to increase the SNR. These  
 250 instruments were originally intended to observe data in the stratosphere and the upper troposphere, so they are  
 251 optimized to work at night, to improve the SNR up to very high in the atmosphere. That is why acquisitions are  
 252 only made during the night. Measurements also require the absence of low-clouds or rain. The position of the  
 253 Maïdo observatory on the west side of Reunion Island often protects the site from the clouds brought by trade  
 254 winds. Notably, a ceilometer was installed at the Maïdo facility in 2019 and continuous observations revealed an  
 255 average cloud frequency of respectively 20% and 40% during winter and summer nights (not shown).

256 Routinely, Maïdo lidars are operated two nights per week and measurements last from 7pm to 1am (local time,  
 257 i.e. from 15 to 21 UTC). Specific campaigns (once or twice a year) can occasionally require to significantly  
 258 increase the number of measurements. Operating these instruments implies to follow a strict, well-prepared  
 259 protocol including basic check-ups and laser power control. A metadata file is routinely fed with technical specifics

261 for each night of observation and after any instrumental modification. Automatization is currently in progress and  
262 could increase the frequency of routine measurements.

263 Maïdo lidars are large and cannot be moved to make horizontal measurements: the beams of the different lidars  
264 are always vertical. To avoid any problems with flying objects, a no-fly zone around the Observatory is requested  
265 before each lidar measurement and during operating hours (exclusively nighttime). The research building hosting  
266 these instruments has a restricted access. It is located far from any residential areas. The instruments themselves  
267 can only be accessed by trained authorized personnel equipped with personal protective equipment (including eye  
268 protection glasses for the laser wavelengths) and Optical Enclosures.

## 270 4. Data processing chain

### 271 4.1. Data processing levels

272  
273 Our datasets follow a classification detailed in the following description. Data processing levels range from Level  
274 0 to Level 2.

- 275 (i) Level 0 products ( $L_0$ ) are uncorrected and uncalibrated raw data files in Licel format at full  
276 resolution produced by the instrument.
- 277 (ii) Level 1 products ( $L_1$ ) provide cloud-free data cleaned from any instrumental artifact (electronic  
278 parasites, synchronization problems, power disrupt, etc.). The cloud mask is currently manual.  
279 These corrections are essential for any user to be able to apply their own specific aerosol  
280 preprocessing without errors linked to the instrument itself or the weather.
- 281 (iii) Level 2 products ( $L_2$ ) provide processed lidar data including: saturation correction, background-  
282 sky correction, geometrical form factor correction and gluing between high and low-energy  
283 channels. These products also provide the aerosol optical properties and their corresponding  
284 uncertainties.

### 285 4.2. $L_0$ to $L_1$ processing chain

286  
287 Each instrument is equipped with an acquisition system provided by the Licel firm. The description of the  
288 acquisition program producing output files in Licel format can be downloaded at  
289 [http://licel.com/raw\\_data\\_format.html](http://licel.com/raw_data_format.html). This process concerns three main sources of interferences: (i) Detection-  
290 related interferences, (ii) Acquisition problems and (iii) Interferences linked to the lidar environment.

291 Any significant step of this process is tagged in the  $L_1a$  output files to identify the corrections applied.

#### 292 4.2.1. Detection interferences

293 Detection-related interferences can generally be linked to electromagnetic disturbances, which can occur in  
294 three different ways.

295 (i) An increased background signal concerning variable altitude ranges can impact the complete profile as  
296 shown in **Figure 4a**. This disturbance affects one or several channels across a significant altitude range, making  
297 the data acquisition unusable and requiring its withdrawal. ~~The strong disturbance in the signal made it easy to~~  
298 fully automatize their detection. Notably, obturated detectors are more sensitive to these disruptions. Experience  
299 proved that they are directly related to the use of cell phones and Talky-Walkies. These instruments have been

Code de champ modifié

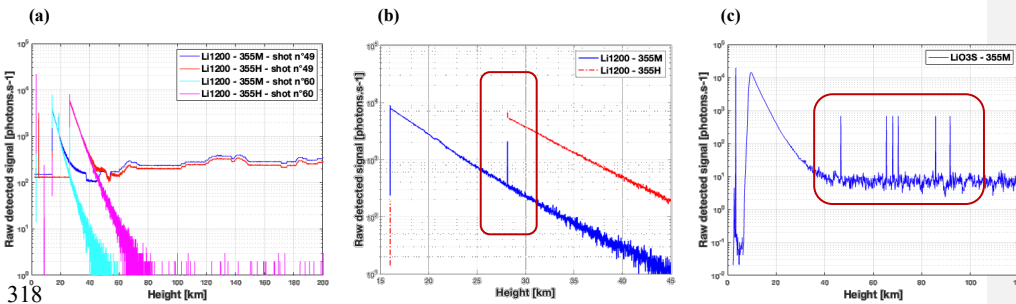

a supprimé: This is one of the reasons files of a few minutes are created.

a supprimé: enabled

303 banned from the instrumental rooms during the measurements, significantly decreasing the frequency of these  
304 cases.

305 (ii) A second electronic problem often encountered comes from electronic gating. In fact, if a high and low-  
306 energy channel coexist, a peak can be observed on the low-energy channel raw signal, at the gated altitude of the  
307 high-energy channel (Figure 4b). This parasite peak usually appears on 2 consecutive range bins. This type of  
308 problem occurs when the detectors are obturated and can have a significant impact on the measurement. It is  
309 therefore necessary to remove the corresponding values and replace them by an averaged value between the  
310 previous and following range bins.

311 (iii) The third detection disturbance corresponds to a sudden peak of the signal on a single randomly located  
312 range bin. They only concern LiO3S and LiO3T. The consequence on the nighttime averaged profile is shown on  
313 Figure 4c. Generally, the intensity of these spurious peaks is consistent and significantly higher than the  
314 atmospheric background noise. They are easily identified when the intensity of the received signal is much lower  
315 and become negligible with a stronger signal. However, there is an intermediate zone where the intensity of the  
316 received signal is close to the intensity of these peaks, making their detection more challenging. They are replaced  
317 by an averaged value.

318 Figure 4: (a) Raw Li1200 signal: background signal anomaly, (b) Raw Li1200 signal: peak from electronic gating, (c) Raw  
319 LiO3S nighttime averaged signal: random peaks in the far-range.

#### 320 4.2.2. Acquisition problems

321 The acquisition program computes 1- or 2-minute integrated profiles, depending on the instrument. However,  
322 with this acquisition program, the measurement cannot be stopped at the end of the current cycle. As a result, the  
323 last file is generally shorter than the others and must be removed to guarantee consistent measurements.

324 Another issue was a time desynchronization of several minutes between the computer acquisition clocks in  
325 2021, revealing a configuration default in the corresponding Network Time Protocol time servers. Time differences  
326 could increase up to 15 minutes between the different computers. This default has been fixed and a time-correction  
327 is applied for signals between 2012 and 2021.

328 Last, interaction between the different lidars working at the same time and emitting the same wavelength can  
329 also lead to interferences and disturbances on sensitive channels. To avoid this issue, the lasers are synchronized  
330 out of phase. However, errors with this offset can lead to files with a higher sky background than others. These  
331 files are removed.

#### 332 4.2.3. Disturbance from clouds.

333 The SNR is most sensitive to the presence of low-altitude clouds. These clouds strongly absorb the emitted  
 334 photons and lead to high extinction levels and weak SNRs. They must be removed. High-altitude cirrus clouds can  
 335 also be removed if stratospheric aerosols are studied. Cloud-detection can be both automatic and/or manual. An  
 336 automatic detection of low clouds under 5 km height has been developed and can be used from 2019 up to now  
 337 using data from a Campbell CS135 ceilometer set up at the Maïdo facility in 2019. A manual cloud screening is  
 338 done for any remaining cirrus or low clouds. Automatization is in progress for this time-consuming work.

### 339 4.3. L<sub>1</sub> to L<sub>2</sub> processing chain

340 The goal of this second processing chain is to retrieve vertical profiles of aerosol optical products. It involves  
 341 several key steps.

#### 342 4.3.1. Saturation correction

343 Saturation affects photomultiplier tube detectors with an acquisition card in photocounting mode. It concerns  
 344 the lower layers of the atmosphere and appears when the number of backscattered photons overcomes the capacity  
 345 of the acquisition card to discriminate them individually. Therefore, the backscattered signal is attenuated in the  
 346 corresponding layers. On the contrary, acquisition in analog mode is not affected by saturation, but has a weaker  
 347 SNR.

348 One solution is to combine (namely glue) analog and photocounting channels if both are available, which is  
 349 not always the case for our instruments.

350 The second option is to compare high and low-energy channels (or analog and photocounting channels if  
 351 available) in the lower layers and apply a dead-time correction to the photocounting channel using the Müller  
 352 equation. This is the solution we adopted for Maïdo lidars concerning aerosol, which is similar to what is done  
 353 for ozone and temperature processings (Leblanc et al., 2016a; Leblanc et al., 2016b). The dead-time parameter  
 354 ( $\tau_d$ ) corresponds to the minimum time for discriminating two consecutive photons. Our photocounting modes are  
 355 non-extensive, which means that the dead-time value is independent from the number of backscattered photons.  
 356 We then apply the Müller equation (Müller, 1973):

$$357 S_{desat} = \frac{S_{sat}}{1 - \tau_d \cdot \frac{c}{2 \cdot \delta_z} \cdot L \cdot S_{sat}} \quad (1)$$

358  
 359 With  $S_{sat}$  (resp.  $S_{desat}$ ) corresponding to the saturated (resp. desaturated) detected signal in number of photons  
 360 per second,  $\delta_z$  the vertical resolution in meters,  $c$  the light celerity in meters per second, and  $L$  the number of shots.

361 A value of  $\tau_d = 3.7 \text{ ns}$  is chosen. This value is the one recommended by Licel manufacturers and was confirmed  
 362 after several experimental tests which are available in a summary document.

#### 363 4.3.2. Background correction

364 The background sky signal ( $S_{BC}$ ), is one of the main sources of noise affecting the SNR. It corresponds to: (i)  
 365 the detector noise, and (ii) the natural light emitted by the atmosphere and can be affected by the presence of the  
 366 moon during the night. The value of this signal is supposed to be constant with the altitude but in practice it  
 367 sometimes follows a linear variation due to the effect of the signal induced noise on the detector. Our instruments  
 368 are not equipped with any pre-trigger. Our method to calculate the ( $S_{BC}$ ) value consists in performing a linear

369 regression or an averaging of the desaturated signal in an altitude range high enough to neglect the impact of the  
370 backscattered signal compared to the ( $S_{BC}$ ), typically between 80km and 120km.

#### 371 **4.3.3. Geometrical form factor correction**

372 The overlap function  $F(z)$  or crossover function is one of the major sources of uncertainties for ground-based  
373 lidar measurements. It describes the fraction of the laser beam cross section contained by the telescope field of  
374 view as a function of range. Its values vary between 0 (blind zone, no overlap) and 1 (full overlap). Originally,  
375 Maïdo lidars were designed to study the high troposphere and the stratosphere and at these altitudes, the full overlap  
376 is obtained, which is why there has not yet been a more specific study on these instruments.

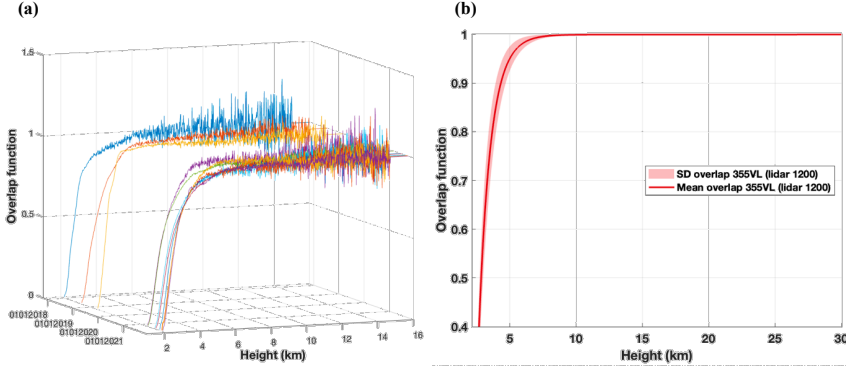

377 Should this parameter not be corrected, the received lidar signal would be attenuated between the blind zone  
378 and the full overlap, leading to incorrect optical values. Two approaches can be followed to determine this  
379 parameter. (i) A theoretical calculation using equations found in Measures (1984) can be performed. However, it  
380 implies the knowledge of several optical parameters which can vary over the timeseries, and different equations  
381 must be used for coaxial and biaxial systems. (ii) The second and most common approach is experimental and  
382 implies the use of horizontal measurements (Chazette et al., 2017). In fact, considering a constant and homogenous  
383 atmosphere along the line of sight, a linear regression can be performed in an altitude range high enough to be far  
384 from the full overlap. The difference between the logarithm of the signal and this linear regression gives an accurate  
385 estimation of  $F(z)$ .

$$386 \quad F(z) = \exp(\ln(S_2(z)) - y(z)) \quad (2)$$

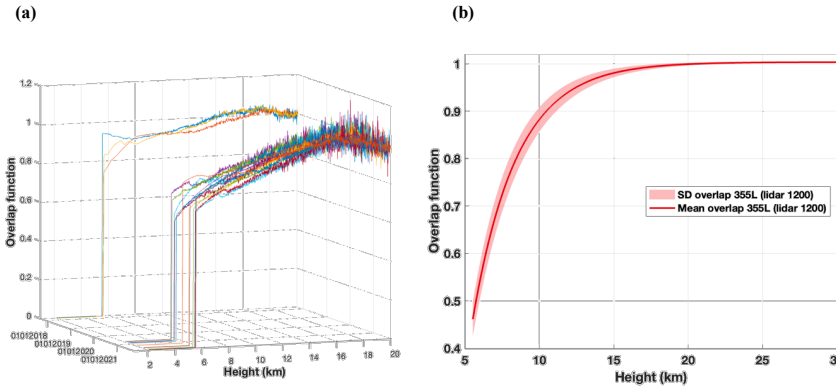

387 With  $S_2$  the desaturated, background corrected, and range corrected lidar signal,  $y(z)$  the linear regression and  
388  $z$  the altitude range.

389 It is physically impossible for these research instruments to measure horizontally. Therefore, the experimental  
390 approach using vertical measurements (instead of horizontal) in aerosol-free conditions was performed to correct  
391 overlap for the very low and low channels of the lidar 1200. As of today, no overlap correction was needed for the  
392 LiO3S (full overlap under 10km) and LiO3T (full overlap between 3 and 4km).

393 **Figures 5a and 6a** reveal the variability of the overlap function over the time-series for both Li1200 VL and  
394 L channels. This variability can be explained by slight misalignments of the lidar. Indeed, given the important  
395 number of optical elements between the laser and the emission point, the risk of misalignment, even minor, is  
396 significant. **Figures 5b and 6b** show the mean and standard deviation (std) of the overlap function from an  
397 exponential regression. The small values of std are an indicator of a low-varying function, a result that allows to  
398 use a unique overlap function rather than different functions for different periods. The estimated altitude of full  
399 overlap was 10 km for the Very Low channel and 15k m for the Low channel.

400  
401 **Figure 5: Li1200 VL channel. (a) Time series of overlap functions, (b) Mean and standard deviation of**  
402 **the overlap function.**

403  
404 **Figure 6: Li1200 L channel. (a) Time series of measured overlap functions, (b) Mean and standard**  
405 **deviation of the exponential regression of the overlap function.**

#### 405 4.3.4. Smoothing

406 Smoothing is applied on the lidar signal to increase the accuracy of the retrieved aerosol profiles. For the three  
407 time-series, smoothing was achieved using a low-pass filter with a Blackman window (Blackman and Tukey,  
408 1958). The number of points for the filter was altitude-dependent and channel-dependent.

$$409 S_{filt}(z) = S_2(z)/F(z) * \frac{coef}{\sum coef} \quad (3)$$

$$410 coef(n) = 0.42 - 0.5 * \cos\left(\frac{2\pi n}{W-1}\right) + 0.08 * \cos\left(\frac{4\pi n}{W-1}\right), 0 \leq n \leq M-1 \quad (4)$$

411 With  $S_{filt}$  the smoothed signal,  $S_2$  the desaturated, background corrected, and range corrected lidar signal,  $M$  half  
412 the length of the window and  $W$  the weight of the filter.

413 **Figures 7a-c** represent the new vertical resolution for each channel of each instrument. Two methods can be used  
414 to estimate vertical resolution after smoothing: (i) Impulse response method and (ii) Digital Filter. The latter was  
415 chosen for these time-series. It involves the mathematical calculation of the filter transfer function, using a cut-off  
416 frequency at -3dB (NDACC\_resolDF, (Leblanc et al., 2016)).

Figure 7: NDACC vertical resolution of (a) LiO3S, (b) Li1200, and (c) LiO3T.

419

420

421

#### 4.3.5. Gluing near and far-range channels

422

423

424

425

High and low energy channels were combined for the LiO3S and the Li1200 using the gluing method of the square sinus and cosinus functions. The altitude range chosen for the gluing corresponded to a region where the high energy channel was not affected by electronic distortions and the low energy channel was not affected by too much noise.

426

$$\begin{cases} v1(z) = 0, & z < altmin \\ v1(z) = \sin^2\left(\frac{0 \rightarrow 1}{n} * \frac{\pi}{2}\right), & altmin \leq z \leq altmax \\ v2(z) = 1, & z < altmin \end{cases} \quad (5)$$

427

$$\begin{cases} v2(z) = 1, & z < altmin \\ v2(z) = \cos^2\left(\frac{0 \rightarrow 1}{n} * \frac{\pi}{2}\right), & altmin \leq z \leq altmax \end{cases} \quad (6)$$

428

429

With  $n$  the number of range bins between  $altmin$  and  $altmax$ ,  $v1$  the vector to apply to the high energy channel and  $v2$  the vector to apply to the low energy channel.

430

431

432

433

The channels glued and used for inversion were: (i) 355VL + 355L + 355M + 355H and 355L + 355M + 355H and 355M + 355H for the Li1200, and (ii) 355H + 355M for the LiO3S. Each of these glued channels is available in the  $L_{1b}$  files. Inversion was applied for each glued channels and corresponding optical products can be found in the  $L_2$  files.

434

#### 4.3.6. Calibration depolarization value for the LiO3T

435

436

437

438

Polarization channels enable to detect changes in the backscattered polarization state produced by the atmospheric particles. The laser provides quasi pure linear polarization. A polarizing cube beam splitter transmits the received linear polarized light and reflects the received cross polarized light. It is necessary to determine the polarization calibration factor before combining the two signals (Biele et al., 2000).

439

440

Three methods can be used: (i) Rayleigh calibration method (Behrendt and Nakamura, 2002), (ii)  $\pm 45^\circ$  or  $\Delta 90^\circ$  calibration methods (Freudenthaler, 2016), and (iii) 3 signals (total, cross and parallel) method (Reichardt et al.,

441 2003). While methods 2 and 3 provide the smallest uncertainties, method 1 can be used retrospectively if no total  
 442 channel existed. The apparent Volume Linear Depolarization Ratio (VLDR\*) can then be calculated following:

443  
 444 
$$VLDR^* = \frac{K}{\eta^*} \frac{S_r}{S_t} \quad (7)$$

445  
 446 With  $t$  and  $r$  the respective transmitted and reflected parts of the signal  $S$ ,  $\eta^*$  the apparent calibration factor and  $K$   
 447 the calibration factor correction parameter.

448 The VLDR can then be computed using the polarization crosstalk parameters for the transmitted and reflected  
 449 signals ( $G_{t,r}$  and  $H_{t,r}$ ):

450  
 451 
$$VLDR = \frac{VLDR^* (G_t + H_t) - (G_r + H_r)}{(G_r - H_r) - VLDR^* (G_t - H_t)} \quad (8)$$

452  
 453 The total signal will also be reconstructed following:

454  
 455 
$$S_{total} = \frac{\eta^* H_r S_t - H_t S_r}{H_r G_t - H_t G_r} \quad (9)$$

456 The aerosol backscatter  $\beta_a$  will then be deduced from the total signal  $S_{total}$  using Klett inversion. The backscatter  
 457 ratio  $R$  will be calculated following:

458  
 459 
$$R = \frac{(\beta_a + \beta_{mol})}{\beta_{mol}} \quad (10)$$

460 Finally, the Particle Linear Depolarization Ratio (PLDR) can be computed following:

461  
 462 
$$PLDR = \frac{(1 + LDR_{mol}) * VLDR * R - (1 + VLDR) * LDR_{mol}}{(1 + LDR_{mol}) * R - (1 + VLDR)} \quad (11)$$

463  
 464 In our case, we used the Rayleigh method before 2017 and the 3 signals method after 2017. We used a linear  
 465 molecular depolarization ratio ( $LDR_{mol}$ ) of 0.00398 at 532nm (Behrendt and Nakamura, 2002) to estimate  $\eta^*$ , and  
 466 a  $K$  factor of 1 to estimate  $VLDR^*$ . Crosstalk parameter values were considered ideal:  $G_t = 1$ ,  $H_t = 1$ ,  $G_r = 1$  and  
 467  $H_r = -1$ .

#### 470 4.3.7. Optical products: Klett inversion

471 This step is mandatory to retrieve aerosol optical properties from the detected lidar signals. However, it implies  
 472 to resolve an order 1 Bernoulli equation with several unknown parameters. Several methods exist such as: (i) One  
 473 or two-components Klett inversion (Klett, 1981, 1985), (ii) Raman inversion (Ansmann et al., 1990, 1992), and  
 474 (iii) a synergistic method using Klett inversion and sunphotometer measurements to evaluate the lidar ratio (Raut  
 475 and Chazette, 2007).

476 Because Raman channels have currently a very low SNR, they are not included in this work and the two-  
 477 component Klett inversion method was chosen for the three systems. It implies to determine an *a priori* constant  
 478 value of Lidar Ratio (LR) and a clean, aerosol-free zone in the atmosphere (Rayleigh zone). Details about the  
 479 elastic two-component algorithm from Klett are available in **Appendix A**.

480 The solution proposed in Appendix A is:

481

$$482 \beta(\lambda, z) = \beta_a(\lambda, z) + \beta_m(\lambda, z) = \frac{S_2(\lambda, z) \cdot \exp\left\{2 \cdot \int_{z'=z}^{z_{ref}} \left(\frac{LR_a(\lambda, z')}{LR_m(\lambda, z')} - 1\right) \cdot \alpha_m(\lambda, z') dz'\right\}}{\beta(\lambda, z_{ref}) + 2 \cdot \int_{z'=z}^{z_{ref}} LR_a(\lambda, z') \cdot S_2(\lambda, z') \cdot \exp\left\{2 \cdot \int_{x'=z}^{z_{ref}} \left(\frac{LR_a(\lambda, x')}{LR_m(\lambda, x')} - 1\right) \cdot \alpha_m(\lambda, x') dx'\right\} \cdot dz'} \quad (12)$$

483

484 With **a** (resp. **m**) the particular (resp. molecular) contribution,  $\alpha(\lambda, z)$  (resp.  $\beta(\lambda, z)$ ) the summed molecular and  
 485 particular extinction (resp. backscatter), and **LR** the Lidar Ratio.  $S_2$  corresponds to the range-corrected, sky  
 486 background corrected and desaturated signal. However, the signal used in this study for the inversion algorithm is  
 487 smoothed as explained in paragraph 4.3.4. and could be glued (Li1200, LiO3S) or recombined (LiO3T).

488 Several unknown parameters must be determined:

- 489 (i) To retrieve the  $LR_a$ , we chose a constant LR value of 50 sr for the three instruments to be consistent  
 490 between the time-series and to target the most frequent aerosol types. Moreover it enables easier  
 491 comparisons with satellite data such as CALIOP products (Cattrell et al., 2005).  
 492 (ii) The equation used to retrieve the molecular extinction was (Bates, 1984):

493

$$494 \alpha_m(\lambda, z) = \frac{P}{k * T} * \frac{4.02 \cdot 10^{-28}}{\lambda^{4+(0.389\lambda+0.09426\lambda^{-1}-0.3228)}} \quad (13)$$

495 With  $k$  corresponding to the Boltzmann constant. Atmospheric pressure  $P$  and temperature  $T$  were  
 496 retrieved from the Arletty AERIS product (<https://www.aeris-data.fr/>), relying on data from the  
 497 European weather forecast model ECMWF (European Centre for Medium-Range Weather Forecasts),  
 498 and producing interpolated data every 6h around Maïdo observatory (Hauchecorne, n.d.).

499 The molecular backscatter was then computed following:

500

$$501 \beta_m(\lambda, z) = \alpha_m(\lambda, z) * \frac{3 * K_f}{8\pi} \quad (14)$$

502 The King factor's value ( $K_f$ ) is considered equal to 1 (King, 1923), and  $\frac{3}{8\pi}$  corresponds to the  $LR_m$ .

- 503 (iii) The last step was to determine for each daily measurement and each channel a reference 'Rayleigh'  
 504 zone  $z_{ref}$  supposed free of any aerosols.

505

#### 506 **4.3.8. Raman and 1064 nm channel issues**

507 Klett inversion brings the problem of considering a lidar ratio constant with height. In fact, a single aerosol  
 508 plume is often made of several layers of particles with heterogenous backscattered lidar signals. Raman inversion  
 509 is one solution to deduce a vertical profile of lidar ratio from elastic and Raman channels. However, our Raman

510 channels have a poor SNR and are not usable for stratospheric or high tropospheric aerosols. The retrieval of  
 511 aerosol optical products using Raman inversion for low-energy channels (low and middle troposphere) is still  
 512 ongoing. There is also a misalignment issue for the 1064-nm channel leading to a poor SNR. This channel is  
 513 currently unexploitable.

514 **5. Quality assessment**

515 **5.1. Database statistics**

517 A total of 1737 nighttime measurements were preprocessed between 2013 and 2023: 710 files for Li1200, 534  
 518 files for LiO3S, and 493 files for LiO3T. Notably, the mean percentage of rejected files was higher for Li1200  
 519 (52.7%), than LiO3T (44.8%) and LiO3S (32.7%). **Figure 8** shows the cumulated monthly number of validated  
 520 L<sub>2</sub> profiles for each instrument, the monthly mean number of rejected files and corresponding tags (cloud detection,  
 521 technical issue, low SNR). It should be noted that most observations were made during the May to November  
 522 period (austral winter, dry season) compared to the December to April period (austral summer, wet season), which  
 523 is consistent with the higher cloud and rain occurrence during the wet season. The mean percentage of validated  
 524 L<sub>1</sub> files was 62.4% during the dry season and 48.5% during the wet season. The lower frequency of measurements  
 525 in January, July, August, and December also concurs with two important holiday periods. The frequency of  
 526 technical issues and lower SNR is statistically higher during the months with a greater number of measurements.

527 **Figure 8: Number of validated files for the three instruments in the period 2013-2023. In the table below, mean**  
 528 **percentage of rejected files and tagged files for each month.**

529 **5.2. Instrumental capabilities**

530 The gluing technique allowed to determine different altitude ranges for each lidar depending on the channels  
 531 available. **Table 1** provides a summary of the theoretical instrumental performances in terms of altitude ranges.  
 532 Apart from the number of glued channels, other parameters can influence the maximum altitude (SNR) or the  
 533 minimum altitude (Overlap, SNR) of the validated L<sub>2</sub> vertical profile. The LiO3T at 532 nm is ideal to investigate

534 the low and mid troposphere. The high troposphere and stratosphere can be studied at 355 nm (Li1200 and LiO3S)  
535 or 532 nm (LiO3T – from 2017 until now).

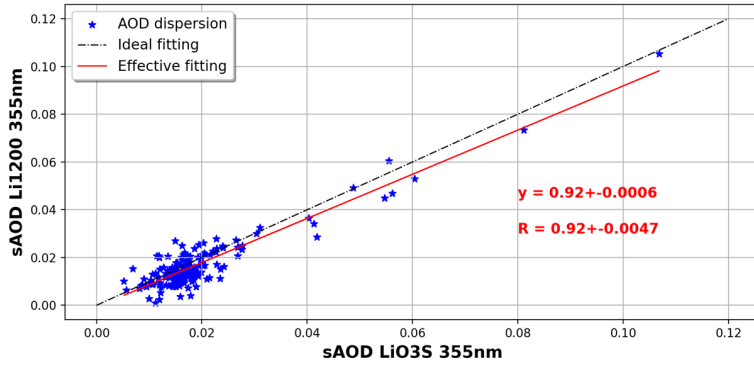

### 536 5.3. Instrumental intercomparison

537 In this study, we performed a comparison between the three instruments to detect any major discrepancies  
538 using the Stratospheric Aerosol Optical Depth (sAOD) between 17 and 30 km. **Figure 9** displays the time-series  
539 of sAOD at 355 nm (Li1200 and LiO3S) for concomitant measurements and corresponding uncertainties. There is  
540 a good overall consistency between the two instruments. The differences between the two time-series could be the  
541 consequence of technical modifications (channel addition, optimization, misalignments). Three peaks periods  
542 of high sAOD values can be identified: the emission of volcanic aerosols in the stratosphere during the Hunga-Tonga  
543 eruption in 2022 (Kloss et al., 2022; Baron et al., 2023; Sicard et al., 2023), the Calbuco volcanic eruption in 2015  
544 (Bègue et al., 2017) and the Australian bushfires in 2020 (Khaykin et al., 2020). Higher differences in 2021 could  
545 be the consequence of repeated misalignments for the Li1200.

546 **Figure 9:** Nighttime AOD (17 to 30 km layer) at 355 nm, from the Li1200 (red) and LiO3S (blue) (concurrent  
547 measurements) with corresponding uncertainties (dashed colored lines). Exceptional events circled in red. The  
horizontal timeline is not linear: one date out of eight is represented for visual purposes.

548 The dispersion of sAOD values is represented in **Figure 10**. The sAOD at 355 nm varies between 0.001 and  
549 0.107 for LiO3S and Li1200, with a mean of  $0.019 \pm 0.012$  and  $0.017 \pm 0.012$ , respectively. A good correlation  
550 is found between the two lidars (correlation  $R = 0.924 \pm 0.005$ ).

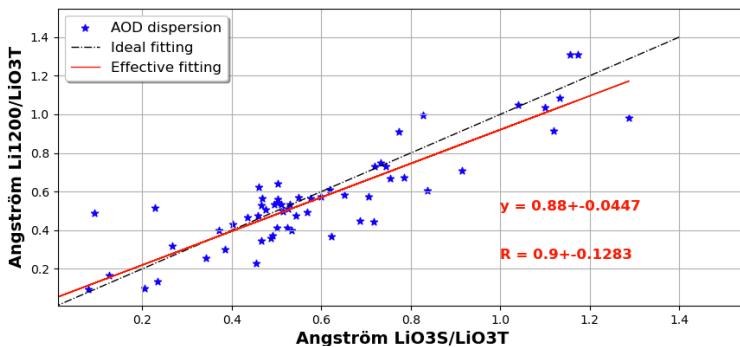

551  
552 **Figure 10: Dispersion of the AOD (17 to 30 km layer) at 355 nm, between the Li1200 and LiO3S. The red line represents the theoretical linear regression.**

553 The correlation between the two instruments at 355 nm in terms of extinction values is higher above 17 km but  
554 lower from 10 to 17 km (**Appendix D, Figure D1**). In fact, for the Li1200: (i) low energy channels were added in  
555 2017, (ii) there were changes in the minimal altitude of detection for the 355M channel, and (iii) this instrument  
556 had many misalignments and underwent several optical upgrades, leading to modifications of the overlap function.

557 For further retrospective trend studies, it is important to note that the LiO3S has been the most stable instrument  
558 throughout the time-series and is considered the reference instrument at 355 nm. However, data from the Li1200  
559 can be used to fill the gaps of the LiO3S database depending on the altitude range targeted, but also for specific  
560 case studies with the need to retrieve optical products for the middle and low troposphere.

561 The same analysis was performed for the LiO3T. To compare the two wavelengths, Ångström exponents (AE)  
562 were computed between the LiO3T (532 nm) and alternatively the LiO3S (355 nm) and Li1200 (355 nm). **Figure**  
563 **11** shows the dispersion of AE values. The order of magnitude of AE values varies between 0.0794 and 1.288 with  
564 a mean of  $0.56 \pm 0.29$  and  $0.54 \pm 0.28$ , respectively. Again, a good correlation is found between both datasets  
565 ( $R = 0.901 \pm 0.128$ ). These values also demonstrate the variability of stratospheric aerosol size distribution  
566 between 17 and 30 km (Gobbi et al., 2007; Burton et al., 2012).

567 **Figure 11: Dispersion of the AE (17 to 30 km layer) between 355 and 532 nm. The black line represents the theoretical linear regression and the red line the actual linear regression.**

568 **Table 2** summarizes the metrics used to intercompare the three instruments. The relative Mean Bias Error (MBE)  
 569 was added the analysis. After identifying the LiO3S as the reference instrument at 355 nm, we found a negative  
 570 MBE (- 6.55 %) concerning sAOD, meaning that the Li1200 tends to underestimate sAOD compared to LiO3S.

a supprimé: ¶

	Relative Mean Bias Error	Linear Regression Slope	Correlation coefficient
sAOD	- 7.59 %	0.92	0.92 ± 0.0047
Ångström exponent	- 6.55 %	0.88	0.90 ± 0.1283

571 **Table 2: Intercomparison between the three instruments in terms of sAOD and Ångström exponent.**

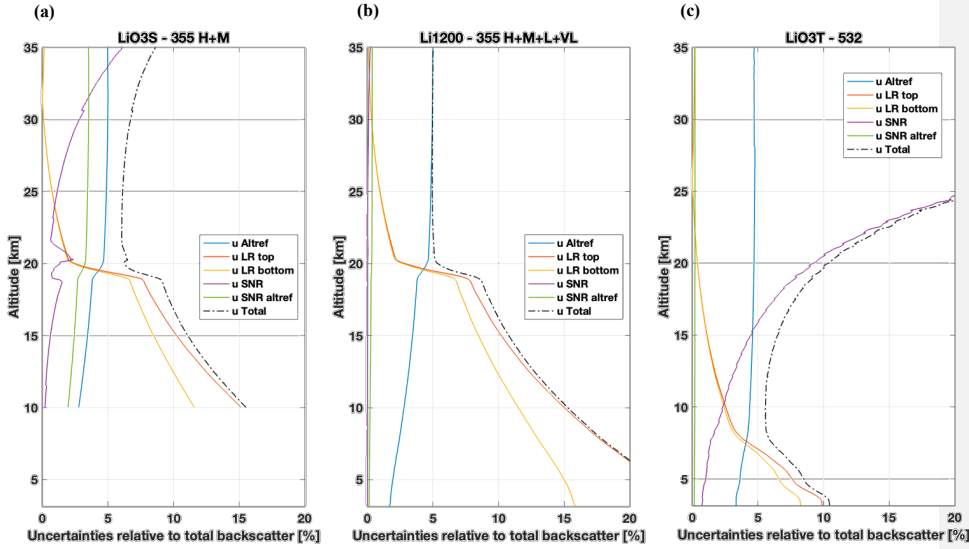

#### 572 5.4. Main sources of uncertainties

573 The total uncertainty budget of each lidar is described in **Appendix B**. Four sources of uncertainty were  
 574 propagated in quadrature (Sicard et al., 2009; Rocadenbosch et al., 2010): (i) uncertainty due to the Rayleigh  
 575 calibration value ( $u_{altref}$ ), (ii) uncertainty due to the lidar ratio value ( $u_{LR}$ ) with a distinction between *LR, top* and  
 576 *LR, bottom* defining the respective upper and lower error bars, (iii) uncertainty due to the SNR vertical distribution  
 577 ( $u_{SNR}$ ), (iv) and uncertainty due to the SNR value at the calibration altitude ( $u_{SNR,altref}$ ). **Figures 12a-12c**  
 578 represent for three case reports the importance of each uncertainty relatively to the total backscatter in percentage,  
 579 and **Figures 12d-12f** represent the corresponding propagated total backscatter uncertainty for the three  
 580 instruments.

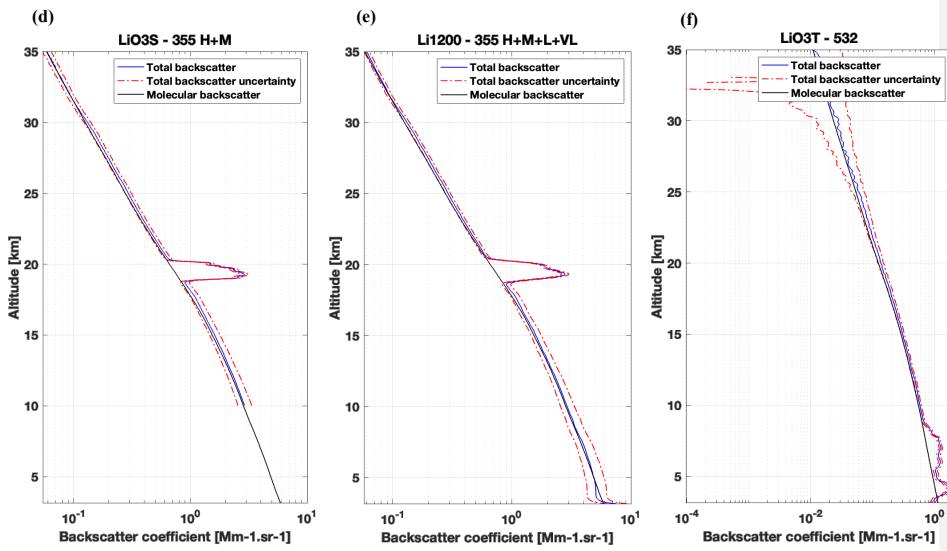

581 In **Figures 12a-12c**, the behavior of the uncertainties  $u_{altref}$  (blue curves) and  $u_{SNR,altref}$  (green curves) is  
 582 stable over the different altitude ranges. Notably,  $u_{altref}$  comes from the 5% uncertainty of the molecular  
 583 backscatter, which determines the lower threshold for the total uncertainty. The  $u_{SNR}$  uncertainty (purple curves)  
 584 is strongly influenced by the altitude, with minimal values at lower altitude ranges where the lidar signal is stronger,  
 585 and values increasing with the altitude. In fact, lidar signals are filtered before inversion, making  $u_{SNR}$  the  
 586 predominant error at higher altitude levels. Oppositely, the  $u_{LR}$  uncertainty (orange and yellow curves) is the lowest  
 587 at the calibration altitude and increases in the lower levels, where it becomes predominant. The systematic  
 588 uncertainty on the LR value was set to 30% for this study. Therefore, the total uncertainty is the lowest in mid-  
 589 altitude ranges before increasing in lower and higher altitude levels. Sharp spikes in  $u_{LR}$  can be observed just  
 590 below 20km for the LiO3S and Li1200, and below 8 km for the LiO3T. They are linked to the presence of aerosol  
 591 plumes and emphasize the impact of aerosols on the uncertainty values in lower altitude levels.

592 For the LiO3S (H+M glued channel), the total relative uncertainty reaches 15% at 10 km, decreases down to  
 593 6% around 20 km, and increases up to 8% around 35 km. (**Figure 12a**). Without the aerosol layer, the minimum  
 594 error would be reached around 15 km. For the Li1200 (H+M+L+VL glued channel), the total relative uncertainty  
 595 reaches 20% at 7 km and decreases down to 5% from 20 km up. (**Figure 12b**). The uncertainty due to the SNR is  
 596 very low compared to the LiO3S, as this instrument is designed to reach very high-altitude levels, and the signal  
 597 used for inversion is made of four filtered signals with complementary vertical capacities. Without the aerosol  
 598 layer, the minimum error would be reached around 17 km. For the LiO3T, the total relative reaches 10% at 4 km,  
 599 decreases down to 6% around 8 km, and increases up to 20% around 25 km. (**Figure 12c**). The uncertainty due to  
 600 the SNR is higher than the previous lidars because this instrument is designed for tropospheric measurements.

603

604

605

Figure 12: Upper row: random cases showing the molecular backscatter (black), the backscatter coefficient (blue) and its apparent uncertainty (red dotted line) for the (a) LiO3S (25/01/2022), (b) Li1200 (25/01/2022) and (c) LiO3T (25/09/2017). Lower row: corresponding relative uncertainties for the (d) LiO3S, (e) Li1200 and (f) LiO3T.

606

607

608

609

610

611

In Figures 12d-12f, the three instruments demonstrate their capacity to detect aerosol layers with relatively low error rates and a high resolution. Figures 12d-12e specifically show their ability to identify variations within the aerosol layer between 18 and 20 km. For the LiO3T (Figures 12f), the aerosol layer between 4 and 8 km is exceptionally well defined, with relatively low error values. Apart from these aerosol layers, the molecular backscatter (in black) tends to align closely with the uncertainty of the total backscatter (in red). In fact, background

612 aerosols are characterized by very low backscatter and extinction values, leading to the relatively high sAOD  
 613 uncertainties observed in **Figure 9**: higher for background aerosols but lower for cases with a stronger aerosol  
 614 load, such as from Australian fires or volcanic aerosols. Focusing on the uncertainty specific to aerosol backscatter  
 615 (rather than the total) is essential to improve the uncertainty analysis, along with a statistical analysis of the dataset  
 616 to minimize disruptions caused by transient aerosol events. Time-series of aerosol backscatter relative total  
 617 uncertainties were computed for the three instruments and the corresponding mean and standard deviation are  
 618 represented **Figures 13a-c**. Values are high and easily reach 100% for the three instruments because of the very  
 619 low values of aerosol backscatter coefficients above Maïdo observatory. The mean uncertainty is the lowest for  
 620 the LiO3S between 18 and 25 km ( $64.4 \pm 31.6$  %). It increases under 18 km and above 25 km with relative  
 621 uncertainty values reaching more than 100% due to the very weak aerosol backscatter values at these altitude  
 622 ranges. The mean uncertainty for the Li1200 is also the lowest between 18 and 25 km ( $50.3 \pm 29.0$  %). It increases  
 623 under 18 km and above 25 km with relative uncertainty values relatively lower than the LiO3S due to a lower  
 624 SNR, and the presence of low and very low channels detecting aerosol plumes at lower altitudes. The LiO3T  
 625 exhibits a low relative uncertainty below 20 km, it varies around  $69.1 \pm 42.7$  %. The strong increase above 20 km  
 626 is essentially explained by the very low SNR for this instrument at these altitude ranges.

627

628

629

## 6. Data availability

Raw L<sub>0</sub> files, cleaned L<sub>1</sub> files and processed L<sub>2</sub> files with optical products are generated locally. L<sub>0</sub> files are made of 1-minute integrated raw files in licel format. L<sub>1</sub> products contain 1-minute integrated time-series and overnight averaged cleaned signals in mat file format and netcdf format. L<sub>2</sub> products in mat file format contain overnight averaged processed signals, as well as range-corrected signals for Raman channels. L<sub>2</sub> products are also computed in netcdf format following NDACC guidelines in anticipation for a future NDACC label request. **Table C1** in **Appendix C** summarizes the optical products and other variables available in these L<sub>2</sub> netcdf files.

Each of these files is available on request in our local datacenter by FTP (<ftp://tramontane.univ-reunion.fr/>). L<sub>1</sub> and L<sub>2</sub> files are currently available at <https://doi.org/10.26171/rwcm-q370> (Gantois et al., 2024). Mat files and netcdf files with L<sub>2</sub> data will soon be available on AERIS database, but only L<sub>2</sub> netcdf files will be openly accessible.

## 7. Summary

This study supports the first ever long-term time-series of multiwavelength aerosol optical properties generated from three lidars operating at the Observatory of Atmospheric Physics of La Réunion (OPAR) since 2013. A full description of the technical specifications for the three instruments is provided, as well as details about the preprocessing and processing methods used to produce the different dataset levels. The three time-series consist in vertical profiles of aerosol elastic backscatter and extinction coefficients at 355 and 532 nm, and linear depolarization ratio at 532 nm above Maïdo observatory (2160 m asl, west side of Reunion Island, Southern Hemisphere) from 2013 until now.

The preprocessing step required manual cleaning of more than 1700 files, and the highest frequency of cloud occurrence resulted in a lower number of validated profiles during the wet season. Data processing methods and the Klett inversion technique chosen for this work are detailed and referenced. One issue concerns the random misalignments and technical modifications for the three instruments leading to highly variable parameters such as the geometrical form factor. As an alternative to the Klett method, the Raman inversion technique has been attempted but failed for stratospheric and high tropospheric levels due to a poor SNR.

667 Intercomparison between the three instruments show a good correlation in terms of sAOD values. The  
 668 uncertainty analyses reveal a strong influence of the LR value in the low-altitude ranges and a strong influence of  
 669 the SNR in the high-altitude ranges. Uncertainty values relative to the total backscatter coefficient are low for the  
 670 three instruments. Uncertainty values relative to the aerosol backscatter coefficient are high for the three  
 671 instruments because of the very low aerosol backscatter coefficient values generally observed above Maïdo  
 672 observatory. Among the three instruments, the LiO3S stands out as the most stable (less misalignments, less  
 673 technical modifications) and should be considered the reference instrument at 355 nm. However, data from the  
 674 Li1200 can be used to fill the gaps of the LiO3S database and for specific case studies.

## 675 Appendices

### 676 Appendix A

677 The equation describing the desaturated lidar signal can be written as:

$$678 \quad S_{desat}(\lambda, z) = C(\lambda) \cdot \frac{F(z)}{(z - z_0)^2} \cdot \left\{ \sum_i \beta_i(\lambda, z) \right\} \cdot \left\{ \exp \left[ - \frac{2}{\cos(\theta)} \cdot \sum_i \tau_i(\lambda, z_0, z) \right] \right\} + S_{bck}(\lambda) \quad (A1)$$

679 With  $C$  the instrumental constant,  $F$  the overlap function,  $\beta_i$  the backscatter coefficient of the component  $i$ ,  $\tau_i$  the  
 680 integrated extinction coefficient of the component  $i$  between altitude  $z_0$  and  $z$ , and  $S_{bck}$  the background signal.

681 The range-corrected, sky background corrected and desaturated signal can then be considered:

682

$$683 \quad S_2(\lambda, z) = [S_{desat}(\lambda, z) - S_{bck}(\lambda, z)] \cdot (z - z_0)^2 \quad (A2)$$

684

685 Derivation of the logarithm of  $S_2$  leads to:

686

$$687 \quad \frac{\delta[\ln(S_2)]}{\delta z} = \frac{1}{\beta(\lambda, z)} \cdot \frac{\delta[\beta(\lambda, z)]}{\delta z} - 2 \cdot LR_a(\lambda, z) \cdot \beta(\lambda, z) - 2 \cdot \alpha_m(\lambda, z) \cdot \left( 1 - \frac{LR_a(\lambda, z)}{LR_m} \right) \quad (A3)$$

688

689 With  $\mathbf{a}$  (resp.  $\mathbf{m}$ ) the particular (resp. molecular) contribution,  $\alpha(\lambda, z)$  (resp.  $\beta(\lambda, z)$ ) the summed molecular and  
 690 particular extinction (resp. backscatter), and  $LR$  the Lidar Ratio:

691

$$LR_a(\lambda, z) = \frac{\alpha_a(\lambda, z)}{\beta_a(\lambda, z)} \quad (A4)$$

692

$$LR_m(\lambda, z) = \frac{\alpha_m(\lambda, z)}{\beta_m(\lambda, z)} = \frac{8\pi}{3} * K_f \quad (A5)$$

693

With  $K_f$  corresponding to the King factor's value.

694

The two-component solution of this Bernoulli equation is:

695

696  $\beta(\lambda, z) = \beta_a(\lambda, z) + \beta_m(\lambda, z)$   
697 
$$= \frac{S_2(\lambda, z) \cdot \exp\{2 \cdot \int_{z'=z}^{z_{ref}} \left( \frac{LR_a(\lambda, z')}{LR_m(\lambda, z')} - 1 \right) \cdot \alpha_m(\lambda, z') dz'\}}{\beta(\lambda, z_{ref}) + 2 \cdot \int_{z'=z}^{z_{ref}} LR_a(\lambda, z') \cdot S_2(\lambda, z') \cdot \exp\{2 \cdot \int_{z'=z}^{z_{ref}} \left( \frac{LR_a(\lambda, x')}{LR_m(\lambda, x')} - 1 \right) \cdot \alpha_m(\lambda, x') dx'\} \cdot dz'} \quad (A6)$$

698  
699 **Appendix B**

700 The uncertainty budget was determined from the Klett elastic one components inversion technique. Mathematical  
701 details can be found in (Rocadenbosch et al., 2010) for the total backscatter inversion uncertainty budget and  
702 (Sicard et al., 2009) for the two components inversion uncertainty budget.

703 The Klett inversion was applied to the filtered signal following (see section 4.3.4.):

704 
$$S_{filt}(z) = \frac{S_2(z)}{F(z)} * \frac{coef}{\sum coef} \quad (3)$$

705 Considering  $C = \frac{coef}{\sum coef}$  and  $S_{geo}(z) = \frac{S_2(z)}{F(z)}$ , the uncertainty of the filtered signal followed the equation:

706 
$$u_{filt}(z) = \sqrt{\left[ \frac{\partial S_{filt}(z)}{\partial S_{geo}(z)} \cdot u_{S_{geo}(z)} \right]^2 + \left[ \frac{\partial S_{filt}(z)}{\partial C} \cdot u_C(z) \right]^2} = \sqrt{\left[ C(z) \cdot u_{S_{geo}(z)} \right]^2 + \left[ S_{geo}(z) \cdot u_C(z) \right]^2} \quad (B1)$$

707  
708 **Table B1** is a summary of the Total-Backscatter analytical error bars to compute in Klett's backward inversion  
709 method.

Uncertainty source	Equation
Uncertainty due to the Rayleigh calibration value ( $u_{altref}$ )	$u_{altref} = \left  \left( \frac{\beta_j}{\beta_N} \right)^2 \frac{U_N}{U_j} \right  \sigma_{\beta_N}$
Uncertainty due to the lidar ratio value ( $u_{LR}$ )	$u_{LR} = \left  \pm p \frac{2\beta_j^2}{U_j} G_j + p^2 \frac{4\beta_j^3}{U_j^2} G_j^2 \right $ Where: $G_j = \sum_{i=j}^N w_i S_i U_i$
Uncertainty due to the SNR vertical distribution ( $u_{SNR}$ ).	$u_{SNR} = \sqrt{\left( \frac{\beta_j}{U_j} \right)^2 \sigma_{U_j}^2 + \left( \frac{2\beta_j}{U_j} \right)^2 \sigma_{G_j}^2}$ Where: $\sigma_{G_j}^2 = \sum_{k=j}^N (w_k S_k)^2 \sigma_{U_k}^2$
Uncertainty due to the SNR value at the calibration altitude ( $u_{SNR,altref}$ ).	$u_{SNR,altref} \approx \left  \frac{\beta_j^2}{\beta_N U_j} \right  \sigma_{U_N}$

710 **Table B1:** Total-Backscatter analytical error bars from Klett's backward inversion method (from Rocadenbosch et al.,  
711 2010)

712  
713 With  $\beta_j$  the total backscatter at the altitude cell j,  $U_j$  the range-corrected signal at the altitude cell j, N the calibration  
714 altitude cell,  $\sigma_{U_j}$  the uncertainty if the range-corrected signal U,  $\sigma_{\beta_j}$  the uncertainty of the total backscatter,  $S_j$  the  
715 total lidar ratio.

716 The uncertainty of the total backscatter error bars  $u_{\beta_T}$  can then be written as:

717

$$\mathbf{u}_{\beta T} = \sqrt{\mathbf{u}_{\text{altref}}^2 + \mathbf{u}_{LR}^2 + \mathbf{u}_{SNR}^2 + \mathbf{u}_{SNR,\text{altref}}^2} \quad (\mathbf{B2})$$

720 Appendix D

721

722

723

Figure D1: Dispersion of the AOD (10 to 17 km layer) at 355 nm, between the Li1200 and LiO3S. The black line represents the theoretical linear regression and the red line the actual linear regression.

724 **Author contributions.** DG conducted this study with the help of MS, GP, VD and NB. DG performed the  
725 processing of the lidar measurements, the uncertainty analysis, prepared the figures and the manuscript. GP and  
726 MS both contributed to the improvement of the text, figures, and uncertainty analysis of this manuscript. GP  
727 designed two original softwares used for data processing, which were improved by DG. NM designed the lidar  
728 optical schemes. TP and SGB were responsible for the LiO3S instrument and dataset, VD and NM were  
729 responsible for the LiO3T instrument and dataset, and VD and GP were responsible for the Li1200 instrument and  
730 dataset. PH and EG performed the lidar measurements and the instrumental maintenance and reviewed the  
731 technical aspects of this paper. All co-authors contributed to reviewing drafts of this manuscript.

732 **Competing interests.** The authors declare that they have no conflict of interest.

733 **Acknowledgments.** The authors gratefully acknowledge Louis Mottet and Yann Hello, who are deeply involved  
734 in the routine lidar observations at the Maïdo facility.

735 **Financial support.** The authors acknowledge the support of the European Commission through the REALISTIC  
736 project (GA 101086690). OPAR is presently funded by CNRS (INSU), Météo France, and Université de La  
737 Réunion, and managed by OSU-R (Observatoire des Sciences de l'Univers de La Réunion, UAR 3365). OPAR is  
738 supported by the French research infrastructure ACTRIS-FR (Aerosols, Clouds, and Trace gases Research  
739 InfraStructure – France) and by the French Center for Spatial Studies (CNES). The projects OBS4CLIM (Equipex  
740 project funded by ANR: ANR-21-ESRE-0013), EECLAT and AOS (CNES) are acknowledged.
