Abstract

Long-term PM_{2.5} data are essential for the atmospheric environment, human health, and climate change. PM_{2.5} measurements are sparsely distributed and of short duration. In this study, daily PM_{2.5} concentrations are estimated using a machine learning method from 1959 to 2022 in the Northern Hemisphere based on near-surface atmospheric visibility, which are extracted from the Integrated Surface Database (ISD). Daily continuous monitored PM_{2.5} concentration is set as the target, and near-surface atmospheric visibility and other related variables are used as the inputs. The 80% of the samples of each site are the training set, and the 20% are the testing set. The training result shows that the slope of linear regression with a 95% confidence interval (CI) between the estimated PM_{2.5} concentration and the monitored PM_{2.5} concentration is 0.955 [0.955, 0.955], the coefficient of determination (R²) is 0.95, the root mean square error (RMSE) is 7.2 μg/m³, and the mean absolute error (MAE) is 3.2 μg/m³. The test result shows that the slope within a 95% CI between the predicted PM_{2.5} concentration and the monitored PM_{2.5} concentration is 0.864 [0.863, 0.865], the R² is 0.79, the RMSE is 14.8 μg/m³, and the MAE is 7.6 μg/m³. Compared with a global PM_{2.5} concentration dataset derived from satellite aerosol optical depth product with 1 km resolution, the slopes of linear regression on the daily (monthly) scale are 0.817 (0.854) from 2000 to 2021, 0.758 (0.821) from 2000 to 2010, and 0.867 (0.879) from 2011 to 2022, indicating the accuracy of the model and the consistency of the estimated PM_{2.5} concentration on the temporal scale. The interannual trends and spatial patterns of PM_{2.5} concentration on the regional scale from 1959 to 2022 are analyzed by Generalized Additive Mixed Model (GAMM), suitable for the situation with an uneven spatial distribution of monitoring sites. The trend is the slope of the Sen-Theil estimator. In Canada, the trend is -0.10 μg/m³/decade and the PM_{2.5} concentration exhibits an east-high to west-low pattern. In the United States, the trend is -0.40 μg/m³/decade, and PM_{2.5} concentration decreases significantly after 1992, with a trend of -1.39 μg/m³/decade. The high PM_{2.5} concentration areas are in the east and west and the low are in the central and northern regions. In Europe, the trend is -1.55 μg/m³/decade. High concentration areas are distributed in eastern Europe, and the low areas are in northern and western Europe. In China, the trend is 2.09 μg/m³/decade. High concentration areas are distributed in northern China and the low areas are distributed in southern China. The trend is 2.65 μg/m³/decade up to 2011 and -22.23 μg/m³/decade since 2012. In India, the trend is 0.92 μg/m³/decade. The concentration exhibits a north-high to south-low pattern, with high

41 concentration areas distributed in northern India, such as Ganges Plain and Thar Desert and the low
42 area is in Deccan Plateau. The trend is $1.41 \mu\text{g}/\text{m}^3/\text{decade}$ up to 2013 and $-23.36 \mu\text{g}/\text{m}^3/\text{decade}$ since
43 2014. The variation in regional $\text{PM}_{2.5}$ concentrations is closely related to the implementation of air
44 quality laws and regulations. The daily site-scale $\text{PM}_{2.5}$ concentration dataset from 1959 to 2022 in
45 the Northern Hemisphere is available at National Tibetan Plateau / Third Pole Environment Data
46 Center (<https://doi.org/10.11888/Atmos.tpsc.301127>) (Hao et al., 2024).

48 Fine particulate matter; $\text{PM}_{2.5}$; Visibility; Machine learning; Dataset.

49 **1 Introduction**

50 Fine particulate matter ($\text{PM}_{2.5}$) refers to particulate matter suspended in air with an aerodynamic
51 diameter of less than 2.5 micrometers. $\text{PM}_{2.5}$ has various shapes and is composed of complex
52 components, such as inorganic salts (e.g., sulfate, nitrate, and ammonium), as well as organic carbon
53 and elemental carbon, metallic elements, and organic compounds (Chen et al., 2020; Fan et al.,
54 2021). $\text{PM}_{2.5}$ can be emitted directly into the atmosphere (Viana et al., 2008; Zhang et al., 2019) and
55 generated through photochemical reactions and transformations (Guo et al., 2014). $\text{PM}_{2.5}$ exhibits
56 high concentrations near emission sources, which gradually decreases with distance. Due to the
57 smaller size and longer life span compared with coarse particulate matter, $\text{PM}_{2.5}$ can be transported
58 over long distances by atmospheric movements, leading to wide-ranging impacts. Studies indicate
59 that regional transport contributes significantly to local $\text{PM}_{2.5}$ concentration (Wang et al., 2014;
60 Chen et al., 2020).

61 $\text{PM}_{2.5}$ reduces atmospheric visibility and facilitates the formation of fog and haze conditions (Fan
62 et al., 2021). Direct and indirect effects of $\text{PM}_{2.5}$ on solar radiation in the atmosphere (Albrecht,
63 1989; Ramanathan et al., 2001; Bergstrom et al., 2007; Chen et al., 2022) alter the energy balance
64 and the number of condensation nuclei, thereby influencing atmospheric circulation and the water
65 cycle (Wang et al., 2012; Liao et al., 2015; Samset et al., 2019; Li et al., 2022).

66 $\text{PM}_{2.5}$ is also known as respirable particulate matter. Due to its complex composition, $\text{PM}_{2.5}$ may
67 carry toxic substances that can significantly impair human health. The World Health Organization
68 states explicitly that $\text{PM}_{2.5}$ is more harmful than coarse particles, and long-term exposure to high
69 $\text{PM}_{2.5}$ concentrations increases the risk of respiratory diseases, cardiovascular diseases, and lung
70 cancer (Lelieveld et al., 2015), regardless of a country's development status. A Global Burden of
71 Diseases study reveals that exposure to environmental $\text{PM}_{2.5}$ causes thousands of deaths and
72 millions of lung diseases annually (Chafe et al., 2014; Kim et al., 2015; Cohen et al., 2017).

73 $\text{PM}_{2.5}$ is an important parameter for assessing particulate matter pollution and air quality (Wang et
74 al., 2012). $\text{PM}_{2.5}$ can lead to soil acidification, water pollution, disruption of plant respiration, and
75 ecological degradation (Wu and Zhang, 2018; Liu et al., 2019). Due to globalization and economic
76 integration, preventing and controlling particulate matter pollution is a challenge at city, country
77 and global scales.

78 Therefore, long-term $\text{PM}_{2.5}$ concentration data are needed for studies on the environment, human
79 health, and climate change. At present, ground-based measurements, chemical models, and
80 estimations of alternatives are the primary sources of $\text{PM}_{2.5}$ concentration data.

81 Ground-based measurements are the most effective means to measure $PM_{2.5}$ concentration. $PM_{2.5}$
82 monitoring has been ongoing since the 1990s in North America and Europe (Van Donkelaar et al.,
83 2010), and large-scale $PM_{2.5}$ monitoring has been implemented in other regions since 2000,
84 including China in 2013 (Liu et al., 2017). As a result, the records for $PM_{2.5}$ concentration are short,
85 with only a few years of data available in many countries. The scarcity of $PM_{2.5}$ measurements
86 makes it challenging to provide long-term historical data for research.

87 Many studies have employed statistical methods, machine learning and deep learning methods to
88 estimate $PM_{2.5}$ concentrations based on aerosol optical depth. Van Donkelaar et al. (2021) has
89 utilized satellite aerosol optical depth data, aerosol vertical structure of chemical transport models,
90 and ground-level measurements to estimate monthly $PM_{2.5}$ concentrations and their uncertainties
91 over global land from 1998 to 2019, and there are several related studies (Van Donkelaar et al., 2010;
92 Boys et al., 2014; Van Donkelaar et al., 2015; Van Donkelaar et al., 2016; Hammer et al., 2020).
93 Many studies have been conducted at the regional scale, such as in the United States (Beckerman et
94 al., 2013), China (Wei et al., 2019b; Xue et al., 2019; Wei et al., 2020; He et al., 2021; Wei et al.,
95 2021), and India (Mandal et al., 2020). Although the $PM_{2.5}$ concentrations derived from satellite
96 retrievals have high spatial coverage, there are some limitations that need to be considered. Aerosol
97 optical depth describes the column property of aerosol, while $PM_{2.5}$ concentration describes the
98 near-surface properties of aerosol. Therefore, aerosol vertical structure is crucial in establishing the
99 relationship between the two. The daily representativeness is also considerable, as $PM_{2.5}$
100 concentration is continuously monitored while the daily frequency of satellite observations is low
101 (1-2 times). Surface types, cloud conditions (Wei et al., 2019a) and resolution (Nagaraja Rao et al.,
102 1989; Hsu et al., 2017) affect the accuracy of satellite products, thereby increasing uncertainty of
103 estimation of $PM_{2.5}$ concentration.

104 Reanalysis datasets provide estimates of long-term particulate matter concentrations. The Modern-
105 Era Retrospective Analysis for Research and Applications version 2 (MERRA-2) is an excellent
106 reanalysis dataset from NASA that uses the Goddard Earth Observing System version 5 (GEOS-5),
107 which provides global $PM_{2.5}$ data since 1980 (Buchard et al., 2015; Buchard et al., 2016; Buchard
108 et al., 2017; Gelaro et al., 2017; Sun et al., 2019). There are some emission inventories in the aerosol
109 model, including: volcanic material; monthly biomass burning from 1980 to 1996; monthly SO_2 ,
110 SO_4 , POM, and BC from 1997 to 2009; annual anthropogenic SO_2 between 100 and 500 m above
111 the surface from 1980 to 2008; annual anthropogenic SO_4 , BC, and POM concentrations from 1980
112 to 2006. In assimilation systems, satellite aerosol products from MISR and MODIS Aqua/Terra are
113 assimilated after 2000. Another reanalysis dataset is the Copernicus Atmosphere Monitoring Service
114 (CAMS) global reanalysis, which is a global reanalysis dataset of the atmospheric composition
115 produced by the European Centre for Medium-Range Weather Forecasts (ECMWF) and has
116 provided $PM_{2.5}$ data since 2003 (Che et al., 2014; Inness et al., 2019). Although reanalysis provides
117 long-term $PM_{2.5}$ data, the uncertainty in emission inventories increases the uncertainty in $PM_{2.5}$
118 concentration (Granier et al., 2011). The validation of the reanalysis based on emission inventories
119 shows that $PM_{2.5}$ concentration is still overestimated or underestimated in some regions (Buchard
120 et al., 2017; Ali et al., 2022; Jin et al., 2022). The assimilation of aerosol optical depth products
121 improves the aerosol column properties (Buchard et al., 2017), thereby improving the estimation of
122 surface $PM_{2.5}$ concentration, as it to some extent constrains the vertical structure of aerosols.
123 However, the lack of high spatiotemporal resolution emission inventories and long-term

124 assimilation data greatly limits the accuracy of surface PM_{2.5} concentrations.

125 Another alternative for estimating PM_{2.5} concentrations is the near-surface atmospheric horizontal
126 visibility, which is the maximum distance at which observers with normal visual acuity can discern
127 target contours under current weather conditions. In addition to manual observations, automated
128 visibility measurement has been implemented early, typically relying on the aerosol scattering
129 principle (Wang et al., 2009; Zhang et al., 2020). Both visibility and PM_{2.5} concentration are
130 measurements of near-surface aerosols. They describe atmospheric horizontal transparency and are
131 used to describe atmospheric pollution. Long-term visibility records have been used to quantify
132 long-term aerosol properties (Molnár et al., 2008; Wang et al., 2009; Zhang et al., 2017; Zhang et
133 al., 2020). Visibility observation stations are densely distributed across the world. Compared to
134 satellite retrievals, visibility observations have longer historical records dating back to the early 20th
135 century (Noaa et al., 1998; Boers et al., 2015), are not affected by cloud interference and provide
136 continuous measurements.

137 Visibility has been used as a proxy for PM_{2.5} concentration (Huang et al., 2009) and to estimate
138 PM_{2.5} concentration (Liu et al., 2017; Li et al., 2020; Singh et al., 2020). Singh et al. (2020) has
139 analyzed the air quality in East Africa from 1974 to 2018 using visibility data. Liu et al. (2017) has
140 developed a statistical model and utilized ground-level visibility data to estimate long-term PM_{2.5}
141 concentrations in China from 1957 to 1964 and 1973 to 2014. Gui et al. (2020) has proposed a
142 method to establish a virtual ground observation network for PM_{2.5} concentration in China using
143 extreme gradient boosting modeling in 2018. Zeng et al. (2021) has used LightGBM to establish a
144 virtual network for hourly PM_{2.5} concentrations in China in 2017. Zhong et al. (2021; 2022) has
145 used LightGBM to predict 6-hour PM_{2.5} concentrations based on visibility, temperature, and relative
146 humidity in China from 1960 to 2020. Meng et al. (2018) has utilized a random forest model to
147 estimate the daily PM_{2.5} components in the United States from 2005 to 2015. These studies have
148 provided various methods for estimating PM_{2.5} using visibility data. However, some have focused
149 on only methodological innovations without providing long-term trends in PM_{2.5} concentration.
150 Other studies offer long-term trends, but the primary focus is at urban or national scale. There are
151 few studies on long-term and high-temporal-resolution PM_{2.5} concentration at the global scale or
152 across different countries.

153 This study uses a convenient, accurate, and easily understandable machine learning approach to
154 estimate daily PM_{2.5} concentrations based on visibility at 5023 land-based sites from 1959 to 2022.
155 First, we build a machine learning model and then analyze the importance of the variables. Second,
156 we evaluate the model's performance and predictive ability. Third, we discuss the errors and
157 limitations of the dataset. Fourth, we compare the estimated PM_{2.5} concentration with the other
158 dataset. Finally, we analyze the long-term trends and spatial patterns of PM_{2.5} concentration in
159 different regions. We hope the PM_{2.5} dataset will provide support for the atmospheric environment,
160 human health, and climate change studies.

161 **2 Data and methods**

162 **2.1 Study Area**

163 The study area is the Northern Hemisphere. Figure 1 shows the distributions of visibility stations (a)
164 and the PM_{2.5} monitoring sites (b). Table 1 lists information of stations such as the number and time

165 span in each region. The number of visibility stations and PM_{2.5} monitoring sites is 5023. Due to its
 166 relevance to national or regional development, the record length and distribution of PM_{2.5}
 167 observation are uneven. In this study, the site-scale PM_{2.5} observations are met at least three years.
 168 These sites are densely populated in North America, East and South Asia, and Europe, and are very
 169 sparse in regions such as Africa and South America, and West Asia.

170

171 **Figure 1.** Study area and distributions of visibility stations (a) and PM_{2.5} monitoring sites (b). The
 172 color of marker (circle) represents the year number of visibility observations and PM_{2.5}
 173 concentration observations.

2.2 PM_{2.5} Data

176

2.2.1 PM_{2.5} Data in the United States

177

The hourly PM_{2.5} concentration data for the United States from 1998 to 2022 are sourced from the
 178 Air Data System (AQS), which are available at <https://www.epa.gov/aqs>. The AQS provides PM_{2.5}
 179 mass monitoring and routine chemical speciation data and contains other ambient air pollution data
 180 collected by the Environmental Protection Agency (EPA), state, local, and tribal air pollution control
 181 agencies from thousands of monitors, comprising the Federal Reference Method (FRM) and Federal

182 Equivalent Method (FEM). The primary purpose of both methods is to assess compliance with the
183 PM_{2.5} National Ambient Air Quality Standards (NAAQS). FRMs include in-stack particulate
184 filtration, and FEMs include beta-attenuation monitoring, very sharp cut cyclones, and tapered
185 element oscillating microbalances (TOEMs). The measurement precision is $\pm (1\sim 2) \mu\text{g}/\text{m}^3$ (hour)
186 (Hall and Gilliam, 2016). The TEOM and beta-attenuation are automatic and near real-time
187 monitoring methods. The TEOM, which is based on gravity, measures the mass of particles collected
188 on filters by monitoring the frequency changes in tapered elements. The beta-attenuation method
189 uses beta-ray attenuation and particle mass to measure the PM_{2.5} concentration. In this study, we use
190 two PM_{2.5} measurement methods, FRM/FEM (88101) and non-FRM/FEM (88502). The 88502
191 monitors are “FRM-like” but are not used for regulatory purposes. Both the 88101 and 88502
192 monitors are used for reporting daily Air Quality Index values.

193 **2.2.2 PM_{2.5} Data in Canada**

194 The hourly PM_{2.5} concentration data for Canada from 1995 to 2022 are sourced from the National
195 Air Pollution Surveillance (NAPS) program, which are available at <https://www.canada.ca>. The
196 NAPS program is a collaborative effort between the Environment and Climate Change Canada and
197 provincial, territorial, and regional governments and is the primary source of environmental air
198 quality data. Since 1984, PM_{2.5} concentrations have been measured in Canada using a dichotomous
199 sampler. Continuous or real-time particle monitoring began in the NAPS network in 1995 using
200 TEOM and beta-attenuation monitoring (Demerjian, 2000). The samples are supplemented by EPA
201 FRM samples obtained after 2009 (Dabek-Zlotorzynska et al., 2011).

202 **2.2.3 PM_{2.5} Data in Europe**

203 The hourly PM_{2.5} concentration data for Europe from 1998 to 2012 are obtained from the AirBase
204 database, which is available at <https://european-union.europa.eu>. The hourly PM_{2.5} concentration
205 data (E1a) from 2013 to 2022 are obtained from the AirQuality database, which is available at
206 <https://www.eea.europa.eu>. AirBase is maintained by the European Environment Agency (EEA)
207 through its European Topic Center on Air Pollution and Climate Change Mitigation. Airbase
208 contains air quality monitoring data and information submitted by participating countries
209 throughout Europe. After the Air Quality Directive 2008/50/EC was enforced, the PM_{2.5}
210 concentration data began to be stored in AirQuality database. The main monitoring methods for
211 PM_{2.5} concentration include TEOM and beta attenuation (Green and Fuller, 2006; Chow et al., 2008).
212 The sites are distributed across rural, rural-near city, rural-regional, rural-remote, suburban, and
213 urban areas.

214 **2.2.4 PM_{2.5} Data in China**

215 The hourly PM_{2.5} concentration data for China from 2014 to 2022 are obtained from the China
216 National Environmental Monitoring Center, which are available at <https://www.cnemc.cn>. The
217 continuous monitoring of PM_{2.5} nationwide began in 2013 and PM_{2.5} concentration data are
218 available to the public. (Su et al., 2022), and there are about 2000 air quality observation sites in
219 2022. PM_{2.5} concentrations are measured using the TEOM and beta-attenuation method (Zhao et al.,
220 2016b; Miao and Liu, 2019). According to the China Environmental Protection Standards,
221 instrument maintenance, data transmission, data assurance and quality control ensure the reliability
222 of PM_{2.5} concentration measurements. The uncertainty in the PM_{2.5} concentration is $< 5 \mu\text{g}/\text{m}^3$ (Pui

223 et al., 2014).

224 **2.2.5 PM_{2.5} Data in India**

225 The hourly PM_{2.5} concentration data for India from 2010 to 2022 are obtained from the Central
226 Pollution Control Board (CPCB), which are available at <https://app.cpcbcecr.com>. The Air
227 (Prevention and Control of Pollution) Act of 1981 is enacted by the Central Pollution Control Board
228 (CPCB) of the Ministry of Environment, Forest and Climate Change (MoEFCC). The National Air
229 Quality Monitoring Programme (NQAMP) is a key air quality monitoring programme employed by
230 the Government of India, which is managed by the CPCB in coordination with the State Pollution
231 Control Boards (SPCBs) and UT Pollution Control Committees (PCCs). A standard of 60 µg/m³
232 PM_{2.5} concentration over 24 hours is added in 2009. The methods used by the Indian National
233 Ambient Air Quality Standards (NAAQS) for PM_{2.5} concentration and related component
234 measurements include the FRM and FEM (Pant et al., 2019). The measurement precision is ± (1-2)
235 µg/m³ (hour).

236 **2.2.6 PM_{2.5} data in other regions**

237 The hourly PM_{2.5} concentration data of other regions from 2016 to 2022 are from openAQ
238 (<https://openaq.org>), which is a nonprofit organization providing air quality data. These air quality
239 data are collected from environmental protection departments and other departments over the world
240 without any processing, therefore they have good accuracy. The PM_{2.5} concentrations almost are
241 measured by the TEOM and beta-attenuation method, and have been used for scientific research
242 (Jin et al., 2022; Tan et al., 2022).

243 **2.3 Visibility and Meteorological Data**

244 The hourly visibility and meteorological data are from the Integrated Surface Database (ISD) (Smith
245 et al., 2011), which is a global database consisted of hourly and synoptic surface observations and
246 archived at the NOAA's National Centers for Environmental Information (NCEI), available at
247 <https://www.ncei.noaa.gov/products/land-based-station/integrated-surface-database>. The ISD
248 database integrates data from more than 100 original data sources and incorporates data from over
249 35000 stations around the world and includes observations data dating back to 1901. The strict
250 quality control algorithms are used to ensure data quality by checking data format, extreme values
251 and limits, consistency between parameters, and continuity between observations. Detailed
252 information about the quality control are in [http://www.ncei.noaa.gov/pub/data/inventories/ish-
253 gc.pdf](http://www.ncei.noaa.gov/pub/data/inventories/ish-gc.pdf). The best spatial coverage of stations is evident in North America, Europe, Australia, and
254 parts of Asia, and the coverage in the Northern Hemisphere is better than the Southern Hemisphere.

255 Visibility and meteorological records are filtered by the geophysical report type code. The codes of
256 FM-12 and FM-15 are selected. FM-12 code represents the report is from Surface Synoptic
257 Observations (SYNOP) report, which is a coding system developed by the World Meteorological
258 Organization (WMO) for reporting observation data from ground meteorological stations. FM-15
259 code represents the report is from Meteorological Terminal Aviation Routine Weather Report
260 (METAR), providing weather information at the airport and its surrounding areas. The format and
261 content of the METAR report are consistent globally and comply with WMO's international
262 meteorological observation and reporting standards. The frequency of SYNOP report is generally
263 every three or six hours, and the frequency of METAR report is usually once per hour.

264 In this study, visibility is an essential variable for PM_{2.5} concentration. The reciprocal of visibility
265 is directly proportional to the aerosol extinction coefficient, which is closely related to the PM_{2.5}
266 concentration (Wang et al., 2009; Wang et al., 2012). Considering that temperature, wind speed,
267 humidity, and precipitation are factors that impact particle dispersion, particle growth, and
268 secondary generation (Zhang et al., 2020), temperature, dew point temperature, wind speed, and
269 precipitation are selected.

270 **2.4 Data Preprocessing**

271 When processing the visibility and meteorological variables, we use some screening conditions from
272 previous studies (Husar et al., 2000; Wang et al., 2009; Li et al., 2016; Zhong et al., 2021). We
273 remove the records with missing visibility, temperature, dew point temperature, wind speed and
274 hourly precipitation greater than 0.1 mm. Relative humidity is calculated using the Goff-Gratch
275 formula (Goff, 1957). When relative humidity is greater than 90%, the record is removed to reduce
276 the influence of fog, even precipitation. In high latitude regions, the low visibility records caused
277 by ice fog and snow are removed, when the temperature is less than -29 °C and the wind speed is
278 greater than 16 km/h. Since PM_{2.5} exhibits hygroscopic growth, dry visibility is calculated, when
279 relative humidity is between 30% and 90% (Yang et al., 2021).

$$280 \quad \mathbf{VISD} = \mathbf{VIS}/(\mathbf{0.26} + \mathbf{0.4285} * \mathbf{log}(100 - \mathbf{RH})) \quad (1)$$

281 where VIS is the visibility, RH is the relative humidity, and VISD is the dry visibility.

282 For a single visibility site, there should be at least 5 non-repetitive visibility values and at least three
283 valid records per day. The upper limit of visibility is set to the 99% percentile of visibility (Li et al.,
284 2016). The harmonic mean is used to calculate the daily VIS and VISD because it can better capture
285 rapid weather changes and enhance daily representativeness (Noaa et al., 1998). The arithmetic
286 mean is used for other variables.

287 The maximum hourly PM_{2.5} concentration is set to 1000 µg/m³. The daily PM_{2.5} concentration needs
288 at least 3 hourly records. We select the PM_{2.5} monitoring sites with a condition of at least 3-year
289 continuous monitoring. The distribution of PM_{2.5} sites is shown in Figure 1, and the details are
290 shown in Table 1.

291 The spatial matching between PM_{2.5} site and visibility station adopts the nearest principle, and the
292 upper limit of distance is set to 100 km. Through experiments that the upper limit of distance has
293 little effect on model training and prediction, but when the upper limit is small, the number of site
294 pairs significantly decreases, especially in Asia. Matched visibility stations are not be used again.
295 To match more PM_{2.5} monitoring sites, we construct a 'virtual' visibility station, whose variables are
296 established by the average of variables of the two nearest visibility stations.

297 We merge daily PM_{2.5} concentration and visibility and other meteorological variables. We have
298 adopted two matching methods: (1) merge at the hourly scale first and then calculate the daily mean
299 (2) and calculate the daily mean first and then match. The results of two methods have no impact
300 on the training of the model, but there are differences in the predicted results. Since SNOPY's
301 visibility is not continuously observed hourly, we select the second method to merge PM_{2.5}
302 concentration and visibility data on the daily scale to improve the daily representativeness of
303 estimated PM_{2.5} concentration.

304 **2.5 PM_{2.5} Data for Comparison**

305 The long-term gap-free high-resolution air pollutants (LGHAP) dataset provides daily PM_{2.5}
306 concentrations from 2000 to 2021 over global land, with a 1 km grid resolution, which is available
307 at https://zenodo.org/communities/ecnu_lghap. The PM_{2.5} concentration is estimated using aerosol
308 optical depth and other factors such as geographic location, land cover type, climate zone, and
309 population density, based on a deep-learning approach, termed the scene-aware ensemble learning
310 graph attention network. The correlation coefficient with ground-based measurements is 0.95 and
311 the RMSE is 5.7 $\mu\text{g}/\text{m}^3$ (Bai et al., 2024). This dataset provides global PM_{2.5} concentration with a
312 high spatiotemporal resolution.

313 For most regions in the Northern Hemisphere, except for North America and Europe, the duration
314 of continuous monitoring PM_{2.5} concentration data is relatively short, making it difficult to evaluate
315 historical PM_{2.5} concentration. For example, PM_{2.5} monitoring network in China was implemented
316 from the end of 2012, resulting in the inability to verify the PM_{2.5} concentrations before 2012.
317 Therefore, we compare our data with the LGHAP PM_{2.5} concentration to evaluate the predictive
318 ability of the model and the consistency of our data on the temporal scale.

319 **2.6 Decision Tree Regression**

320 We employ decision tree regression (Teixeira, 2004) to estimate daily PM_{2.5} concentrations. The key
321 to decision tree regression is to find the optimal split variable and optimal split point. The optimal
322 split point of the predictor is determined by the minimum mean squared error, which determines the
323 optimal tree structure. Decision tree regression is a commonly used nonlinear machine learning
324 method that partitions the feature space based on the mapping between feature attributes and
325 response values, with each leaf node representing a specific output for each feature space region.
326 It's ability to handle complex relationships with relatively few model parameters is advantageous,
327 minimizing the risk of overfitting and enabling the prediction of continuous and categorical
328 predictive variables.

329 The sample data includes predictor and response. The predictor is composed of 9 variables: the
330 reciprocal of dry visibility (Vis_Dry_In), the reciprocal of visibility (Vis_In), temperature (Temp),
331 dew point temperature (Td), temperature-dew point difference (Temp-Td), relative humidity (RH),
332 wind speed (WS), wind numerical time (DateTime) and daily record number (DailyObsNum). Both
333 visibility and meteorological variables are daily means. The response variable is the daily monitored
334 PM_{2.5} concentration.

335 For each site, we sort the sample data by time, with the first 80% being the training set and the last
336 20% being the test set. Due to the inconsistent sample length among different sites, this approach is
337 friendly for sites with small sample sizes (such as only 3-year observations). We use 10-fold cross-
338 validation method (Browne, 2000) to train the model. The test set is used to evaluate the predictive
339 ability of the model.

340 **2.7 Evaluation Metrics**

341 **2.7.1 Statistical Metrics**

342 We use the root mean squared error (RMSE), mean absolute error (MAE), and correlation
343 coefficient (ρ) as evaluation metrics to evaluate the model's performance and predictive ability. The

344 formulas are given as follows:

$$345 \quad \mathbf{MSE} = \sqrt{\frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2} \quad (2)$$

$$346 \quad \mathbf{MAE} = \frac{1}{n} \sum_{i=1}^n |y_i - \hat{y}_i| \quad (3)$$

$$347 \quad \rho = \frac{\sum_{i=1}^n (y_i - \bar{y})(\hat{y}_i - \bar{\hat{y}})}{\text{sqrt}(\sum_{i=1}^n (y_i - \bar{y})^2 \sum_{i=1}^n (\hat{y}_i - \bar{\hat{y}})^2)} \quad (4)$$

348 where y_i and \bar{y} are the predicted value and the average of the predicted values. \hat{y}_i and $\bar{\hat{y}}$ are
349 the target and the average of the target. $i = 1, 2, \dots, n$. n is the length of sample.

350 2.7.2 Partial Dependence

351 The importance of predictor variables is assessed via partial dependence. Partial dependence
352 represents the relationship between the individual predictive variable and the predicted response
353 (Friedman, 2001). By marginalizing the other variables, the expected response of the predicted
354 variable is calculated. All the partial dependences of the predicted response on the subset of
355 predicted variables are calculated. The calculation process of the partial dependency method is
356 described as follows:

357 The dataset of the predictor is X , $X = [X^1, X^2, \dots, X^n]$, and n represents the number of predictive
358 factors. The complement of subset X^s is X^c , where X^s is a single variable in X and X^c is all
359 other variables in X . The predicted response $f(x)$ depends on all variables in X , and it is expressed
360 as follows:

$$361 \quad \mathbf{f}(x) = \mathbf{f}(X^s, X^c) \quad (5)$$

362 The partial dependence of the predicted response to X^s is expressed as follows:

$$363 \quad \mathbf{f}^s(X^s) = \int \mathbf{f}(X^s, X^c) \mathbf{pC}(X^c) dX^c \quad (6)$$

364 where $\mathbf{pC}(X^c)$ is the marginal probability of X^c , that is, $\mathbf{pC}(X^c) \approx \int \mathbf{f}(X^s, X^c) dX^s$. Assuming
365 that the likelihood for each observation is equal, the dependence between X^s and X^c and the
366 interactions of X^s and X^c in response are not strong. The partial dependence is shown below:

$$367 \quad \mathbf{f}^s(X^s) \approx \frac{1}{N} \sum_{i=1}^N \mathbf{f}(X^s, X_i^c) \quad (7)$$

368 where N is the number of observations and i represents the i th observation.

369 2.7.3 Generalized Additive Mixed Model

370 Generalized Additive Mixed Model (GAMM) originates from two independent yet complementary
371 statistical methods: Generalized Additive Model (GAM) and Mixed Effects Models. GAM is
372 introduced by Trevor Hastie and Robert Tibshirani in the 1980s (Hastie and Tibshirani, 1987). GAM
373 employs smooth functions (such as splines) to replace linear terms in traditional regression,
374 capturing nonlinear relationships between response and explanatory variables. The primary aim of
375 GAM is to enhance model flexibility, allowing the data to determine the form of the nonlinear
376 relationships rather than pre-specifying them. Mixed Effects Model includes both fixed and random

377 effects, enabling the analysis of hierarchical and correlated data (Verbeke and Lesaffre, 1996). Fixed
378 effects apply to the entire sample, whereas random effects account for variations within individuals
379 or groups, explaining data correlation and variability. GAMM represents the evolution of statistical
380 models from linear to nonlinear, from simple to complex, and from single effects to mixed effects.
381 GAMM has been widely applied in various fields such as ecology and climate, air pollution
382 becoming essential tools for studying complex nonlinear relationships and hierarchical data (Park
383 et al., 2013; Polansky and Robbins, 2013; Chang et al., 2017; Ravindra et al., 2019).

384 The relationship between PM_{2.5} concentrations and time (e.g., months, seasons) is typically
385 nonlinear and exhibits seasonal variation. GAMM model uses smooth functions (such as splines) to
386 capture the nonlinear variations and model the periodic features with cyclical smooth functions.
387 Interannual variations in PM_{2.5} concentrations can also be captured using smooth functions. Due to
388 the inherent autocorrelation in time series, GAMM model effectively handles the autocorrelation by
389 incorporating time-related smooth functions or random effects, thereby enhancing the model
390 accuracy. PM_{2.5} concentrations from neighboring locations often exhibit spatial correlation. GAMM
391 model can address this spatial correlation by introducing spatially correlated smooth functions or
392 random effects. Therefore, it is also suitable for spatial variations, especially when the spatial
393 distribution of sites observations is uneven.

394 Based on the GAMM, the PM_{2.5} concentration $y(i, t)$ at site i and time t can be expressed as:

$$395 \mathbf{y}(i, t) = \mathbf{x}\boldsymbol{\beta} + \mathbf{f}(\cdot) + \mathbf{b}(i, t) + \boldsymbol{\varepsilon}(i, t) \quad (8)$$

396 The following is an explanation of the expression and parameter settings.

397 *Linear terms* $\mathbf{x}\boldsymbol{\beta}$: \mathbf{x} is the vector of explanatory variables, including site elevation and the overall
398 mean PM_{2.5} concentration. $\boldsymbol{\beta}$ is a coefficient vector.

399 *Smooth terms* $\mathbf{f}(\cdot)$ can be decomposed into three individual smooth terms: seasonal smooth term,
400 interannual smooth term, and spatial smooth term, as shown in equation (9).

$$401 \mathbf{f}(\cdot) = \mathbf{f}(\mathbf{month}) + \mathbf{f}(\mathbf{year}) + \mathbf{f}(\mathbf{spatial}) \quad (9)$$

402 They are composed of linear combinations using spline basis functions. For seasonal smooth term,
403 it is a function of the month, smooth function is the penalized regression cyclic cubic splines
404 (assumed with periodic nature) (Wood et al., 2016) and the knot number is 12. For interannual
405 smooth term, it is a function of the year, smooth function is the penalized regression cubic splines
406 (Wood et al., 2016) and the knot number is 64. For spatial smooth term, it is a function for longitude
407 and latitude, smooth function is the gaussian process penalized regression splines (Kammann and
408 Wand, 2003) and the knot number is 80. In this study, they are used to describe the regional long-
409 term PM_{2.5} concentration annual cycle, interannual trends and spatial distribution, respectively.

410 Station-specific effects term $\mathbf{b}(i, t)$ is a random effect term to describe the differences between
411 observation sites, based on the assumption that observations are independent.

412 The residual noise term $\boldsymbol{\varepsilon}(i, t)$ 1-order autoregressive term.

413 More explanations about GAMM model are detailed in the package mgcv of R. Some studies also
414 provide an introduction and selection of parameters (Polansky and Robbins, 2013; Chang et al.,
415 2017; Ravindra et al., 2019).

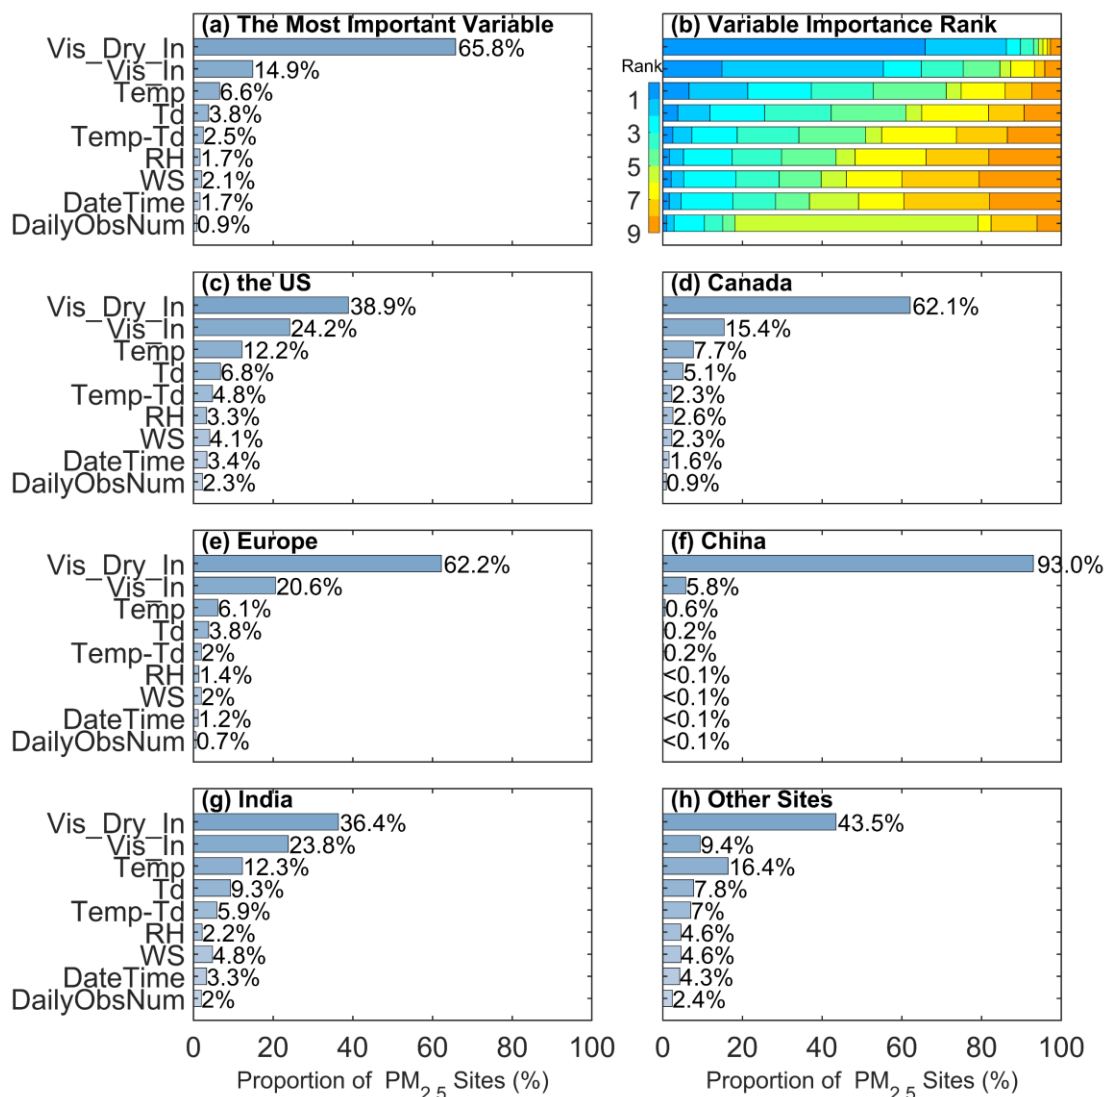

416 **3. Results and Discussion**

417 **3.1 Evaluation of Variable Importance**

418 We evaluate the contribution of each variable to the response by partial dependence. The variable
419 with the highest partial dependence value is the most important variable in the model. Figure 2 (a)
420 shows the proportion of the most important variables for all sites and Figure 2 (b) shows the ranking
421 of the importance of all variables. Reciprocal of dry visibility is the most important variable at 65.8%
422 of sites, and Reciprocal of visibility is the second most important variable at 14.9% of sites. The
423 contribution of meteorological variables ranges from 2.1% to 6.6%. The time variable contributes
424 1.7%. The lowest contribution is daily number of visibility record at only 0.9%, because it is only a
425 variable that describes the daily representativeness of visibility. It also indicates that daily visibility
426 has high daily representativeness (under the conditions of at least three hourly records)

427 The $PM_{2.5}$ concentration level varies spatially, which are related to regional geographical
428 environment, climate, and air quality laws and regulations. Therefore, we analyze the importance
429 of variables in different regions, as shown in Figure 2 (c-h). The two most important variables are
430 still reciprocal of dry visibility and reciprocal of visibility, with a proportion of 73.1% in the United
431 States, 77.5% in Canada, 80.8% in Europe, 98.8% in China, and 60.2% in India. It indicates that
432 $PM_{2.5}$ concentration is the most significantly correlated with visibility in China. The contribution of
433 meteorological variables is significantly higher in the United States and India than in other regions.
434 It indicates that meteorological conditions have a significant contribution to $PM_{2.5}$ concentration in
435 these regions, which may be related to the formation mechanism and transport of particulate matter.

436 The above results indicate a strong correlation between the $PM_{2.5}$ concentration and visibility, as
437 visibility can be considered an indicator of air quality without fog or precipitation. Meteorological
438 factors play secondary roles, which influence the formation, dispersion and deposition of $PM_{2.5}$ (Gui
439 et al., 2020; Zhong et al., 2022). Although the number of daily records and time have the most
440 negligible impacts on the $PM_{2.5}$ concentration in the model, they have significant impacts on the
441 cyclical changes and daily representativeness of $PM_{2.5}$ concentration (Wang et al., 2012; Zhang et
442 al., 2020).

443

444 **Figure 2.** The most important variable (a) and the ranking (b) at all sites. The most important
 445 variable in each region (c-h). The stacked bar shows the importance rankings of the variables
 446 ('rank=1' represents the most important variable). The bar shows the proportion of the most
 447 important variable. The variables are the reciprocal of dry visibility (Vis_Dry_In), reciprocal of
 448 visibility (Vis_In), temperature (Temp), dew point temperature (Td), temperature-dew point
 449 difference (Temp-Td), relative humidity (RH), wind speed (WS), numerical time (DateTime) and
 450 daily number of visibility record (DailyObsNum).

451 **3.2 Evaluation of Model Performance**

452 We analyze the linear regression relationship between all estimated and corresponding response
 453 values to evaluate the model's performance. Figure 3 is the density scatter plot of the monitored
 454 PM_{2.5} concentration (response values) and the estimated PM_{2.5} concentration (estimated values).
 455 There is a total of 8031473 data pairs for all the sites. The linear regression slope (95% confidence
 456 interval) is 0.955 [0.955, 0.955], the R² is 0.95, the RMSE is 7.2 μg/m³, and the MAE is 3.2 μg/m³.

457

458 **Figure 3.** Density scatter plot (a) between estimated $\text{PM}_{2.5}$ concentration and monitored $\text{PM}_{2.5}$
 459 concentration. The dashed black line is the linear regression line. N is the length of the data pairs,
 460 and Slope is the linear regression coefficient within a 95% confidence interval (CI). R^2 is the
 461 coefficient of determination, RMSE is the root mean square error, and MAE is the mean absolute
 462 error.

463 Figure 4 (a-c) shows the spatial distribution (a-c) and frequency of training of RMSE, MAE, and ρ .
 464 Table 2 lists the model's performance metrics in the United States, Canada, Europe, China, and India.
 465 For all sites, the average RMSE is $6.92 \mu\text{g}/\text{m}^3$, with a median of $4.76 \mu\text{g}/\text{m}^3$. The RMSE of 80%
 466 of the sites is less than $10.01 \mu\text{g}/\text{m}^3$. The RRMSE (the percentage of RMSE to mean of $\text{PM}_{2.5}$
 467 concentration) is 28.7%. The MAE is $3.77 \mu\text{g}/\text{m}^3$, with a median of $2.72 \mu\text{g}/\text{m}^3$. The MAE is less
 468 than $5.66 \mu\text{g}/\text{m}^3$ for 80% of the sites. The RMAE (the percentage of MAE to mean of $\text{PM}_{2.5}$
 469 concentration) is 15.4%. The average ρ is 0.91, and the median is 0.92. The ρ of 80% of the sites is
 470 greater than 0.87. Previous studies have shown that for $\text{PM}_{2.5}$ concentration retrieved from daily
 471 visibility or satellite aerosol optical depth, the R^2 range of the model is from 0.42 to 0.89, and the
 472 RMSE range is from $9.59 \mu\text{g}/\text{m}^3$ to $32.09 \mu\text{g}/\text{m}^3$ (Shen et al., 2016; Liu et al., 2017; Wei et al., 2019b;
 473 Gui et al., 2020; Li et al., 2021; Zhong et al., 2021). This finding indicates that our model performs
 474 well at the daily scale.

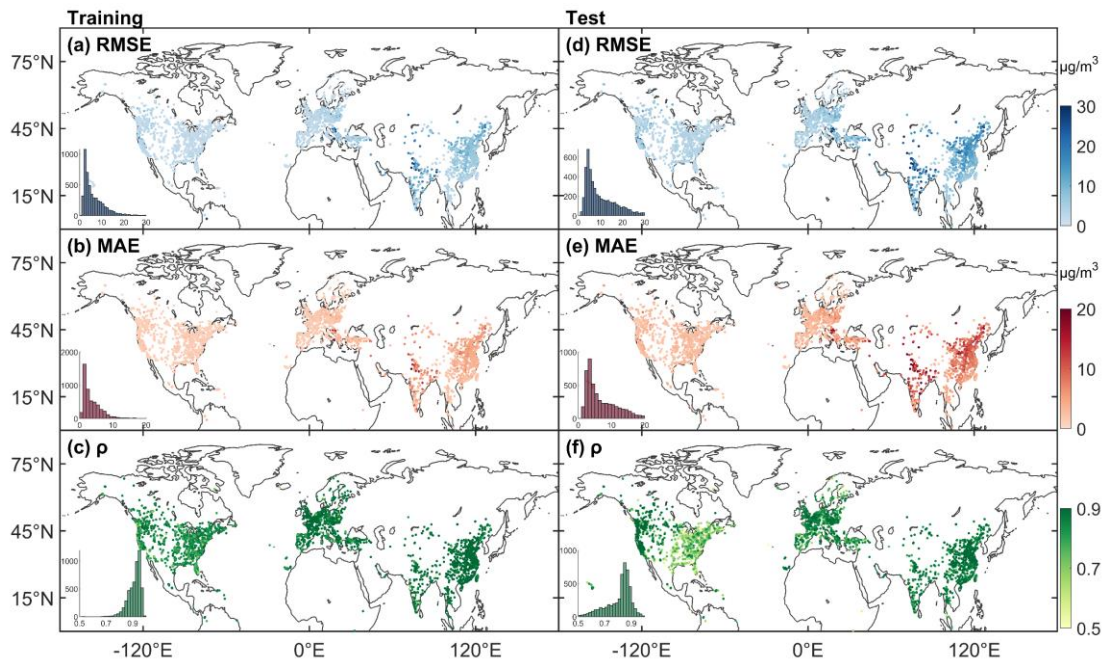

475 On the regional scale, the RMSE values for the United States, Canada, Europe, China, and India are
 476 $3.10 \mu\text{g}/\text{m}^3$, $2.78 \mu\text{g}/\text{m}^3$, $4.92 \mu\text{g}/\text{m}^3$, $9.65 \mu\text{g}/\text{m}^3$ and $17.46 \mu\text{g}/\text{m}^3$, respectively. and the RRMSE
 477 values are 34.9%, 40.4%, 29.8%, 23.1%, and 28.8%, respectively. The MAEs for the United States,
 478 Canada, Europe, China, and India are $1.61 \mu\text{g}/\text{m}^3$, $1.35 \mu\text{g}/\text{m}^3$, $2.54 \mu\text{g}/\text{m}^3$, $5.47 \mu\text{g}/\text{m}^3$, and 9.13

479 $\mu\text{g}/\text{m}^3$, respectively. The RMAEs are 17.9%, 19.5%, 16.3%, 13.1%, and 14.4%, respectively. The ρ
 480 values for the United States, Canada, Europe, China, and India are 0.87, 0.88, 0.91, 0.94, and 0.92,
 481 respectively. The correlation coefficients are higher in China and India, low in the United States and
 482 Canada.

483 The largest RMSE and MAE are in India, and the smallest are in Canada. The RRMSE and RMAE
 484 are larger in the United States, Canada and Europe than in China and India and other regions.

485 **Table 2.** The metrics for all sites and sites in the United States (the US), Canada, Europe, China and
 486 India. RRMSE is the percentage of RMSE to mean of $\text{PM}_{2.5}$ concentration. RMAE is the percentage
 487 of MAE to mean of $\text{PM}_{2.5}$ concentration.

<i>Region</i>	<i>RMSE</i> ($\mu\text{g}/\text{m}^3$)	<i>MAE</i> ($\mu\text{g}/\text{m}^3$)	ρ	<i>Mean</i> ($\mu\text{g}/\text{m}^3$)	<i>RRMSE</i> (%)	<i>RMAE</i> (%)
<i>All</i>	6.92	3.77	0.91	26.7	28.7	15.4
<i>the US</i>	3.10	1.61	0.87	9.1	34.9	17.9
<i>Canada</i>	2.78	1.35	0.88	6.9	40.4	19.5
<i>Europe</i>	4.92	2.54	0.91	15.7	29.8	16.3
<i>China</i>	9.65	5.47	0.94	42.1	23.1	13.1
<i>India</i>	17.46	9.13	0.92	63.1	28.8	14.4
<i>Other</i>	6.11	3.32	0.91	23.4	24.8	14.1

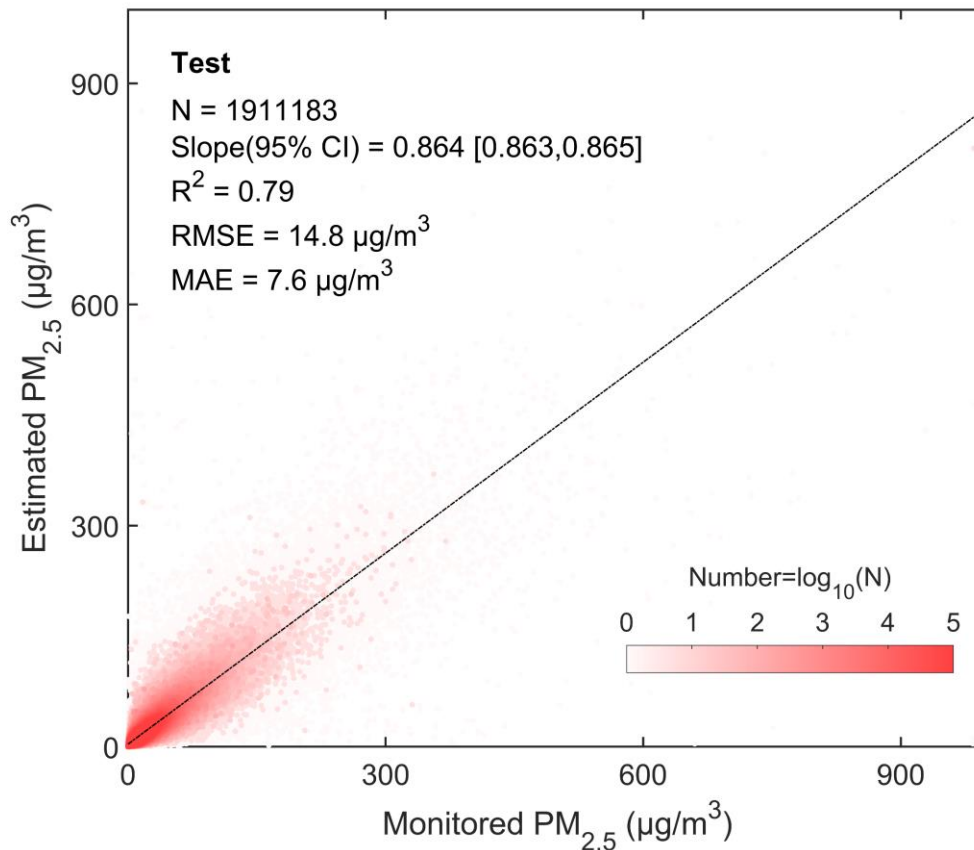

488
 489 **Figure 4.** Statistical Metrics distribution of training (left) and test (right). The bar is the frequency
 490 of sites. RMSE is the root mean square error, MAE is the mean absolute error, and ρ is the correlation
 491 coefficient.

492 3.3 Evaluation of Model's Predictive Ability

493 A total of 1911183 pairs of test data is employed to evaluate the model's predictive ability. Figure 5
 494 is the density scatter plot between the predicted $\text{PM}_{2.5}$ concentration and the test $\text{PM}_{2.5}$ concentration.
 495 The linear regression slope (95% CI) is 0.864 [0.863, 0.865], R^2 is 0.79, RMSE is $14.8 \mu\text{g}/\text{m}^3$, and

496 MAE is $7.6 \mu\text{g}/\text{m}^3$. Previous studies have shown that the R^2 range of the model's predictive results
 497 at the daily scale is 0.31 - 0.84, and the RMSE range is $13.8\text{-}29.0 \mu\text{g}/\text{m}^3$ (Gui et al., 2020; Zhong et
 498 al., 2021). The test results exhibit excellent predictive capability.

499

500 **Figure 5.** Density scatter plot (a) between the predicted $\text{PM}_{2.5}$ concentration and monitored $\text{PM}_{2.5}$
 501 concentration of the test results. The dashed black line is the linear regression line. N is the length
 502 of the data pairs, and Slope is the linear regression coefficient within a 95% confidence interval (CI).
 503 R^2 is the coefficient of determination, RMSE is the root mean square error, and MAE is the mean
 504 absolute error.

505 We analyze the test results for Canada, the United States, Europe, China, and India to assess the
 506 predictive ability of the model in different regions. Figure 4 (d - f) shows the spatial distributions of
 507 the test RMSE, MAE, and ρ and their frequency. Table 3 lists the test results of the metrics. For all
 508 sites, the average RMSE is $11.50 \mu\text{g}/\text{m}^3$. The RRMSE is 46.0%. The average MAE is $7.72 \mu\text{g}/\text{m}^3$.
 509 The RMAE is 30.7%. The ρ is 0.81. For the United States, the RMSE, MAE, and ρ are $5.06 \mu\text{g}/\text{m}^3$,
 510 $3.25 \mu\text{g}/\text{m}^3$, and 0.72, respectively. For Canada, the RMSE, MAE, and ρ are $4.73 \mu\text{g}/\text{m}^3$, $2.88 \mu\text{g}/\text{m}^3$,
 511 and 0.77, respectively. The results in the United States and Canada are better in the west than in the
 512 east. The RMSE, MAE, and ρ for Europe are $7.79 \mu\text{g}/\text{m}^3$, $5.10 \mu\text{g}/\text{m}^3$, and 0.80, respectively. For
 513 China, the RMSE, MAE, and ρ are $16.83 \mu\text{g}/\text{m}^3$, $11.50 \mu\text{g}/\text{m}^3$, and 0.85, respectively. For India, the
 514 RMSE, MAE, and ρ are $27.05 \mu\text{g}/\text{m}^3$, $17.89 \mu\text{g}/\text{m}^3$, and 0.85, respectively. The results show that in
 515 developing regions (China and India), ρ is better than that in developed regions (the United States,
 516 Canada, and Europe), which means that the predictive ability of the model is better for severely
 517 polluted regions.

518 **Table 3.** The test results of the model's performance metrics for all sites and sites in the United
 519 States, Canada, Europe, China and India. RRMSE is the percentage of RMSE to mean of PM_{2.5}
 520 concentration. RMAE is the percentage of MAE to mean of PM_{2.5} concentration.

<i>Region</i>	<i>RMSE</i> ($\mu\text{g}/\text{m}^3$)	<i>MAE</i> ($\mu\text{g}/\text{m}^3$)	ρ	<i>Mean</i> ($\mu\text{g}/\text{m}^3$)	<i>RRMSE</i> (%)	<i>RMAE</i> (%)
<i>All</i>	11.50	7.72	0.81	27.1	46.0	30.7
<i>the US</i>	5.06	3.25	0.72	9.4	54.3	35.0
<i>Canada</i>	4.73	2.88	0.77	7.2	65.6	40.0
<i>Europe</i>	7.79	5.10	0.80	15.9	47.0	32.0
<i>China</i>	16.83	11.50	0.85	42.6	39.6	27.1
<i>India</i>	27.05	17.89	0.85	63.7	42.9	27.8
<i>Other</i>	8.86	6.16	0.81	23.4	36.7	26.1

521 3.4 Uncertainties and Limitations

522 3.4.1 Uncertainty in the Pollution Level

523 Figure 6 shows the uncertainty in the predicted PM_{2.5} concentration with respect to the pollution
 524 level of the monitored PM_{2.5} concentration. For all sites, the uncertainty in the bias increases as the
 525 pollution level increases. The mean and median of the bias shift from positive to negative with
 526 increasing pollution levels. 83.6% of PM_{2.5} concentration data is less than 45 $\mu\text{g}/\text{m}^3$, and the mean
 527 bias ($< 0.8 \mu\text{g}/\text{m}^3$) is positive. 36.8% is less than 10 $\mu\text{g}/\text{m}^3$, and the median ($< 0.4 \mu\text{g}/\text{m}^3$) of the bias
 528 is positive. 16.4% of PM_{2.5} concentration is great than 45 $\mu\text{g}/\text{m}^3$, and the mean bias is negative. 63.2%
 529 of PM_{2.5} concentration is great than 10 $\mu\text{g}/\text{m}^3$, and the median is negative. It indicates that the model
 530 overestimates at low pollution level and underestimates at high pollution level.

531 The bias for each region also increases with pollution level. For the United States, the mean bias of
 532 69.4% is positive and less than 0.8 $\mu\text{g}/\text{m}^3$, and the PM_{2.5} concentration is less than 10 $\mu\text{g}/\text{m}^3$. When
 533 the PM_{2.5} concentration is greater than 10 $\mu\text{g}/\text{m}^3$, the mean bias is negative. For Canada, the mean
 534 bias of 74.1% is positive and less than 0.7 $\mu\text{g}/\text{m}^3$. When the PM_{2.5} concentration is greater than 8
 535 $\mu\text{g}/\text{m}^3$, the mean bias is negative. For Europe, the mean bias of 67.1% is positive and less than 0.9
 536 $\mu\text{g}/\text{m}^3$. When the PM_{2.5} concentration is greater than 15 $\mu\text{g}/\text{m}^3$, the mean bias is negative. For China,
 537 67.7% of the bias is positive and less than 2.7 $\mu\text{g}/\text{m}^3$. When the PM_{2.5} concentration is greater than
 538 45 $\mu\text{g}/\text{m}^3$, the mean bias is negative. For India, 80.1% of the bias is positive and less than 4.2 $\mu\text{g}/\text{m}^3$,
 539 and when the PM_{2.5} concentration is greater than 100 $\mu\text{g}/\text{m}^3$, the mean bias is negative. When the
 540 PM_{2.5} concentration is greater than 60 $\mu\text{g}/\text{m}^3$, the bias median is negative, with a percentage of
 541 40.3%. The uncertainty in each region is similar, and the uncertainty increases as the pollution level
 542 increases.

543

544 **Figure 6.** Boxplots of the pollution level and bias (predicted $PM_{2.5}$ concentration - monitored $PM_{2.5}$
 545 concentration) for all sites (a), sites in the United States (b), Canada (c), Europe (d), China (e), and
 546 India (f). The box's upper and lower limits represent ± 1 standard deviation, the whiskers represent
 547 2 times the standard deviation, the red circle represents the median, and the short line represents the
 548 mean bias. The frequency (%) on the right y-axis represents the percentage of data with different
 549 pollution levels (dashed line).

550 3.4.2 Uncertainty in the Station Elevation

551 With the spatial variability in $PM_{2.5}$ concentration, we analyze the mean bias at different visibility
 552 station elevations. Figure 7 shows the relationships between the elevations of the visibility stations
 553 and the bias. The bias exhibits variations across different elevations for all stations. The mean bias
 554 of all sites ranges from -0.04 to $0.02 \mu\text{g}/\text{m}^3$. A total of 90.1% of the stations has positive biases. The
 555 median of the bias is almost positive, with a positive bias of 99.5% stations, except for the elevation
 556 at 4 km. The elevations of 86.5% of the stations are less than 1 km, with a positive median of the
 557 bias. High uncertainties in bias occur at elevations of 0.05 km, 0.2 km, and 0.3 km. Negative biases
 558 are observed at elevations of 0.4 km, 0.9-1 km, and 4 km. This finding indicates a nonsignificant
 559 overestimation of the predicted $PM_{2.5}$ concentration due to the various elevations.

560 The bias patterns vary across regions. For the United States, a total of 88.8% of the stations have
 561 negative biases. The median of the bias is negative with a percentage of 63.4%. High uncertainties
 562 in bias occur at elevations of 0.05 km, 2 km, and 0.3 km. For Canada, 52.3% of the stations have
 563 positive biases. The median of the bias is negative with a percentage of 33.8%. High uncertainties
 564 in bias occur at elevations of 0.05 km and 1 km. For Europe, 58.9% of the stations have positive
 565 biases. The median of the bias is negative with a percentage of 40.2%. High uncertainties in bias
 566 occur at elevations of 0.05 km and 0.9 km. For China, 76.7% of the stations have negative biases.

567 The median of the bias is negative with a percentage of 54.1%. High uncertainties in bias occur at
 568 elevations of 0.05 km, 0.5 km and 3 km. For India, 68.1% of the stations have positive biases. The
 569 median of the bias is negative with a percentage of 63.8%. The elevation of most stations with a
 570 high uncertainty is at 0.05 km. High uncertainties in bias occur at elevations of 0.1 km and 3 km.
 571 More stations with negative bias are in the United States and China. More stations with positive bias
 572 are in Canada, Europe and India.

573

574 **Figure 7.** Boxplots of the bias (predicted PM_{2.5} concentration - monitored PM_{2.5} concentration) and
 575 the elevation of the visibility station for all sites (a), sites in the United States (b), Canada (c),
 576 Europe (d), China (e), and India (f). The box's upper and lower limits represent ± 1 standard deviation,
 577 the whiskers represent 2 times the standard deviation, the red circle represents the median, and the short
 578 line represents the mean bias. The station number (%) on the right y-axis represents the percentage
 579 of station number at different elevations (dashed line).

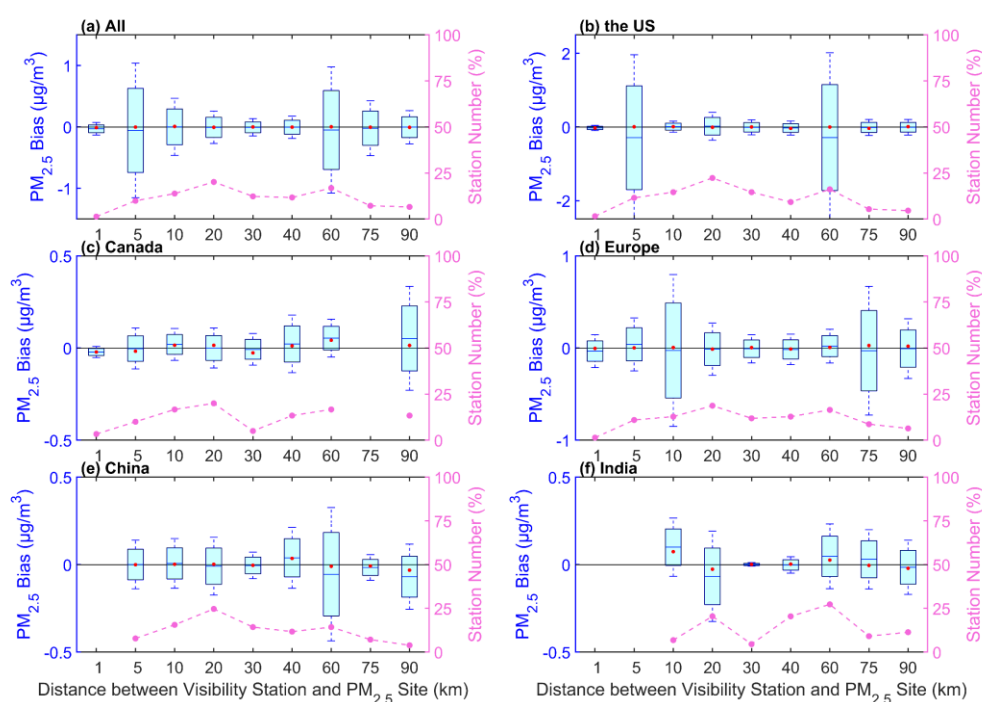

580 3.4.3 Uncertainty in the Station Distance

581 As the visibility stations and PM_{2.5} sites are not collocated, we analyze the mean bias of PM_{2.5}
 582 concentration at different distances, as shown in Figure 8. For all sites, 86.1% of the stations have
 583 negative biases. The median of the bias is negative with a percentage of 70.8%. More stations have
 584 a negative bias caused by the distance. The uncertainty has no signification with the distance. The
 585 distances with low uncertainties are at 1 km and 20-40 km. The distances with high uncertainties
 586 are at 5 km and 60 km.

587 For the United States, 63.1% of the stations have negative biases. The median of the bias is negative
 588 with a percentage of 69.2%. The distance with the lowest uncertainty is at 1 km. The distances with
 589 high uncertainties are at 5 km and 60 km. For Canada, 60.0% of the stations have positive biases.
 590 The median of the bias is positive with a percentage of 80.0%. The uncertainty shows an increase
 591 with the distance increasing. For Europe, 72.7% of the stations have negative biases. The median of
 592 the bias is positive with a percentage of 67.1%. When the distance is less than 10 km, the uncertainty

593 increases with the distance. The distances with low uncertainties are at 1 km and 30-40 km. The
 594 distances with high uncertainties are at 10 km and 75 km. For China, 64.3% of the stations have
 595 negative biases. The median of the bias is negative with a percentage of 72.7%. The distance with a
 596 low uncertainty is at 30 km. The distance with a high uncertainty is at 60 km. For India, 62.3% of
 597 the stations have negative biases. The median of the bias is positive with a percentage of 59.1%.
 598 The distance with the lowest uncertainty is at 30 km. The distance with the highest uncertainty is at
 599 20 km.

600 More visibility stations have negative biases, except for the stations in Canada. For the stations in
 601 the United States, Canada and Europe, the lowest uncertainty is at 1 km. For the stations in China
 602 and India, the uncertainty has no significant relationship with distance, though the distance has
 603 caused a negative bias.

604

605 **Figure 8.** Boxplots of the mean bias (predicted PM_{2.5} concentration - monitored PM_{2.5} concentration)
 606 and the distance between the visibility station and the PM_{2.5} site and for all sites (a), sites in the
 607 United States (b), Canada (c), Europe (d), China (e), and India (f). The box's upper and lower limits
 608 represent ±1 standard deviation, the whiskers represent 2 times the standard deviation, the red circle
 609 represents the median, and the short line represents the mean bias. The station number (%) on the
 610 right y-axis represents the percentage of station number under different distances (dashed line).

611 3.4.4 Discussion on the Uncertainties and Limitations

612 There are some uncertainties and limitations in this study. The upper limit of visibility and PM_{2.5}
 613 concentration can cause some uncertainties in model training. The maximum distance between the
 614 visibility stations and PM_{2.5} monitoring sites is 100 km due to the spatial variability in aerosols,
 615 which may increase the uncertainty in the estimated PM_{2.5} concentration. Because of the nonuniform
 616 vertical distribution of aerosols, the different elevations of the visibility stations and the PM_{2.5}
 617 monitoring sites further increase the uncertainty in estimating PM_{2.5} concentration. In addition, the

618 spatial coverage of visibility stations, especially in China and India, is still limited, which may
619 increase the uncertainty in the representativeness of regional PM_{2.5} concentration and pollution
620 levels. With the increasing human concern of air pollution and the implementation of air pollution
621 control measures, the types of major atmospheric pollutants may have changed at regional scale, the
622 composition of particulate matter has also evolved, the scattering and absorption characteristics may
623 have changed, and the relationship between visibility and PM_{2.5} concentration may change. These
624 changes may lead to uncertainties in estimating historical PM_{2.5} concentration. It is challenging to
625 validate by ground observations and satellite-based estimation prior to 2000. Despite these
626 limitations and challenges, we establish a long-term PM_{2.5} concentration dataset based on visibility
627 from 1959 to 2022, which has been carefully validated and evaluated, providing insights into the
628 long-term spatiotemporal characteristics of concentration PM_{2.5} in the Northern Hemisphere.

629 **4 Comparisons with Other PM_{2.5} Concentration Dataset**

630 We compare the daily and monthly estimated PM_{2.5} concentration with the LGHAP PM_{2.5}
631 concentration from 2000 to 2021 to further demonstrate the reliability the estimated PM_{2.5}
632 concentration. When comparing on the regional scale, we split the time range into 2000-2010 and
633 2011-2021, to further validate the accuracy and consistency of estimated PM_{2.5} concentrations, as
634 in some regions such as India and China, there are almost no continuous PM_{2.5} monitoring data
635 before 2010.

636 **4.1 Comparisons on the Daily Scale**

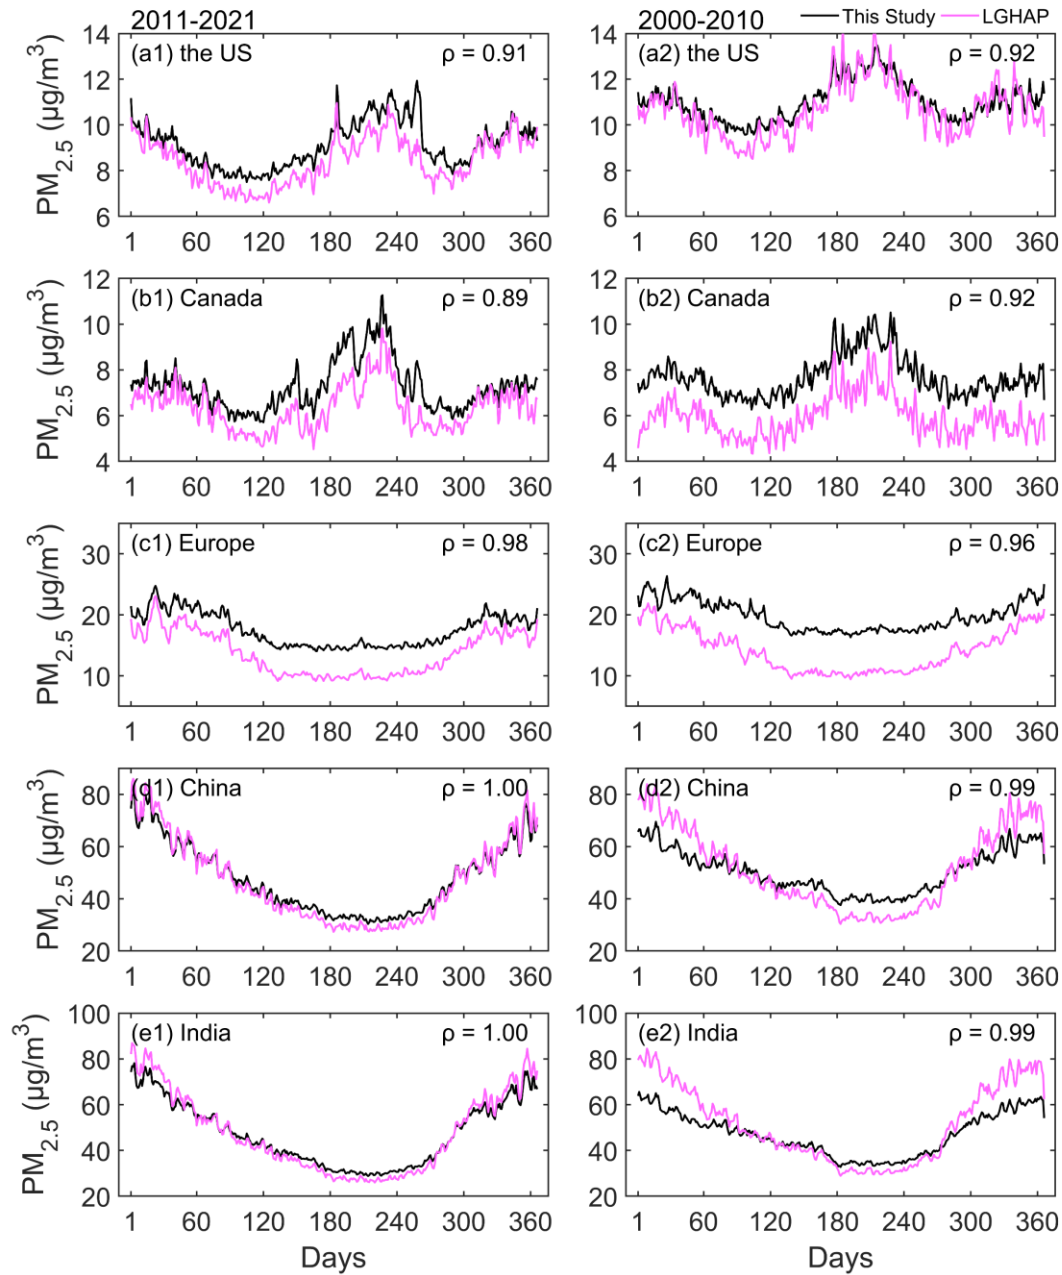

637 We spatiotemporally match the LGHAP PM_{2.5} concentration with the estimated PM_{2.5} concentration.
638 Figure 9 shows the density scatter plot between the estimated PM_{2.5} concentration and LGHAP
639 PM_{2.5} concentration. There is a total of 96188682 pairs during the period of 2000 and 2021,
640 46846389 pairs during the period from 2000 to 2010, and 49342302 during the period of 2011 and
641 2021, with slopes of 0.817, 0.758 and 0.867. The intercepts are 6.928 µg/m³, 8.933 µg/m³, and 5.377
642 µg/m³, respectively. The slope decreases before 2010, which may be related to the upper limit of
643 LGHAP PM_{2.5} concentration with a significantly decreasing quantity of the concentration (> 300
644 µg/m³).

645 We further compare the PM_{2.5} concentrations of the annual calendar cycles on the regional scale in
646 Figure 10. The PM_{2.5} concentration of each day is the mean of the PM_{2.5} concentrations at all sites
647 in the region. The correlation coefficients of the PM_{2.5} concentrations are greater than 0.89 from
648 2011 to 2021 and greater than 0.92 from 2000 to 2010. The correlation is greater in Europe, China,
649 and India than in the United States and Canada. There is no significant difference in the variation of
650 annual calendar cycles between two periods on the regional scale. In the United States, PM_{2.5}
651 concentration between 2000 and 2010 is more similar than the concentration between 2011 and
652 2021, and the bias decreases. In Canada, the correlation coefficient increases, although the bias
653 increases. In Europe, the correlation coefficient and bias increase. There are similar changes in
654 China and India. The bias increases on days 1 to 60 and 300 to 366, but the correlation remains
655 significant. The difference of PM_{2.5} concentration during the two periods is mainly reflected in the
656 increasing bias in Canada and Europe, which is a non-seasonal bias and the increasing bias in winter
657 in China and India, which is a seasonal bias. Overall, PM_{2.5} concentrations show a good consistency
658 before and after 2010 on the daily scale.

659

660 **Figure 9.** Density scatter plot between the estimated PM_{2.5} concentration (this study) and LGHAP
 661 PM_{2.5} concentration on the daily scale from 2000 to 2021 (a), from 2000 to 2010 (b) from 2011 to
 662 2021. The dashed black line is the linear regression line. N is the length of the data pairs, and Slope
 663 is the linear regression coefficient. Intercept represents the y-intercept.

664

665 **Figure 10.** Comparison of annual calendar cycle of $PM_{2.5}$ concentration on the regional scale from
 666 2011 to 2021 (left) and from 2000 to 2010 (right) between the estimated $PM_{2.5}$ concentration (this
 667 study) and LGHAP $PM_{2.5}$ concentration on the daily scale. ρ is the correlation coefficient.

668 **4.2 Comparisons on the Monthly Scale**

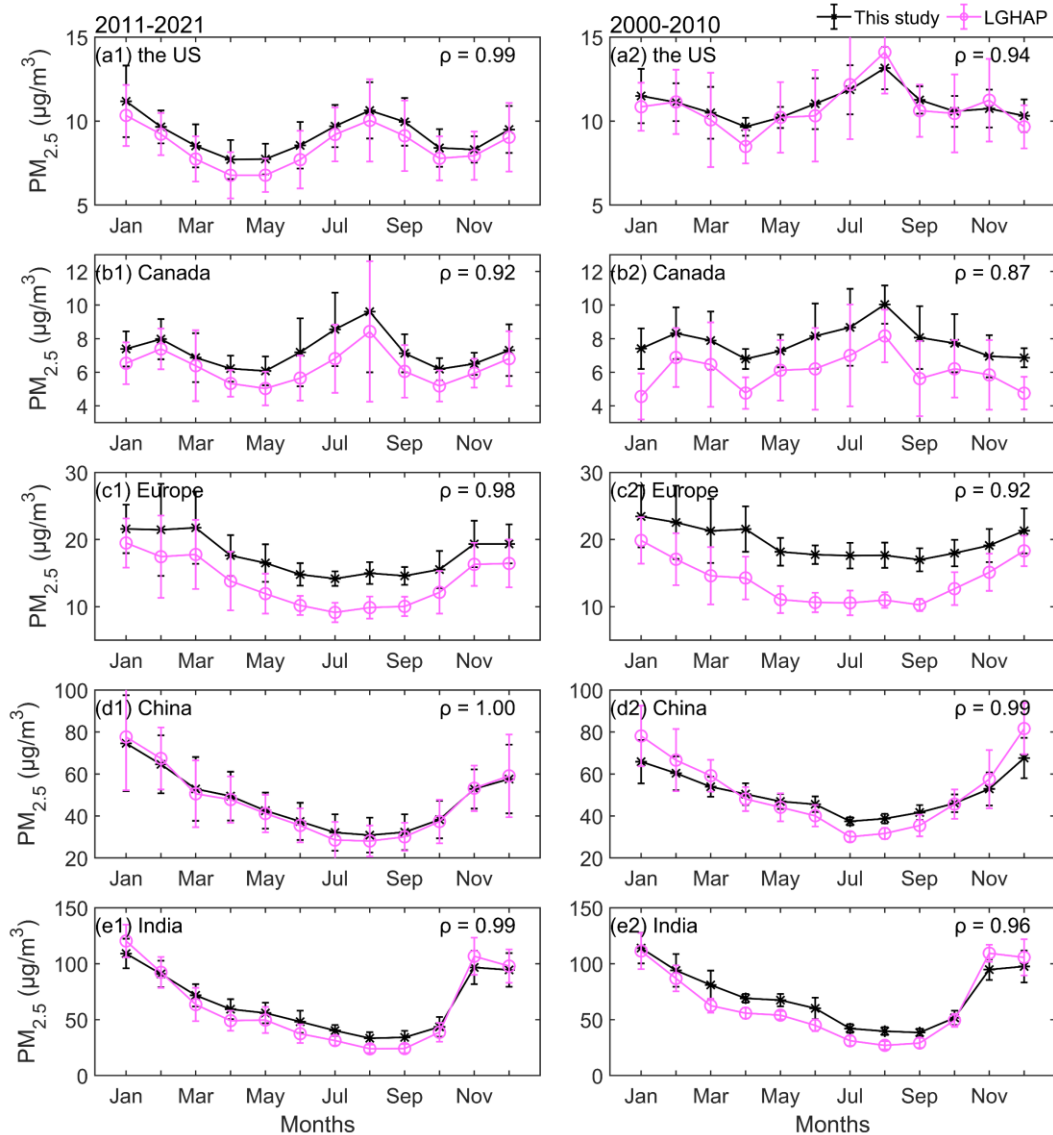

669 Figure 11 shows the density scatter plot between the estimated $PM_{2.5}$ concentration and LGHAP
 670 $PM_{2.5}$ concentration on the monthly scale. The monthly $PM_{2.5}$ concentration is calculated by the
 671 matched daily concentrations. There is a total of 3296739 pairs during the period from 2000 to 2021,
 672 1582161 pairs during the period from 2000 to 2010, and 1714578 during the period from 2011 to
 673 2021, with slopes of 0.857, 0.821 and 0.879. The intercepts are 6.774 $\mu\text{g}/\text{m}^3$, 8.716 $\mu\text{g}/\text{m}^3$, and 5.272
 674 $\mu\text{g}/\text{m}^3$, respectively. The slope of monthly concentration significantly improves before 2010, and
 675 slightly increases after 2010 compared to the daily scale.

676 We also compare the $PM_{2.5}$ concentrations of the annual cycles on the regional scale in Figure 12.
 677 The $PM_{2.5}$ concentration of each month is the mean of the $PM_{2.5}$ concentrations at all sites in the
 678 region. The correlation coefficients of the $PM_{2.5}$ concentrations are greater than 0.92 from 2011 to
 679 2021 and greater than 0.87 from 2000 to 2010. In the United States, the $PM_{2.5}$ concentrations before
 680 2010 are closer compared to those after 2010, except in April and August, and the biases in other
 681 months has significantly decreased. In Europe and Canada, the biases have increased. In China, the
 682 result is similar with the result on the daily scale. In India, the performance of the two is almost
 683 consistent, with a correlation coefficient of 0.99 and 0.96. The two datasets have a very high
 684 similarity in annual cycles, indicating that the estimated $PM_{2.5}$ concentration in this study is accurate
 685 and consistent before and after 2010.

686

687 **Figure 11.** Density scatter plot between the estimated $PM_{2.5}$ concentration (this study) and LGHAP
 688 $PM_{2.5}$ concentration on the monthly scale from 2000 to 2021 (a), from 2000 to 2010 (b) from 2011
 689 to 2021. The dashed black line is the linear regression line. N is the length of the data pairs, and
 690 Slope is the linear regression coefficient. Intercept represents the y-intercept.

691

692 **Figure 12.** Comparison of annual cycle of monthly $PM_{2.5}$ concentration on the regional scale from
 693 2011 to 2021 (left) and from 2000 to 2010 (right) between the estimated $PM_{2.5}$ concentration (this
 694 study) and LGHAP $PM_{2.5}$ concentration on the daily scale. ρ is the correlation coefficient.

695 **4.3 Discussion on the Differences of $PM_{2.5}$ Concentration from Visibility and Aerosol Optical**
 696 **Depth**

697 Both visibility and aerosol optical depth are excellent alternatives for estimating $PM_{2.5}$ concentration,
 698 with its own advantages. However, they have differences in principle, which may be the reason for
 699 the difference between the two datasets in comparison.

700 Fine particulate matter near the ground surface affects atmospheric visibility through scattering.
 701 Studies have shown visibility has a negative correlation with $PM_{2.5}$ concentration, and the reciprocal
 702 of visibility has a positive correlation with the extinction coefficient and has a negative correlation
 703 with the particulate matter concentration (Wang et al., 2012; Zhang et al., 2017; Zhang et al., 2020).
 704 Therefore, visibility is often used as a proxy for particulate matter pollution (Huang et al., 2009;
 705 Singh et al., 2020) and it is the basis to estimate $PM_{2.5}$ concentration. In addition, studies have shown

706 that meteorological observations such as temperature and humidity also play an important role in
707 estimating PM_{2.5} concentration using visibility (Shen et al., 2016; Xue et al., 2019; Zhong et al.,
708 2021). Therefore, when estimating PM_{2.5} concentration based on visibility data, only conventional
709 meteorological variables need to be added, which is convenient and accurate observational data.
710 Besides, the long-term, complete and high-temporal ground-based observations are the advantage
711 of historical estimation of PM_{2.5} concentration. The daily mean from continuous or equidistant
712 hourly observations greatly increases the daily representativeness.

713 The aerosol optical depth is a physical quantity that describes aerosol column properties, which is
714 the integration of the extinction coefficient in the vertical direction. When establishing a connection
715 between aerosol optical depth and near-ground PM_{2.5} concentration, it is essential to consider the
716 vertical structure of aerosols. Studies have shown that the aerosol vertical profiles usually are
717 provided by observations, assumptions, or chemical transport models to obtain the aerosol
718 properties near the surface (Van Donkelaar et al., 2010; Wei et al., 2019b; Van Donkelaar et al.,
719 2021). Van Donkelaar et al. (2006; 2010) have demonstrated that aerosol vertical profile errors in
720 chemical transport models and aerosol optical depth retrieval and sampling result in an
721 approximately 25% uncertainty of one standard deviation. Sensitivity testing shows that a 1%
722 estimation error in the aerosol optical depth can lead to a 0.27% estimation error in the PM_{2.5}
723 concentration (Wei et al., 2021). Besides, the retrieval of aerosol optical depth is affected by clouds
724 or surface types and a finite number of daily observations (usually 1-2 times), though it has the
725 advantage of high spatial coverage (Liu et al., 2017; Singh et al., 2020; Zhong et al., 2021).

726 Another difference is the upper limit of PM_{2.5} concentration. In this study, the upper limit of the
727 estimated daily PM_{2.5} concentration is set to 1000 µg/m³ (the same for input data). When the PM_{2.5}
728 concentration is greater than 500 µg/m³ during heavy pollution, which may contribute to the higher
729 frequency at high pollution levels than in the LGHAP dataset, especially before 2010. We do not
730 remove visibility records during dust weather when preprocessing the data, which may lead to an
731 overestimation of PM_{2.5} concentration in dusty areas, such as northern China and northwestern India.
732 In section 3.4, the uncertainty analysis has provided an explanation for the overestimation. Overall,
733 our PM_{2.5} concentration dataset has a good consistency with PM_{2.5} concentration based on aerosol
734 optical depth.

735 **5 Regional Trends and Spatial Patterns**

736 We use the estimated PM_{2.5} concentrations (at least 10-day records in a site) to calculate monthly
737 PM_{2.5} concentrations, and analyze the annual cycles, interannual trends, and spatial patterns of PM_{2.5}
738 concentrations in different regions based on the GAMM model. The annual variation comes from
739 the monthly smooth term of GAMM, the interannual variation comes from the annual smooth term,
740 and the spatial pattern comes from the spatial smooth term. The regions include Canada, the United
741 States, Europe, China, and India. The results are shown in Figure 13. The trend from 1959 to 2022
742 in each region is the slope of the Sen-Theil (ST Slope) estimators (Sen, 1968; Theil, 1992), and
743 Mann-Kendall test (Mann, 1945; Kendall, 1948) is used to calculate the significance of the trend.
744 The test results show the p-values are all less than 0.01 in all regions.

745 In the United States, the annual cycle curve shows that the PM_{2.5} concentration is a 'double peaks
746 and double valleys' shape. The peaks occur in July and December, respectively, with the highest
747 PM_{2.5} concentration in July throughout the year. The valley values are in April and October, and the

748 PM_{2.5} concentration levels are equivalent. The trend is -0.40 µg/m³/decade, and PM_{2.5} concentration
749 decreases significantly after 1992, with a trend of -1.39 µg/m³/decade. The high PM_{2.5} concentration
750 areas are in the east and west. The areas with low PM_{2.5} concentrations are mainly located in the
751 central and northern regions. The high concentration in the eastern and western regions is related to
752 extensive industrial activities and densely populated cities. The low concentration in the central and
753 northern regions is relatively to high vegetation coverage, low industrial activity and low population
754 density.

755 In Canada, the annual cycle curve also shows that the PM_{2.5} concentration is a 'double peaks and
756 double valleys' shape. The peak values occur in August and February, with the highest PM_{2.5}
757 concentration in August. The valley values are in April and October. The trend is -0.10 µg/m³/decade,
758 and PM_{2.5} concentration increases after 2010. The PM_{2.5} concentration exhibits an east-high to west-
759 low pattern. The eastern regions, such as Ontario and Quebec, are characterized by high population
760 density and significant industrial and transportation activities.

761 In Europe, the annual cycle of PM_{2.5} concentration shows that the PM_{2.5} concentration is the highest
762 in February, and is low from May to September. The valley values are in April and October. The
763 trend is -1.55 µg/m³/decade. High concentration areas are distributed in eastern Europe, while low
764 concentration areas are in northern and western Europe. Eastern Europe exhibits more
765 industrialization, particularly with a prevalence of traditional heavy industries and the use of coal
766 and other high-pollution energy sources. In contrast, the energy structure in western Europe tends
767 to favor cleaner energy sources.

768 In China, the annual cycle curve of PM_{2.5} concentration presents a V-liked shape. It indicates that
769 high concentrations are in winter, while low concentrations are in summer. The trend is 2.09
770 µg/m³/decade. The trend is 2.65 µg/m³/decade from 1959 to 2011 and -22.23 µg/m³/decade from
771 2012 to 2022. High concentration areas are distributed in northern China, such as North China Plain,
772 Northeast China, Sichuan Basin, Taklimakan Desert, and Badain Jaran Desert. Low concentration
773 areas are in southern China and Northern Tianshan Mountains. Besides dust, industrial activities
774 and coal combustion for heating during winter are significant contributors to the PM_{2.5} concentration
775 in northern regions.

776 In India, the annual cycle curve of PM_{2.5} concentration also presents a V-liked shape. High
777 concentrations are in winter, and low concentrations are in summer. The trend is 0.92 µg/m³/decade.
778 The trend is 1.41 µg/m³/decade from 1959 to 2013 and -23.36 µg/m³/decade from 2014 to 2022.
779 Some studies have shown that the PM_{2.5} concentration in India has decreased since 2014, especially
780 in northern cities. Singh et al. (2021) have found that five major cities in India show a downward
781 trend from 2014 to 2019, with the largest decline of approximately -4.2 µg/m³ per year in New Delhi.
782 Ravindra et al. (2024) also finds that the trend in New Delhi is about -5 µg/m³ per year from 2014
783 to 2020. These studies have shown a faster downward trend than our study, as these PM_{2.5}
784 monitoring sites are mainly concentrated in urban areas. The PM_{2.5} concentration exhibits a north-
785 high to south-low pattern. High concentration areas are distributed in northern India, such as Ganges
786 Plain and Thar Desert, because there are more industrial and densely populated areas and the terrain
787 leads to the retention of air pollutants. Low concentration areas are in Deccan Plateau.

788 Above all, the PM_{2.5} concentrations in developed countries and regions are significantly lower than
789 those in developing countries in the Northern Hemisphere. Regional trends are similar with those

790 of previous studies in different periods (Van Donkelaar et al., 2010; Wang et al., 2012; Boys et al.,
791 2014; Ma et al., 2016; Li et al., 2017; Hammer et al., 2020). The trends in PM_{2.5} concentration
792 changes in different regions are closely associated with the implementation of relevant policies. The
793 earlier pollution control measures are taken, the earlier the decreasing trend in the PM_{2.5}
794 concentration occurs, and the lower the threat of particulate matter pollution is to humans. In 1997,
795 the United States EPA classified PM_{2.5} as a hazardous substance in the National Ambient Air Quality
796 Standard, and subsequent regulations in 2006 further strengthened the source control and
797 management of fine particulate matter (Hall and Gilliam, 2016). In 1988, the Canadian federal
798 government enacted the Canadian Environmental Protection Act, which enhanced the regulation of
799 PM_{2.5} (Davies, 1988). The European Union introduced the Air Quality Directive in 1996, followed
800 by multiple revisions and updated to regulate and restrict air pollutants, including PM_{2.5} (Kuklinska
801 et al., 2015). However, Europe stands out due to its early adoption of clean production practices in
802 heavy industries since the 1970s. Since 2012, China has implemented numerous regulations and
803 standards for PM_{2.5}. For instance, the Monitoring Method for Atmospheric Particulate Matter (PM_{2.5})
804 was issued in 2012, and the Chinese Ministry of Environmental Protection released the Ambient Air
805 Quality Standards in 2013, including emission standards for PM_{2.5} (Zhao et al., 2016a). In 2009, the
806 Indian Ministry of Environment and Forests issued the National Ambient Air Quality Standards,
807 which include control standards for PM_{2.5}. Since 2015, the Indian government has launched the
808 National Clean Air Programme (NCAP) to improve air quality by implementing a series of measures
809 to reduce the emissions of PM_{2.5} and other pollutants (Ganguly et al., 2020). These environmental
810 regulations have contributed significantly to the decline of PM_{2.5} concentrations. Some studies have
811 shown that the variation of PM_{2.5} concentrations is also related to several factors, such as the energy
812 structure, urbanization process, population distribution and vegetation coverage (Shi et al., 2018;
813 Wu et al., 2018; Li et al., 2019; Wang et al., 2019; Lim et al., 2020; Qi et al., 2023).

814

815 **Figure 13.** Annual cycles, interannual trends and spatial patterns of $PM_{2.5}$ concentrations in the
 816 United States (a1-a3), Canada (b1-b3), Europe (c1-c3), China (d1-d3), and India (e1-e3). The left
 817 column 'f(month)' is the annual cycle, the middle column 'f(year)' is the interannual trend, and the
 818 right column 'f(spatial)' is the spatial distribution from Generalized Additive Mixed Model
 819 (GAMM). The blue dashed lines represent ± 1 standard error of the month and annual mean of $PM_{2.5}$
 820 concentrations. The red or black dashed lines represent the trends of the Sen-Theil estimators (ST
 821 Slope). Mann-Kendall test of trends shows that the p-values are less than 0.01 in all regions. The
 822 scatter points in right column are the locations of $PM_{2.5}$ monitoring sites.

823 6 Conclusions

824 In this study, we use a machine learning method to estimate daily $PM_{2.5}$ concentration for 5023
 825 terrestrial sites in the Northern Hemisphere from 1959 to 2022 based on daily visibility and related
 826 meteorological variables. The first 80% of $PM_{2.5}$ concentration data in each site are used to train the
 827 model, and the last 20% are used to test. The model's performance and predictive ability are
 828 evaluated and a dataset of daily $PM_{2.5}$ concentration based on aerosol optical depth is used to
 829 compare and evaluate the estimated $PM_{2.5}$ concentration. We analyze the uncertainty and discuss
 830 the limitations of our dataset. Finally, the $PM_{2.5}$ concentration variation (annual calendar cycle,
 831 interannual cycle and spatial distribution) in 5 regions over the past 64 years is analyzed based on
 832 GAMM. We hope our dataset will be useful for studying the atmospheric environment, human
 833 health, and climate change and provide auxiliary support for assimilation. Several key results of this
 834 study are described as follows:

835 **The most important variable.** Visibility is the most important variable at 80.7% of the PM_{2.5} sites,
836 as visibility can be considered an indicator of PM_{2.5} concentration without fog or precipitation. Other
837 meteorological variables play a secondary role in the model, especially temperature and dew point
838 temperature.

839 **Model performance and predictive ability.** The training results show that the slope between the
840 estimated PM_{2.5} concentration and the monitored PM_{2.5} concentration within the 95% confidence
841 interval is 0.955, the R² is 0.95, the RMSE is 7.2 µg/m³, and the MAE is 3.2 µg/m³. The test results
842 show that the slope between the predicted PM_{2.5} concentration and the monitored PM_{2.5}
843 concentration is 0.864 ± 0.0010 within a 95% confidence interval, R² is 0.79, RMSE is 14.8 µg/m³,
844 and MAE is 7.6 µg/m³. The model shows good stability and predictive ability. Compared with a
845 global PM_{2.5} concentration dataset based on satellite retrieval, the slopes of linear regression on the
846 daily (monthly) scale are 0.817 (0.854) from 2000 to 2021, 0.758 (0.821) from 2000 to 2010, and
847 0.867 (0.879) from 2011 to 2022. The result indicates the accuracy of the model and the consistency
848 of the estimated PM_{2.5} concentration on the temporal scale.

849 **Regional trends and spatial patterns.** The interannual trends and spatial patterns of PM_{2.5}
850 concentration on the regional scale from 1959 to 2022 are analyzed based on GAMM. In Canada,
851 the trend is -0.10 µg/m³/decade in Canada and the PM_{2.5} concentration exhibits an east-high to west-
852 low pattern. In the United States, the trend is -0.40 µg/m³/decade, and PM_{2.5} concentration decreases
853 significantly after 1992, with a trend of -1.39 µg/m³/decade. The high PM_{2.5} concentration areas are
854 in the east and west and the low are in the central and northern regions. In Europe, the trend is -1.55
855 µg/m³/decade. High concentration areas are distributed in eastern Europe, while the low is in
856 northern and western Europe. In China, the trend is 2.09 µg/m³/decade. High concentration areas
857 are distributed in northern China and the low are distributed in southern China and Northern
858 Tianshan Mountains. The trend is 2.65µg/m³/decade from 1959 to 2011 and -22.23 µg/m³/decade
859 from 2012 to 2022. In India, the trend is 0.92 µg/m³/decade. The concentration exhibits a north-high
860 to south-low pattern, with high concentration areas distributed in northern India, such as Ganges
861 Plain and Thar Desert and the low in Deccan Plateau. The trend is 1.41 µg/m³/decade from 1959 to
862 2013 and -23.36 µg/m³/decade from 2014 to 2012. The variation of PM_{2.5} concentration is
863 inseparable with the implementation of pollution control laws and regulations, the energy structure,
864 industrialization, population and vegetation coverage.

865 **7 Data Availability**

866 Daily PM_{2.5} concentration data in the Northern Hemisphere from 1959 to 2022 are available at
867 <https://cstr.cn/18406.11.Atmos.tpc.301127> (Hao et al., 2024).

868 All site-scale PM_{2.5} data files are in "PM25-Daily_1959_2022.zip". The file name includes a region
869 name and a site number. For example, the file name, 'China_1001.txt', means that the site is in
870 China, and the site number is 1001, which describes the daily PM_{2.5} concentration at a single site
871 and can be directly opened using a text program (such as Notepad), separated by commas. The data
872 includes four variables: Date, PM25(µg/m³), Longitude(degree_east), and Latitude(degree_north).
873 Date is UTC time, PM25(µg/m³) is the daily PM_{2.5} concentration (unit: µg/m³), Longitude range is
874 [-180 °E, 180 °E] and Latitude range is [0 °N, 90 °N].
