**Abstract.** Accurate greenhouse gas (GHG) emissions inventories are vital for climate mitigation as they can identify areas of need and ensure effective policy and regulation in reducing GHG emissions. Several studies have shown that self-reporting GHG inventories are undercounting methane emissions across all anthropogenic sectors showcasing an increasing need to validate the inventory with direct measurements. This study carried out aerial observations and emission rates of methane and carbon dioxide across multiple sectors in New York State (NYS). Emission rates were calculated for each of the sources using a mass balance method and were subsequently compared to the 2021 Environmental Protection Agency GHG Reporting Program (EPA GHGRP) Inventory. Landfills were the source of the highest observed methane emission estimates, ranging from 161–3440 kg/hr. There was also significant variation in observed emissions within facilities between seasons indicating a significant influence from meteorology. Observed carbon dioxide emission estimates were dominated by combustion facilities followed by landfills. Comparisons with the inventory show that methane emissions averaged over ten observed landfills are underestimated by a factor of 2. However, out of the ten landfills, five landfills had observed methane emission estimates significantly higher than the inventory value, four landfills had an inventory value within the uncertainty range of the observations, and one landfill observed emission estimate was markedly lower than the reported inventory estimate. Seneca Meadows Landfill was the highest emitter from the measurements and was ~4.3x higher than what was reported to the 2021 EPA GHGRP Inventory. The difference in emissions between landfills could be due to operational differences or waste quantities. NYS can use this information to inform the NYS GHG Inventory and improve emission estimation methodologies to better depict actual emissions.

## 1 Introduction

As a leading global greenhouse gas, methane (CH<sub>4</sub>), and the reduction thereof, has presented itself as a low hanging fruit in climate change mitigation. This is due to its warming potential of more than 80 times that of carbon dioxide (CO<sub>2</sub>) over a 20-year timescale and its relatively short atmospheric lifetime of about a decade, as opposed to longer-lived CO<sub>2</sub>, making its mitigation more cost-effective (Shindell et al., 2024; United Nations Environment Programme and Climate and Clean Air Coalition, 2021). There are several natural and anthropogenic sources of methane, with varying contributions to the global methane budget. In New York State (NYS), the largest anthropogenic sources include the fossil fuel, waste, and agriculture sectors, which accounted for 56%, 29%, and 15% of total state-wide anthropogenic methane emissions, respectively, according

to the 2021 NYS GHG Inventory (New York State Department of Environmental Conservation, 2023a). It is important to note that the NYS GHG Inventory and recently passed legislation use the 20-year global warming potential (GWP) metric while most national and international agencies use the 100-year GWP metric. Utilizing the 20-year GWP essentially emphasizes the higher warming impact of methane over 20 years as opposed to over 100 years due to methane's shorter atmospheric lifetime.

40 The 20-year GWP metric yields a much higher relative warming potential, which highlights the urgency in reducing methane over carbon dioxide emissions in the short-term.

There are some complexities that arise when trying to accurately assess the contributions from each of the sources of methane, which are primarily due to uncertainties in emission estimations. This uncertainty comes from inadequate measurements and the inconsistent emission estimation results between top-down and bottom-up methods (Saunio et al., 2024). Top-down methods infer emissions through the use of chemical transport modeling and direct, in situ atmospheric measurements over regional- or global-scales to which they are scaled down to smaller facility- or process-level emissions (National Academies of Sciences, 2018). On the contrary, bottom-up approaches are process-based methods, which estimate emissions based on activity data and emission factors (EF) from individual sources and are extrapolated to regional and national emission totals.

50 These activity data and EFs are a major source of uncertainty in bottom-up GHG inventories because they are not always representative of true emissions, but, given current understanding, are considered 'best estimates' (Miller & Michalak, 2017; Winiwarter & Rypdal, 2001). Several EFs for various sectors are based on data conducted during studies from decades ago, which may not be indicative of current emissions (Lamb et al., 2016; National Academies of Sciences, 2018). In addition to that, emission inventories do not account for seasonal or operational changes between facilities, which have shown to result in significant differences in emissions seasonally and between facilities (Bell et al., 2017; Cusworth et al., 2021, 2024). Lack of direct measurements of facilities to inform the inventories also plays into the highly uncertain emission estimates, which is the case in NYS where there are few studies of methane observations from major sources of methane.

This high uncertainty in emissions inventories has led to a need for verification using top-down direct measurements. A large number of studies have shown that inventories are not accounting for all emissions across multiple sectors (Bergamaschi et al., 2015; Cusworth et al., 2024; Daniels et al., 2023; Foster et al., 2017; Guha et al., 2020; Lamb et al., 2016; Liu et al., 2023; Moore et al., 2023; Wecht et al., 2014; Yu et al., 2021). Consequently, underestimation of source emissions has led to underestimation of city-wide emissions. Urban areas are highly concentrated areas of population and energy consumption, ultimately deeming them as major sources of GHGs, yet many studies have suggested that inventories are underestimating total urban-wide emissions (Lamb et al., 2016; Lopez-Coto et al., 2020; McKain et al., 2015; Pitt et al., 2024; Plant et al., 2019; Ren et al., 2018; Sargent et al., 2021).

Top-down methods can evaluate emissions inventories by comparing these inventories with a combination of direct measurements and chemical transport modeling. Top-down constraints afforded by aircraft or satellite observations have been

critical in estimating and validating the emission rates of facilities or regions by their ability to sample the whole perimeter of the facility or regional area up to the planetary boundary layer height (Conley et al., 2017; Guha et al., 2020). A mass balance approach of a point source can estimate emissions from aircraft data by applying Gauss's Theorem to the reported methane enhancement and observed winds as the aircraft circles in a virtual cylinder around the facility up to the boundary layer height (Conley et al., 2017; Cusworth et al., 2024; Koene et al., 2024). By sampling upwind and downwind of the facility, this allows full characterization of the facility-generated plume (Conley et al., 2017). However, in an urban area it is generally hard to pinpoint exact contributions from a specific facility due to additional emissions from adjacent sources. These top-down estimations may then be compared to the values self-reported to the Environmental Protection Agency (EPA) Greenhouse Gas Reporting Program (GHGRP), which mandates large emitters of GHGs to report their emissions under 40 CFR Part 98 (ECFR :: 40 CFR Part 98 -- Mandatory Greenhouse Gas Reporting, 2009). The self-reporting GHGRP is separate from the NYS GHG Inventory in that it provides nation-wide facility-level emission totals while the NYS GHG Inventory only provides emission source totals across the state (e.g. all landfills or power plants). The NYS Inventory is used for regulatory purposes and allows for tracking and mitigating state-wide greenhouse gas emissions, while the GHGRP provides facility-specific information and allows for direct comparisons with observations.

In 2019, NYS passed the Climate Leadership and Community Protection Act (CLCPA) that mandates a 40% reduction in GHG levels by 2030 and 85% reduction in GHG levels by 2050 as compared to 1990 levels (New York State Climate Action Council, 2022). In order to achieve these goals, the NYS GHG emissions inventory must be accurate since it is the basis for climate policy and regulation. To verify the accuracy of the inventory, aircraft measurements were carried out in NYS at combustion, landfill, wastewater treatment plant (WWTP), and agricultural facilities to compare against the self-reported GHGRP inventory. This paper reports the observed emission estimate results, which were calculated from a mass balance method using Gauss's Theorem across these source sectors and Buffalo and Rochester, NY. The aircraft emission estimates will be compared with the bottom-up EPA GHGRP Emissions Inventory. The results from this paper will help inform the inventory, improve our understanding in estimating accurate emissions, and help NYS meet the goals of the CLCPA.

## 2 Methods

The aircraft measurements were carried out over two separate field campaigns, which occurred in June and November/December 2021. With funding from the NYS Energy Research and Development Authority (NYSERDA), the main objectives of the study were to determine emission rates from major methane sources in NYS to inform the NYS GHG Inventory. The aircraft measurements reported in this study were coordinated with a separate study done by Ravikumar et al. (2024), which focused on identifying and estimating methane emissions from natural gas transmission and storage compressor stations in NYS. This study focuses on aircraft sampling over waste incineration, industrial, power plant, waste, and agricultural facilities.

Table 1 lists the facilities and two urban areas sampled along with the facility name, type, date of sampling, number of laps made around each facility, minimum and maximum flight level, and mean radius of the loops. Figure 1 is a map illustrating all visited facilities for this study. The sites listed in the table were chosen by the project team, which balanced reported and estimated emission rates in the NYS GHG Inventory and their proximity to the airport bases in Rochester and Albany, NY.

The aerial measurements were completed by the Colorado-based scientific research company, Scientific Aviation, Inc. (now, Champion X), which used a Mooney single engine propeller aircraft. There were a total of 25 sites sampled from this study, with 5 sites visited more than once. Additional aircraft missions were flown in the vicinity of New York City, but due to flight restrictions of nearby airports, the aircraft could not sample extensively enough to present reliable fluxes from facilities within the New York City Area. Consistent with the Ravikumar et al. (2024) flights, all measurements were taken in the middle of the day from 10 am up to 5 pm local time to ensure the entirety of the emission plume is captured in a well-mixed and developed boundary layer.

Trace gases were measured by sampling ambient air drawn through rearward-facing inlets mounted on the wing of the aircraft. Observations of CH<sub>4</sub>, CO<sub>2</sub>, carbon monoxide (CO), and water vapor (H<sub>2</sub>O) were recorded using a Picarro G2401 gas analyzer, which is a Wavelength-Scanned cavity ring-down spectrometer ([https://www.picarro.com/environmental/g2401\\_analyzer\\_datasheet](https://www.picarro.com/environmental/g2401_analyzer_datasheet)). The analyzer has a 1  $\sigma$  precision of <1 parts per billion (ppb) of methane at 5 seconds. Calibrations were done inflight, along with measurements of temperature and relative humidity from a Vaisala HMP60 probe, and GPS coordinates from a Hemisphere high-precision differential GPS. Horizontal wind speed and direction were calculated following the method outlined in Conley et al. (2014). Further descriptions and discussion of the Scientific Aviation aircraft, analyzer precision and accuracy, and met data can be found elsewhere (Conley et al., 2017; Karion et al., 2015; Peischl et al., 2016; Ravikumar et al., 2024; Smith et al., 2015).

**Table 1: Information pertaining to all sites included in the analysis. The table provides the site name, location, sector, facility type, date of sampling, total number of laps completed around the facility, the lowest and highest altitudes above mean sea level (AMSL) reached at each facility, and the mean radius of the laps.**

**Figure 1:** Map of all sites sampled in the study, which include combustion facilities, landfills, wastewater treatment plants (WWTP), industrial sites, and greater urban areas of Buffalo and Rochester. Locations of the concentrated animal feeding operations (CAFO) sampled are not identified following United States federal privacy laws. Combustion facilities include a waste incinerator plant,

135 power plant, industrial facility, and a waste, paper, and pulp facility. This map was created in QGIS (<https://qgis.org/>) using Google  
 Satellite Imagery, accessed on 19 August 2024.

## 2.1 Mass Balance Emission Estimation

140 Emission estimates for each sampled facility were calculated from a mass balance method using Gauss's Theorem (Conley et  
 al., 2017; Ravikumar et al., 2024). As the aircraft circles a virtual cylinder around the facility, the total flux contribution from  
 the facility is estimated from the product of the methane observations with the horizontal wind flow and summed over each  
 height level. The total contribution from the facility is estimated by integrating the outward horizontal flux at each point along  
 the flight path. This is done by following the mass balance equation below (Conley et al., 2017):

$$145 \quad Q_c = \int_0^{z_{max}} \oint c' \mathbf{u}_h \cdot \hat{n} \, dl \, dz, \quad (1)$$

where  $Q_c$  is the emission rate,  $z_{max}$  is the top of the sampling height,  $c'$  is the deviation from the mean concentration for each  
 loop, such that  $C = \bar{c} + c'$ , where  $C$  is the measured concentration and  $\bar{c}$  is the mean concentration per loop,  $\mathbf{u}_h$  is the horizontal  
 wind vector,  $\hat{n}$  is the outward pointing unit vector,  $dl$  is the change in length per sample, and  $dz$  is the change in height between  
 150 each loop around the facility. These values for  $Q_c$  are calculated by numerically integrating Eq. (1). Typical average values of  
 the  $dl$  and  $dz$  terms are ~68 m and ~47 m, respectively. The lowest  $dz$  layer extends from the lowest flight altitude to the  
 surface, which varied from site to site.

There is a source of uncertainty in the mass balance method regarding the section of the plume that is not accounted for from  
 155 the ground-level up to the lowest flight level (Cambaliza et al., 2014; Gordon et al., 2015). Assuming a well-mixed boundary  
 layer, the methane mixing ratio is assumed to be constant from the surface up to the lowest flight level. There is also the issue  
 of additional unintended sources included in the analysis in urban areas due to a higher number of adjacent sources, making it  
 difficult to focus on one specific facility. As mentioned in Ravikumar et al. (2024), there was a combined uncertainty of about  
 30% for the individual compressor station emission rates estimated using the mass balance method. Uncertainties are estimated  
 160 following the method outlined in Conley et al. 2017. Referring to Table 2, Table 3, and Table 4 which lists the observed  
 emission rates and their uncertainties for all sectors, the combustion facilities had a methane emission uncertainty average of  
 about 48%, ranging from 18%–82%. Landfills were ~30%, ranging from 10%–80%. WWTPs showed much higher variation  
 in uncertainty, ranging from 34%–1330%. Uncertainty for concentrated animal feeding operations (CAFO) averaged at about  
 60%, ranging from 32% up to 111%, not including one farm, which had an uncertainty of ~300%. The urban area observed  
 165 methane emission estimates had significant uncertainty averaging at about 105% and ranging from 25%–185%. These  
 uncertainties are an estimate of the variation of the flux between each of the loops around a particular site only, which mostly

takes into account the turbulent effects on the plume. It does not include any other potential source of uncertainty, including day-to-day or seasonal differences.

### 3 Results

#### 3.1 Emission Rate Comparisons

The calculated emission rates from the aircraft observations and Eq. (1) for the combustion, landfill and WWTP, and agricultural sources can be seen in Tables 2, 3, and 4, respectively. Observed emission rates were calculated for CH<sub>4</sub> and CO<sub>2</sub> for each of the facilities. Tables 2 and 3 also list the available self-reported 2021 EPA CH<sub>4</sub> and CO<sub>2</sub> GHGRP Inventory estimates. The EPA GHGRP methane estimates are converted from carbon dioxide equivalent using the 100-year GWP values from the Intergovernmental Panel on Climate Change (IPCC) Fourth Assessment Report (IPCC, 2007; United States Environmental Protection Agency Office of Atmospheric Programs, 2021). The only facilities as part of this study required to report methane emissions to the EPA GHGRP are the landfills and combustion facilities, hence no available comparisons between the observations and self-reported inventory values for the WWTP and CAFO facilities. Comparisons with the GHGRP are discussed in Section 3.2.

Observed methane emission rates varied widely both between and within the combustion, landfill, WWTP, and agricultural sectors. As seen in the comparison plots in Fig. 2, landfills were responsible for the highest observed methane emission rates ranging from 161–3440 kg h<sup>-1</sup>, with an average of 1240 kg h<sup>-1</sup>. The large range in values between the facilities can be due to several factors including operational differences, size of landfill, or waste quantity. Seneca Meadows Landfill accounted for the largest observed methane emission estimate, which is consistent with its status as the largest landfill in New York State in terms of both current size and annual permits (NYS Department of Environmental Conservation, 2020).

There was also a large range in values within the facilities that were sampled more than once, and every one of the facilities exhibited higher emission estimates in the winter months compared to the summer months except for High Acres Landfill, which showed the opposite. Between the summer and winter months, there was approximately a 45% difference at Modern, 42% difference at Ontario, 85% difference at High Acres, and 52% difference at Riga Mill Seat Landfill in methane emission estimates. Seneca Meadows Landfill was the only facility with relatively consistent emission rates, showing a ~15% difference between the summer and winter months. Variation in meteorological and environmental conditions, such as ambient pressure and temperature, wind, and soil moisture and temperature has shown to impact methane emissions from landfills, which can explain the seasonal differences in observed emission rates at these landfill facilities (Delkash et al., 2016; Poulsen et al., 2003; Rachor et al., 2013; Xu et al., 2014; Zhang et al., 2013).

There were several facilities that exhibited non-detectable or non-quantifiable observed emission rates, which can be due to several reasons, including inability to detect an upwind background and downwind enhancement, inability to quantify a plume within variable winds, or the facility location within an urban area with adjacent sources nearby. WWTPs showed mostly lower emission rates than landfills, ranging from 12.8–21.6 kg h<sup>-1</sup>. Out of the five WWTPs visited, only two sites had detectable fluxes, likely due to the fact that they were located in urban areas and the aircraft was unable to get close enough to the ground to sample the plume from the urban background. CAFOs and the combustion facilities exhibited a comparable range of methane estimates between each other from 3.5–182.8 kg h<sup>-1</sup> and 6.7–118 kg h<sup>-1</sup>, respectively. The large variation in the CAFOs could be due to a number of reasons. The CAFOs had different types of herds (i.e., dairy cows, swine, sheep and chickens), which would result in varying emissions (EPA, 2024). Although the largest farms were sampled, the exact herd size enclosed within the flight loops during sampling was not known since a particular farm could have several locations and the central operating location given in the database does not always mean the herd is at that location. Lastly, manure management is a large source of methane within the livestock sector and is usually stored in lagoons away from the barns or central operating locations, which could potentially leave it out of the area sampled by the aircraft and ultimately exclude it from the emission rate estimate.

As expected, the Sithe Independence natural gas power plant and Covanta Niagara waste incineration facility had by far the largest observed CO<sub>2</sub> emissions with a maximum emission rate of 300,000 kg h<sup>-1</sup> and 129,783 kg h<sup>-1</sup>, respectively, but emissions from landfills were still quite substantial and larger than the remaining sources with a maximum emission rate of 58,941 kg h<sup>-1</sup>, which can be seen in Fig. 3.

**Figure 2: Observed methane (CH<sub>4</sub>) emission rate comparisons between each of the sectors for (a) landfills, (b) concentrated animal feeding operations (CAFO), and (c) combustion facilities. The wastewater treatment plant observed emission rates were not included due to unreliable and low emissions.**

240

245 **Figure 3: Observed carbon dioxide (CO<sub>2</sub>) emission rate comparisons between each of the sectors for (a) landfills, (b) wastewater treatment plants (WWTP), (c) concentrated animal feeding operations (CAFO), and (d) combustion sources. The power plant and waste incinerator facilities were not included in this plot due to the significantly higher emission estimates.**

Table 5 lists the observed emission rates for Buffalo and Rochester. These flight paths were performed as exploratory analyses, but we do not believe them to be reliable estimates, in part because of relatively large upwind plumes inferred by the measurements that introduced relatively large uncertainties to the mass balance calculation. Out of both cities sampled, the observed CH<sub>4</sub> emission rate was higher in Rochester as compared with Buffalo. Different CH<sub>4</sub> emission rates were measured in Buffalo between the larger and smaller circles of measurements (first and second row of Table 5, respectively) by a factor greater than 3.5. Both the large difference in observed CH<sub>4</sub> emissions between the smaller and larger radius of measurements at Buffalo and the high uncertainty leave little confidence in these estimates and thus will not be used further. The observed CO<sub>2</sub> emission rate was mostly comparable between the larger and smaller circle around Buffalo and between both cities.

**Table 5. Estimated emission rates from Buffalo and Rochester for methane (CH<sub>4</sub>), carbon dioxide (CO<sub>2</sub>), and their uncertainties. A larger circle (first row) and smaller circle (second row) of measurements were made over Buffalo. The smaller circle focused on the city center of Buffalo.**

Buffalo	11/19/2021	182 ± 337	456265 ± 109899
Buffalo - Small Circle	11/19/2021	649 ± 166	456131 ± 51586
Rochester	11/20/2021	860 ± 919	437000 ± 501000

### 3.2 2021 EPA GHGRP CH<sub>4</sub> Emission Inventory Comparisons

The methane emission estimates from this study have been compared to available emission rates self-reported to the EPA GHGRP (United States Environmental Protection Agency Office of Atmospheric Programs, 2021). As mentioned previously, facility-level emission rates are not available under the 2021 NYS GHG Inventory (New York State Department of Environmental Conservation, 2023b). The comparisons between the methane observations from this study and the self-reported EPA GHGRP Inventory can be seen in Table 2, Table 3, Figure 4, and Figure 5. As seen in Table 3, the observed landfill emission estimates were, on average, 2x greater than what was reported in the inventory. The highest observed emission rates were estimated from Seneca Meadows Landfill ranging from 2789–3440 kg h<sup>-1</sup>, which were ~4.3x greater than the GHGRP self-reported value of 726 kg h<sup>-1</sup>. Modern Landfill self-reported as the highest in-state point source emitter of methane at 1343 kg h<sup>-1</sup>, yet the average observed estimate from the facility (~1107 kg h<sup>-1</sup>) was lower than the inventory estimate. Nonetheless, the inventory estimate is still within the uncertainty range of the observed estimate rate at Modern, which is the case for three other landfills as well, including High Acres, Hyland, and Ava Landfill. Albany Landfill was the only landfill where the observed CH<sub>4</sub> emission rate was relatively lower than the self-reported inventory value, at about 60% of the self-reported

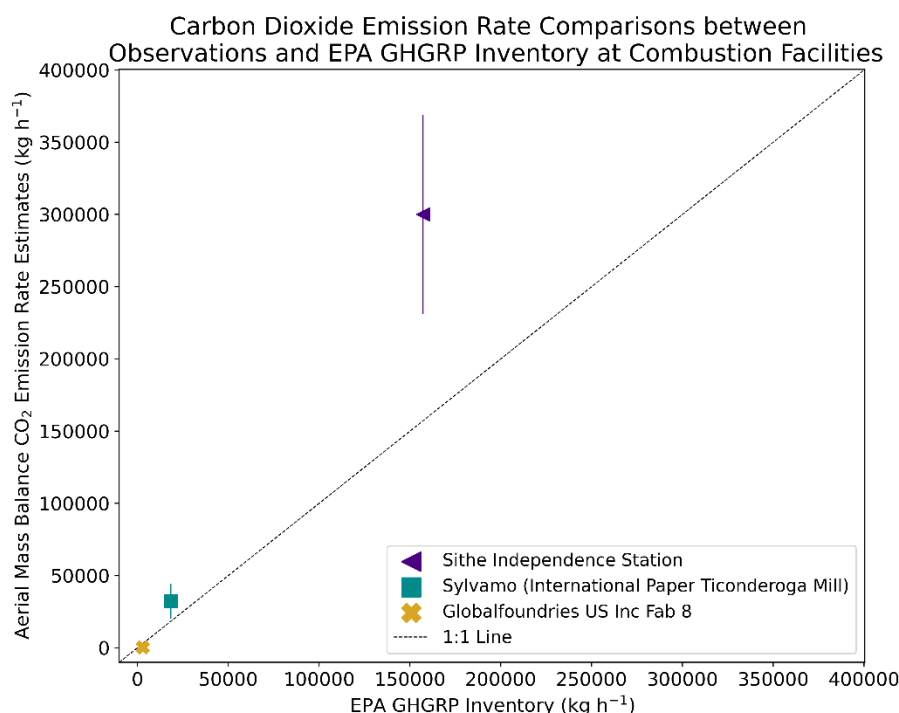

value. The remaining five landfills all exhibited higher observed  $\text{CH}_4$  emission estimates than what was reported in the inventory averaging at  $\sim 3.1\times$  greater, including Seneca Meadows Landfill, Ontario County Landfill, Riga Mill Seat Landfill, Chafee Landfill, and Development Authority of the North Country (DANC) Solid Waste Management Facility. The emission rates varied widely between the combustion facilities for both the observed and the inventory estimates. The differences were also inconsistent– the Sylvamo Paper Mill mass balance estimate was  $\sim 34\times$  lower than the inventory while the Sithe Independence mass balance estimate was  $\sim 41\times$  greater than the inventory.

These results show that the self-reporting of methane emissions from landfills in NYS is underestimated to the EPA GHGRP, and consequently may be underestimated in the NYS GHG Inventory. There are a few cases where the GHGRP values are higher than the observations suggest, which may be explained by operational differences and waste quantity between the landfills, but likely results from the assumptions employed by each landfill operator about the methane captured (all the landfills sampled employ methane capture technologies). The difference in emissions is a major reason behind the uncertainty and inaccuracy in emissions inventories due to the effort of trying to consolidate the emission estimate into a single annual average rate, where there are significant differences seasonally and between facilities. This also points out that these individual observed emission rates may not be a direct comparison to the inventory estimates, since they are a snapshot from a few days of the year, as compared to the annual average from the inventory. A more equivalent comparison can be accomplished through long-term measurements of methane emission rates from satellite observations or possibly from continuous facility-specific ground-based measurements, and we recommend such future studies be performed.

**Figure 4. Comparisons between the methane emission rates estimated from this study and the 2021 EPA GHGRP Inventory at each of the landfills (a) and combustion facilities (b) visited during the study.**

300 **Figure 5. Comparisons between the carbon dioxide emission rates estimated from this study and the available 2021 EPA GHGRP Inventory at the combustion facilities visited during the study.**

The CO<sub>2</sub> emission rate comparisons between the observed and self-reported GHGRP values are significantly different at the landfill facilities due to EPA not accounting for biogenic CO<sub>2</sub> emissions. The inventory only accounts for combustion-related  
 305 emissions of CO<sub>2</sub>.

#### 4 Conclusion

Aircraft observations were carried out for this study to estimate methane and carbon dioxide emission rates from facilities across the combustion, landfill, WWTP, and agricultural sectors and mid-sized urban areas in NYS. A total of 25 sites were sampled with measurements occurring in June and November/December 2021. Emission rates were calculated using a mass  
 310 balance method by applying Gauss's Theorem to the observed mixing ratios and horizontal wind. Landfills were responsible for the highest estimated methane emission rates ranging from 161 kg h<sup>-1</sup> at Albany County Landfill up to 3440 kg h<sup>-1</sup> at Seneca Meadows Landfill. There were large variations in methane emission estimates both among and within facilities between seasons. The combustion and landfill facilities had the highest CO<sub>2</sub> emission rates, with the Site Independence Station Natural

Gas Power Plant significantly the highest at 300,000 kg h<sup>-1</sup>. The self-reporting EPA GHGRP Inventory is, on average, generally undercounting methane emissions from landfills by a factor of 2. However, there are a few facilities where the inventory is overestimating. Out of the ten landfills sampled, five observed methane emission rates were higher than the inventory, four were within the uncertainty range, and the remaining last landfill observed a lower emission rate than the inventory. These differences can be attributed to a number of factors including operational differences, waste quantity, or seasonal influences. However, this study does not provide sufficient data and information to determine both the reason for the differences and the true emission rate. Long-term, continuous monitoring is crucial in establishing accurate and reliable emission estimates to better inform the NYS GHG Inventory and policy aimed at climate mitigation. However, the results from this study provide valuable and very much needed information on methane sources and their emissions in NYS.

## Data Availability

All data described in this manuscript can be accessed at PANGAEA under the temporary links until publication: Raw data - <https://www.pangaea.de/tok/6be3ada8f0e920f6c6106a4bb563c9cc078b6df9> (Catena & Smith, 2025); Calculated emission rates - <https://www.pangaea.de/tok/8652eae4abef260693f44eb6501e4d9b015954f8> (Catena, Alexandra M. & Smith, 2025).

## Author Contribution

The study was conceptualized by JJS, LTM, EML, and MLS. Measurements were carried out by MLS. All data analysis including scrubbing, manipulation, and facility-level emission rate calculations were done by MLS. Visualization including maps and plots were created by AMC. The manuscript was written by AMC with contributions and feedback from all co-authors.
