16

17 **Abstract**

18 Determining the large-scale Rubisco carboxylation maximum rate ($V_{c,max25}$) in relation to leaf age is
19 crucial for assessing the photosynthetic capacity of canopy leaves in global forests. Young leaves (≤ 180 days)
20 with higher $V_{c,max25}$ compared with old leaves (> 180 days) largely control the seasonality of leaf
21 photosynthetic capacity in tropical and subtropical evergreen broadleaved forests (TEFs). Nevertheless, it
22 has not yet been adequately quantified across TEFs. In this study, we propose an innovative method that
23 leverages neighborhood pixel analysis with a nonlinear least squares fitting approach to derive the $V_{c,max25}$
24 of the young leaves at 0.25° spatial resolution from satellite-based solar-induced chlorophyll fluorescence (SIF)
25 products spanning from 2001 to 2018, which were reconstructed using both the TROPOMI (Tropospheric
26 Monitoring Instrument) SIF and MODIS reflectance data (RTSIF). Validations against in situ observations
27 show that the newly developed $V_{c,max25}$ products accurately capture the seasonality of the young leaf area in
28 South America and subtropical Asia, with correlation coefficients equal to 0.837, 0.661, and 0.952,
29 respectively. Additionally, the $V_{c,max25}$ of the young leaves simulated from the RTSIF is effectively correlated
30 ($R > 0.512$) with that dissolved from the gridded gross primary production (GOSIF-derived GPP).
31 Furthermore, the gridded young leaf $V_{c,max25}$ dataset effectively detects the green-up region during the dry
32 seasons in the tropics, where the average annual precipitation exceeds 2000 mm/year. The clustering patterns
33 of the young leaf $V_{c,max25}$ also effectively match those clustered by climatic variables across the TEFs. Overall,
34 the newly developed $V_{c,max25}$ product is the first satellite-based dataset for addressing the $V_{c,max25}$ of
35 photosynthetically efficient young leaves and can provide useful information for modeling the large-scale
36 photosynthesis dynamics and thus carbon cycle across the TEFs. Herein, we provide the time series of $V_{c,max25}$
37 derived from RTSIF GPP as the main dataset and GOSIF- and FLUXCOM- derived as supplementary
38 datasets. These $V_{c,max25}$ products are available at <https://doi.org/10.5281/zenodo.14807414> (Yang et al., 2025).

40 **Keywords:** maximum rate of carboxylation ($V_{c,max25}$), leaf age, photosynthesis, tropical and subtropical forest.

41

42 **1. Introduction**

43 The maximum carboxylation rate ($V_{c,max}$) is the key leaf attribute that strongly influences the seasonal

44 variations in canopy photosynthesis in tropical and subtropical evergreen broadleaved forests (TEFs; Chen
45 et al., 2022; Wu et al., 2018). This is because $V_{c,max}$ is highly correlated with nitrogen-related plant functional
46 traits (Dechant et al., 2017; Lu et al., 2020), such as leaf nitrogen and chlorophyll content (Lu et al., 2020).
47 However, such nitrogen contents differ greatly at the large scale because the assignment of leaf nitrogen
48 varies in response to many other biotic and abiotic factors (Quebbeman and Ramirez, 2016), such as leaf
49 lifespan (Onoda et al., 2017), leaf temperature (Verheijen et al., 2013), light intensity (Hikosaka, 2014) and
50 species (Evans, 1989). While the large-scale leaf nitrogen is difficult to retrieve from remotely sensed data
51 (Knyazikhin et al., 2013), currently, mapping the regional or global scale $V_{c,max}$ is still challenging.

52 $V_{c,max}$ at 25°C (hereafter denoted as $V_{c,max25}$) is used as a benchmark in most ecosystem modeling for
53 simulating various $V_{c,max}$ values at different temperatures. For instance, the Farquhar-von Caemmerer-Berry
54 (FvCB) leaf photosynthetic model has been widely adopted for simulating plant photosynthesis across
55 different ecosystems (Farquhar et al., 1980; Sun et al., 2015), in which $V_{c,max25}$ is an essential parameter in
56 the FvCB model for determining leaf photosynthetic capacity. However, $V_{c,max25}$ also varies greatly across
57 different tree species and may even show a 2-3-fold difference across the same species (Orndahl et al., 2022).
58 Researches on this issue at the continental scale remain limited and inconclusive, mainly due to the diverse
59 seasonal constraints imposed by the water availability and light; these factors affect leaf scour and defoliation
60 across different climatic zones (Sulc et al., 2017; Kiehn et al., 2013). Recently, two independent satellite
61 remote sensing approaches have been developed with the objective of estimating $V_{c,max25}$ on a global scale.
62 The first satellite-based approach to deriving $V_{c,max25}$ is via leaf chlorophyll content (LCC) (Luo et al., 2019;
63 Lu et al., 2020). Chlorophyll harvests light and provides energy for reactions in the Calvin-Benson-Bassham
64 (CBB) cycle of photosynthesis (Luo et al., 2019). Thus, $V_{c,max25}$ is coordinated with LCC as plants optimize
65 their photosynthetic nitrogen resources (Croft et al., 2020; Xu et al., 2022a; 2022b). The retrieval of $V_{c,max25}$
66 from LCC offers the means of reliable and accurate $V_{c,max25}$ estimation over different spatiotemporal scales.
67 The second satellite-based approach is to deriving $V_{c,max25}$ is via solar-induced chlorophyll fluorescence (SIF)
68 (Mohammed et al., 2019). This is because SIF can serve as a good proxy for mapping gross primary
69 productivity (GPP) at the global scale (Frankenberg et al., 2011; Mohammed et al., 2019). To date, a time
70 series of daily $V_{c,max25}$ maps has been derived using SIF data obtained from the Global Ozone Monitoring
71 Experiment-2 (GOME-2) sensor, spanning the period from 2007 to 2017, with a resolution of 36 km (He et
72 al., 2019). However, there are both strengths and weaknesses of the $V_{c,max25}$ products derived from LCC and
73 SIF. LCCs have been reliably derived from multispectral satellite data at much higher resolution in space and
74 time than SIFs (Chen et al., 2022). Nevertheless, the derivation of LCC from remote sensing data is
75 susceptible to errors in the vegetation structural parameters employed in the derivation (Luo et al., 2019).
76 The conversion of LCC to $V_{c,max25}$ is contingent upon empirical relationships for disparate PFTs, which are
77 subject to considerable uncertainties (Chou et al., 2020; Croft et al., 2017; Houborg et al., 2013; 2015). In
78 contrast, SIF is directly related to vegetation photosynthetic rates, but the spatial and temporal resolution of
79 most satellite SIF observations is relatively low (Liu et al., 2024; Chen et al., 2022). One most recent study
80 demonstrated that TROPOMI SIF data with high spatial and temporal resolutions exhibit a linear relationship
81 with GPP, containing robust signals for $V_{c,max25}$ (Chen et al., 2022). Thus TROPOMI SIF data have been
82 extensively employed for simulating plant photosynthesis across diverse ecosystems (Yang et al., 2023).

83 TEFs constitute 40-50% of the carbon sinks in global forest ecosystems and thus play a central role in
84 the global carbon cycle (Yang et al., 2023; Lu et al., 2021). Despite the perennial nature of the TEFs canopy,
85 recent research indicates that photosynthesis in these forests exhibits significant seasonal fluctuations (Wu et
86 al., 2016). This seasonality in canopy photosynthesis across TEFs primarily stems from the seasonal
87 variability of canopy leaf age structures (Chen et al., 2021; 2022), which are mainly driven by climatic

88 seasonality (Li et al., 2021; Yang et al., 2021). Recent studies have demonstrated that young leaves (≤ 180
89 days) often show higher $V_{c,max25}$ compared with old leaves (> 180 days) and thus largely control the seasonality
90 of leaf photosynthetic capacity in TEFs (Locke and Ort, 2014; Wu et al., 2016). Thus, mapping the $V_{c,max25}$
91 seasonality of young leaves becomes more important for modeling the tropical photosynthesis seasonality at
92 the continental scale. However, satellite-based studies still have challenges in accurately differentiating
93 $V_{c,max25}$ across the leaf age groups in TEFs due to the intricate mechanism of climate influences on the leaf
94 age in TEFs (Jensen et al., 2015; Song et al., 2020). This issue thus complicates the accurate depiction of
95 $V_{c,max25}$ seasonality related to young leaf age. While Earth system models (ESMs) frequently struggle to
96 precisely replicate the seasonal variations in $V_{c,max25}$ among the various leaf age categories (Atkin et al., 2014;
97 Ali et al., 2016). The most difficult issue still stems from the insufficiently understood mechanisms that
98 connect the seasonal changes in water and light availability to the patterns of leaf emergence and shedding.

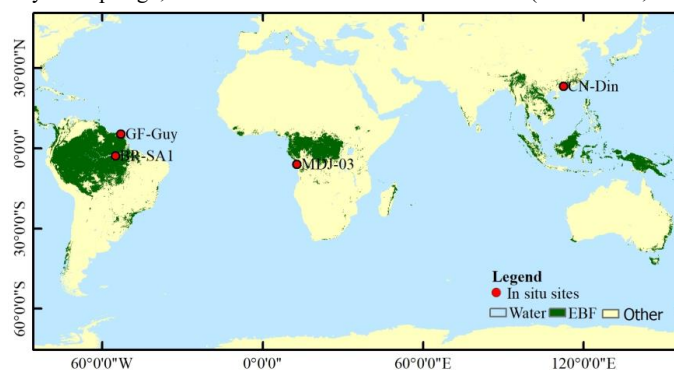

99 To solve above-mentioned gaps in mapping the $V_{c,max25}$ of young leaves, here we categorized the canopy
100 foliage of TEFs into two distinct leaf age groups: young (< 180 days) and old (> 180 days) leaves. Then, we
101 proposed an innovative neighbor-based approach to determine the maximum carboxylation rate ($V_{c,max25}$) for
102 the young leaf cohort by setting a constant $V_{c,max25}$ for the old leaf cohort (Yang et al., 2023), as $V_{c,max25}$ of
103 the old leaf cohort varies very small (Chen et al., 2019; Albert et al., 2018). This research has three specific
104 objectives: (1) to create a global gridded dataset that maps the seasonal variability in young leaf $V_{c,max25}$ across
105 entire TEFs from 2001 to 2018; (2) to evaluate the accuracy of these datasets against ground-based
106 measurements and dissolved $V_{c,max25}$ data from the GOSIF-derived GPP datasets; and (3) to analyze the
107 seasonal fluctuations in the young leaf $V_{c,max25}$ across the entire TEFs. This newly developed $V_{c,max25}$ dataset
108 can help to provide new insights into tropical and subtropical phenology by detailing the seasonality of
109 young leaf $V_{c,max25}$. This valuable information can also aid in the refinement and improvement of the tropical
110 phenological models used in the ESMs.

111

112 2. Materials and methods

113 2.1 Study area

114 The studied TEFs were identified by selecting pixels marked as EBF (Evergreen Broadleaf Forest; Sulla-
115 Menashe et al., 2018) on MODIS MCD12C1 land cover maps at 0.05° spatial resolution (see Fig. 1). TEFs
116 in South America are the largest tropical rainforests in the world and are mainly located at $18^\circ\text{N} \sim 30^\circ\text{S}$ and
117 $40 \sim 90^\circ\text{W}$, followed by TEFs in tropical Africa ($10^\circ\text{N} \sim 10^\circ\text{S}$, $10^\circ\text{W} \sim 30^\circ\text{E}$). TEFs in tropical Asia are mainly
118 located in the Malay Archipelago, Asian Peninsula and northern Australia ($30^\circ\text{N} \sim 20^\circ\text{S}$, $70 \sim 150^\circ\text{E}$).

119

120 **Figure 1.** Tropical and subtropical broadleaved evergreen forests (TEFs) and in situ observation sites. The
121 studied TEFs is determined as those labeled as evergreen broadleaf forest (EBF) from the MODIS land cover
122 maps at a 0.05° spatial resolution. The red dots are in situ observation sites of $V_{c,max25}$.

123

124 **2.2 Data sources for mapping the young leaves $V_{c,max25}$**

125 The continental scale GPP (referred to as RTSIF-derived GPP) at a resolution of 0.125° and spanning
 126 from 2001 to 2018 was derived from TROPOMI (Tropospheric Monitoring Instrument) SIF data, according
 127 to the relationships between the SIF and GPP delineated by Chen et al. (2022), which used a constant value
 128 of 15.343 to transform the SIF to the GPP (see Sect. 2.4.1). Monthly meteorological data, including the air
 129 temperature (T_{air}) from the ERA5-Land dataset (Zhao et al., 2020), vapor pressure deficit (VPD) from ERA-
 130 Interim (Yuan et al., 2019), and downward shortwave solar radiation (SW) provided by the Breathing Earth
 131 System Simulator (BESS; Ryu et al., 2018), were used to calculate the Michaelis–Menton constant for
 132 carboxylase (K_C), the Michaelis–Menton constant for oxygenase (K_O), the CO_2 compensation point (r^*), dark
 133 respiration (R_d), and thus to calculate the An parameter according to the equations in Table S4 (see the
 134 Supplement). All datasets were collected and harmonized to a spatial resolution of 0.125° . Further details
 135 regarding the satellite and input data are provided in Table 1.

136 **Table 1. Data sources for mapping the $V_{c,max25}$ of young leaves across tropical and subtropical**
 137 **broadleaved evergreen forests**

Data name and Abbr.	Source	Usage	Spatial resolution	Temporal resolution	Temporal coverage
Temperature (T_{air})	ERA5-Land	Calculate the K_C , K_O , r^* , and R_d for An	$0.1^\circ \times 0.1^\circ$	Monthly	2001.1-2018.12
Shortwave solar radiation (SW)	BESS	Calculate the J_e for An	$0.05^\circ \times 0.05^\circ$	Monthly	2001.1-2018.12
Vapor pressure deficit (VPD)	ERA5-Land	Calculate the C_i for An	$0.1^\circ \times 0.1^\circ$	Monthly	2001.1-2018.12
Sun induced chlorophyll fluorescence (RTSIF)	TROPOMI SIF	RTSIF-derived GPP	$0.05^\circ \times 0.05^\circ$	Monthly	2001.1-2018.12
Gross primary production retrieved from OCO-2 Solar induced chlorophyll fluorescence (GOSIF)	GOSIF	GOSIF-derived GPP	$0.05^\circ \times 0.05^\circ$	Monthly	2001.1-2018.12
Gross primary production from eddy covariance flux tower measurements (FLUXCOM)	FLUXCOM	FLUXCOM-derived GPP	$0.5^\circ \times 0.5^\circ$	Monthly	2001.1-2013.12
Leaf-age-dependent leaf area index seasonality product (Lad-LAI)	Yang et al., 2023	Dissolved $V_{c,max25}$ from GOSIF-derived GPP	$0.25^\circ \times 0.25^\circ$	Monthly	2001.1-2018.12

138

139 **2.3 Data for validating the young leaves $V_{c,max25}$**

140 The $V_{c,max25}$ of the young and mean leaves age from in situ observations were collected to validate the
 141 $V_{c,max25}$ seasonality simulated from RTSIF-derived GPP by the proposed model (Table S1). Monthly young
 142 leaves and mean leaves age $V_{c,max25}$ observations occurred between August and December 2012 at the
 143 Santarem Primary Forest Ecosystem Research Station (BR-Sa1) sites (Albert et al., 2018). The annual mean
 144 leaves age $V_{c,max25}$ observations were acquired over 12 months during the period of 2004 to 2016 at the

145 Guyaflux Forest Ecosystem Research Station (GF-Guy) sites (Wang et al., 2022) and from 2003 to 2009 at
146 the Dinghushan Forest Ecosystem Research Station (CN-Din) sites ([https://fluxnet.org/data/fluxnet2015-](https://fluxnet.org/data/fluxnet2015-dataset/)
147 [dataset/](https://fluxnet.org/data/fluxnet2015-dataset/)), and in November 2012 at the Mbam–Djerem National Park 3 (MDJ-03) sites (Ishida et al., 2015).
148 The data regarding the young leaves and mean leaves age $V_{c,max25}$ for the BR-Sa1 site were obtained directly
149 from the literature, whereas the remaining three sites were sourced solely through existing literature,
150 providing only the mean leaves age $V_{c,max25}$ for each. To evaluate the simulated young leaves $V_{c,max25}$, the
151 dissolved method (see Sect. 2.5.1) was employed to compute the young leaves $V_{c,max25}$ as the true values in
152 accordance with the Lad-LAI product (Yang et al., 2023). A monthly leaf-age-dependent leaf area index
153 product (referred to as Lad-LAI) at 0.25° spatial resolution over the continental scale during 2001–2018,
154 developed by Yang et al. (2023), was used to derive $V_{c,max25}$ through the dissolved method (see Sect. 2.5.1)
155 from the GOSIF-derived GPP, with the aim of evaluating the efficiency and reliability of the newly proposed
156 methodology. Furthermore, Gross primary production retrieved from OCO-2 Solar induced chlorophyll
157 fluorescence (referred to as GOSIF-derived GPP) data for the period spanning from 2001 to 2018, with a
158 resolution of 0.05°, and Gross primary production from eddy covariance flux tower measurements (referred
159 to as FLUXCOM-derived GPP) data for the period between 2001 and 2013, with a resolution of 0.5°, were
160 also used to test the uncertainty of the proposed model for the simulation of monthly gridded young leaf
161 $V_{c,max25}$ (Table 1).

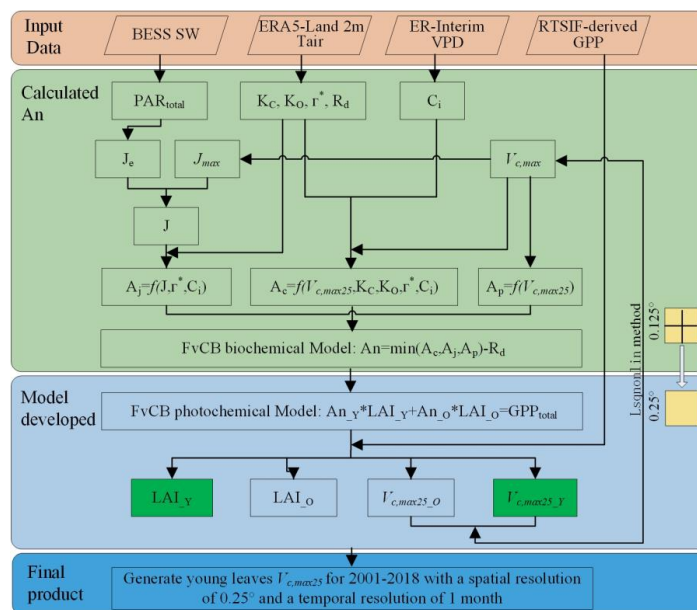

162

163 2.4 Methods for simulating the young leaves $V_{c,max25}$

164 Fig. 2 shows the practical procedures applied to produce the seasonal dynamic product of the young leaf
165 $V_{c,max,25}$. The ‘leaf demographic-identical (LDO)’ hypothesis proposes that the leaf cohorts can be classified
166 into three categories on the basis of their growth, development and lifespan: young leaf (less than 60 days),
167 mature leaf (between 60 days and 180 days), and old leaf (greater than 180 days) (Wu et al., 2017). To ensure
168 comparability between the observations and simulations and simplify the calculations, we categorized the
169 leaf area index (LAI) and the corresponding net CO₂ assimilation rate (An) into two groups based on leaf
170 age: those with a leaf age greater than 180 days were considered ‘old,’ and those with a leaf age less than 180
171 days were considered ‘young’ (Chen et al., 2019). Since the total GPP of the leaf cohort remained constant
172 and the leaf cohorts were composed of leaves of different ages, we calculated the total GPP as a linear sum
173 of the GPP of each leaf age cohort. The total GPP was simulated using the FvCB photochemical model by
174 combining the LAI groups (young leaf LAI_Y vs. old leaf LAI_O; Equation 1) and the corresponding net
175 assimilation rates of CO₂ (young and mature An_Y vs. old leaf An_O ; Equation 1) (Farquhar et al., 1980).

$$176 \quad LAI_Y \times An_Y + LAI_O \times An_O = GPP_{total} \quad (1)$$

177 where LAI_Y represents the LAI of young leaves (<180 days) and LAI_O represents the LAI of old leaves
178 (>180 days). An_Y and An_O represent the net CO₂ assimilation rates of young and old leaves, respectively.
179 The sum of LAI_Y and LAI_O was set as the total canopy LAI. GPP_{total} refers to the total gross primary
180 production of the canopy.

181

182 **Figure 2.** Procedures for mapping the $V_{c,max25}$ of young leaves using a neighbor-based approach.

183 The gridded GPP data over the whole TEFs were derived from SIF (denoted as RTSIF-derived GPP)
 184 using a linear SIF–GPP regression model (see Sect. 2.4.1), which was established based on in situ GPP from
 185 76 eddy covariance (EC) sites (Chen et al., 2022). The majority of the tropical and subtropical TEFs retain
 186 leaves year-round, and their total LAI shows marginally small spatial and seasonal changes (Wu et al., 2016;
 187 Fig. S2). Therefore, previous modeling studies have assumed a constant value for the total LAI in tropical
 188 and subtropical TEFs (Cramer et al., 2001; Arora and Boer, 2005; De Weirdt et al., 2012). Based on this, we
 189 collected observed seasonal LAI dynamics in tropical and subtropical TEFs from previously published
 190 literature, which showed a constant value of LAI at around 6.0 (Fig. S2; Table S3). Consequently, in this
 191 study, we streamlined the data to assume that the seasonal LAI was broadly equivalent to 6.0 in tropical and
 192 subtropical TEFs. This assumption was also found to be reasonable in the region of the TEFs by Yang et al.
 193 (2023). The LAI_o is equal to $6 - LAI_y$. The $V_{c,max25}$ values for old cohorts were set to $20 \mu\text{mol m}^{-2} \text{s}^{-1}$
 194 according to previous ground-based observations (Chen et al., 2019; Zhou et al., 2015) in our method. The
 195 An_o can be calculated according to the FvCB biochemical model (Farquhar et al., 1980; Bernacchi et al.,
 196 2003; see Sect. 2.4.2). An_y can be expressed as the function of $V_{c,max25}$ for young leaves (see Sect. 2.4.2).
 197 Consequently, only LAI_y and $V_{c,max25}$ of young leaves remains as the final parameters to be solved in
 198 Equation 1.

199 The model's complexity is evident due to the two parameters that needed to be solved. To overcome the
 200 challenge of the model calculation, we assumed that the four adjacent pixel points had homogeneous plant
 201 functional types (PFTs) and had consistent leaf age cohorts. The LAI and $V_{c,max25}$ of young leaves were
 202 estimated using nonlinear least squares and constraints on the basis of the GPP values with the four
 203 neighboring pixels, according to Equation 1. The input gridded dataset consisted of the GPP obtained from
 204 the RTSIF and climatic data such as T_{air} , VPD and SW, and the spatial resolution of these data was
 205 homogeneously resampled to 0.125° , resulting in a spatial resolution of 0.25° for the map of the output young
 206 leaf $V_{c,max25}$. We further validated the robustness and reliability of the neighborhood pixel method by scaling

207 the numbers of the neighborhood pixels, yielding a lower spatial resolution version, $V_{c,max25}$ at 0.5° . In the
208 optimization process, an mean $V_{c,max25}$ value was determined by assuming that the leaf cohort was completely
209 young. A reasonable adjustment for the young leaf $V_{c,max25}$ value was then determined based on previously
210 published literature (Chen et al., 2022; Yang et al., 2023) and the initial value. Importantly, the difference
211 between the finely optimized young leaf $V_{c,max25}$ value and the initial value could often be significant and
212 outside the margin of error. Therefore, an appropriate adjustment for the young leaf $V_{c,max25}$ value needs to be
213 carefully determined (He et al., 2019). All analyses were performed using MATLAB (R2 version).

214

215 **2.4.1 Calculating the GPP (RTSIF-derived GPP) from TROPOMI SIF**

216 SIF is a widely used proxy for canopy photosynthesis (Yang et al., 2015; Dechant et al., 2020). Here,
217 we used a long-term reconstructed TROPOMI SIF dataset (RTSIF; Chen et al., 2022) to estimate GPP
218 seasonality. Previous analyses showed that RTSIF was strongly linearly correlated to eddy covariance (EC)
219 GPP and used 15.343 as a transformation coefficient to convert RTSIF to GPP (Chen et al., 2022). We
220 collected seasonal GPP data observed at four EC sites from the FLUXNET2015 tier 1 dataset (**Table S2**;
221 Pastorello et al., 2020) and validated the Chen et al. (2022) simple SIF–GPP relationship (**Fig. S1** in the
222 Supplement). Results confirmed the robustness of the Chen et al. (2022) simple SIF–GPP relationship for
223 estimating the GPP seasonality in tropical and subtropical TEFs ($R > 0.49$). Despite the potential
224 overestimation (**Fig. S1f**) or underestimation (**Fig. S1h**) of the magnitudes, the RTSIF-derived GPP mostly
225 captured the seasonality of the EC GPP at all four sites ($d_{\text{phase}} < 0.29$).

226

227 **2.4.2 Calculating the net CO₂ assimilation rate**

228 The net CO₂ assimilation rate is a significant parameter characterizing the photosynthetic rate.
229 According to Farquhar’s (1980) biochemical model (FvCB), the net CO₂ assimilation rate (A_n) depends on
230 the most limiting conditions for photosynthesis (RuBisCO saturation A_c , RuBP saturation A_j , or TPU
231 saturation A_p) and the intensity of dark respiration (R_d , Bernacchi et al., 2013). The net CO₂ assimilation rate
232 (either A_{n_y} or A_{n_o}) can be expressed by the following equation:

$$233 \quad A_n = \min(A_c, A_j, A_p) - R_d \quad (2)$$

234 **(1) Calculation of A_c**

235 When the CO₂ pressure is low ($C_i < 300 \mu\text{mol mol}^{-1}$), the net photosynthesis rate is mainly constrained
236 by the activity and quantity of the carboxylase RuBisCO. The Rubisco-limited photosynthetic rate A_c can be
237 calculated using the following equation under a limited carboxylation rate:

$$238 \quad A_c = V_{cmax} \times \frac{C_i - \Gamma^*}{C_i + K_c \times (1 + \frac{O}{K_o})} \quad (3)$$

239 where Γ^* represents the CO₂ compensation point and C_i is the intercellular CO₂ pressure. K_c , K_o , O , and
240 Γ^* are estimated based on the leaf temperature using **Equation 4** to calculate their values at the given
241 temperature, which is used to convert from their values at 25° .

$$242 \quad P = P_{25} \times e^{\frac{(T_k - 298.15) \times \Delta H_p}{r \times T_k \times 298.15}} \quad (4)$$

243 where P is the parameter at each temperature that varies with temperature, including the Michaelis constant
244 for O₂ (K_o), the Michaelis constant for CO₂ (K_c), the intercellular concentration (O) and the CO₂
245 compensation point (Γ^*). P_{25} denotes the constant temperature dependence parameter at 25°C (Bernacchi et
246 al., 2001); specifically, K_c , K_o , T and O at 25°C are equal to $404.9 \mu\text{mol mol}^{-1}$, $278.4 \text{mmol mol}^{-1}$, $42.75 \mu\text{mol}$
247 mol^{-1} and 210mmol mol^{-1} , respectively. ΔH_p is the activation energy, which varies with the temperature and
248 parameters. r is the standard gas constant ($8.314 \text{J mol}^{-1} \text{K}^{-1}$). T_k is the leaf temperature (unit: Kelvin).

249 Using the stomatal conductance model, the internal CO₂ concentration (C_i , **Equation 5**) was estimated
250 to depend on the atmospheric CO₂ concentration instead of the ambient relative moisture (Xu et al. 2017; Lin

251 et al., 2015; Medlyn et al., 2011).

$$252 \quad C_i = 380 \times \left(1 - \frac{1}{1.6 \times \left(1 + \frac{3.77}{\sqrt{VPD}}\right)}\right) \quad (5)$$

253 where C_i represents the internal CO₂ concentration and VPD denotes the vapor pressure deficit data in hPa.

254 (2) Calculation of A_j

255 When the concentration of CO₂ is high, leaf photosynthesis is constrained by RuBP regeneration. The
 256 photosynthetic rate (A_j) is then limited by electron transport and calculated using the following equation:

$$257 \quad A_j = J \times \frac{C_i - \Gamma^*}{4 \times (C_i + 2 \times \Gamma^*)} \quad (6)$$

258 where J is the electron transport rate for leaf photosynthesis limited by light. It is a quadratic function of the
 259 full electron transfer rate (J_e) and maximum electron transfer rate (J_{max}) (Bernacchi et al., 2013; Luo et al.,
 260 2001). The maximum electron transport rate (J_{max}), the maximum carboxylation rate ($V_{c,max25}$), and the CO₂
 261 compensation point in the absence of mitochondrial respiration (Γ^*) were used to determine the Michaelis–
 262 Menten constants for oxygenation and carboxylase. For the detailed calculation process, refer to **Equations**
 263 **7-9**.

$$264 \quad J = \frac{J_e + J_{max} - \sqrt{(J_e + J_{max})^2 - 4 \times J_e \times J_{max} \times \theta}}{2 \times \theta} \quad (7)$$

$$265 \quad J_e = PAR_{total} \times \theta \times \phi \times \kappa \quad (8)$$

$$266 \quad J_{max} = J_{max,25} \times e^{\left(\frac{25 - T_{opt}}{\phi} - \frac{T_k - 273.15 - T_{opt}}{\phi}\right)^2} \quad (9)$$

267 where J_{max} denotes the maximum electron transfer rate at a given temperature and varies with temperature.
 268 $J_{max,25}$ is the maximum electron transfer rate at 25°C, is usually assigned $1.67 \times V_{c,max25}$ in TEFs. T_{opt} and
 269 T_{air} are the optimum temperature for electron transfer and the leaf temperature, respectively. J_e is a
 270 function of canopy photosynthetically active radiation (PAR_{total}) and can be calculated by inputting SW and
 271 LAI; for details, refer to Weiss and Norman (1985) and Ryu et al. (2018). θ , ∂ , ϕ , and Φ are constants
 272 and equal to 0.7, 0.85, 0.5, and 0.85, respectively (Xu et al., 2017; Yang et al., 2023). κ is a function of the
 273 optimal temperature, which is the maximum quantum efficiency of PSII photochemistry.

274 (3) Calculation of A_p

275 The rate of photosynthesis is limited by the export of triose phosphate. A_p represents the photosynthetic
 276 capacity to export or utilize the photosynthetic products for the different LAI cohorts, as determined by
 277 multiple on-site observations.

$$278 \quad A_p = c \times V_{c,max25} \quad (10)$$

279 The ratio of the interior foliar CO₂ concentration to the environmental CO₂ concentration was fixed at
 280 0.5 for C3 species and 0.7 for C4 species based on previous investigations. (Fabre et al., 2019; McClain et
 281 al., 2019; Yang et al., 2016).

282 2.5 Methods for evaluating the simulated young leaves $V_{c,max25}$

283 This study assessed the proposed algorithms in three ways: (1) monthly observed $V_{c,max25}$ through in situ
 284 measurements, which were collected from the literature; (2) yearly dissolved $V_{c,max25}$ from the GOSIF-derived
 285 GPP; and (3) monthly Lad-LAI product dependent on new leaf age covering the entire TEF region; these
 286 were obtained from the RTSIF product by Yang et al. (2023). However, the in situ $V_{c,max25}$ of young leaves
 287 remains an unfulfilled need, only one site (BR-Sa1; see **Sect. 2.3**) of annual monthly young leaves $V_{c,max25}$ is
 288 available. In order to compensate for the lack of ground-based validation, three sites (GF-Guy, MDJ-03, CN-
 289 Din) of the seasonality $V_{c,max25}$ of mean leaves age were also collected and calculated the young leaves $V_{c,max25}$
 290 using the dissolved method (see **Sect. 2.5.1**) based on the Lad-LAI product (Yang et al., 2023). To evaluate
 291 the efficiency and reliability of the newly proposed methodology, a comparison was also conducted between
 292 the grid young leaves $V_{c,max25}$ simulated from RTSIF-derived GPP by using the newly proposed method and
 293 that dissolved from GOSIF-derived GPP and the Lad-LAI product by using dissolved method. To investigate
 294 the reliability of the neighborhood-based subdivision technique, we conducted a comparative analysis of the
 295

296 young leaves $V_{c,max25}$ derived from RTSIF-derived GPP using 2×2 (0.25° resolution) and 4×4 (0.5° resolution)
297 neighboring pixels. To assess the uncertainties stemming from the estimation of gross primary productivity
298 (GPP), we incorporated two additional GPP products, GOSIF-derived GPP and FLUXCOM GPP (Jung et al.,
299 2019; Yang et al., 2023), along with the original RTSIF-derived GPP, resulting in three distinct versions of
300 the young leaves $V_{c,max25}$ products.

301

302 2.5.1 Dissolved method for evaluating the young leaves $V_{c,max25}$

303 The total GPP can be expressed as the sum of the GPP of the old and young leaf age cohorts. The GPP
304 of each leaf age cohort is a function of the corresponding LAI cohort and net CO_2 assimilation rate. In
305 accordance with related studies, the $V_{c,max25}$ of old leaves is presumed to be a constant value (Chen et al.,
306 2020). When the LAI of different leaf ages is known, only the $V_{c,max25}$ of the young leaves remains unknown
307 in **Equation 1**. The value of the $V_{c,max25}$ of the young leaves can be determined by solving the aforementioned
308 **Equation 1**. This method involves dividing GPP into old and young GPP according to leaf age, with the
309 $V_{c,max25}$ of young leaves being directly solved by using the Lad-LAI product, hence the term 'dissolved
310 method'. At present, there is a lack of available data regarding the ground $V_{c,max25}$ of different leaf ages. The
311 dissolved method is employed to validate the reasonableness of the proposed algorithm.

312

313 2.5.2 K-means method for classification of the young leaves $V_{c,max25}$

314 We analyzed the spatial patterns of $V_{c,max25}$ across TEFs using the K-means clustering analysis. K-means
315 algorithm is an iterative algorithm that tries to partition the dataset into K predefined distinct non-overlapping
316 subgroups (clusters) where each data point belongs to only one group. It tries to make the intra-cluster data
317 points as similar as possible while also keeping the clusters as different (far) as possible. It assigns data points
318 to a cluster such that the sum of the squared distance between the data points and the cluster's centroid
319 (arithmetic mean of all the data points that belong to that cluster) is at the minimum. The less variation we
320 have within clusters, the more homogeneous (similar) the data points are within the same cluster. The way k-
321 means algorithm works is as follows:

- 322 (1) Specify number of clusters K.
- 323 (2) Initialize centroids by first shuffling the dataset and then randomly selecting K data points for the
324 centroids without replacement.
- 325 (3) Keep iterating until there is no change to the centroids. i.e. assignment of data points to clusters isn't
326 changing.
- 327 (4) Compute the sum of the squared distance between data points and all centroids.
- 328 (5) Assign each data point to the closest cluster (centroid).
- 329 (6) Compute the centroids for the clusters by taking the average of the all data points that belong to each
330 cluster.

331

332 2.5.3 Precision evaluation index

333 Both the root mean square error (RMSE, **Equation 11**) and Pearson's correlation coefficient (R,
334 **Equation 12**) were employed to evaluate the model capabilities.

$$335 \quad RMSE = \sqrt{\frac{\sum_{i=1}^N (V_i - U_i)^2}{N}} \quad (11)$$

$$336 \quad R = \frac{\sum_{i=1}^N (V_i - \bar{V})(U_i - \bar{U})}{\sqrt{\sum_{i=1}^N (V_i - \bar{V})^2} \sqrt{\sum_{i=1}^N (U_i - \bar{U})^2}} \quad (12)$$

337
$$SD_S = \sqrt{\frac{1}{N} \sum_{i=1}^N (V_i - \bar{V})^2} \quad (13)$$

338
$$SD_m = \sqrt{\frac{1}{N} \sum_{i=1}^N (U_i - \bar{U})^2} \quad (14)$$

339
$$LCS = 2SD_S SD_m (1 - R) \quad (15)$$

340 where N is the total point extracted from the $V_{c,max25}$ products simulated from RTSIF-derived GPP; V_i and
341 U_i represent the monthly simulated and observed in situ measurements $V_{c,max25}$, respectively; and \bar{V} and \bar{U}
342 are the mean values of the simulated and observed in situ measurements $V_{c,max25}$. Moreover, the continental
343 $V_{c,max25}$ simulated from the proposed model was compared against that the dissolved from GOSIF-derived
344 GPP and Lad-LAI over the TEF regions. SD_S is standard deviation of the simulation, and SD_m is the
345 standard deviation of the measurement. And the lack of correlation weighted by the standard deviations
346 (phase-related difference; d_{phase} ; $d_{phase} = LCS$).

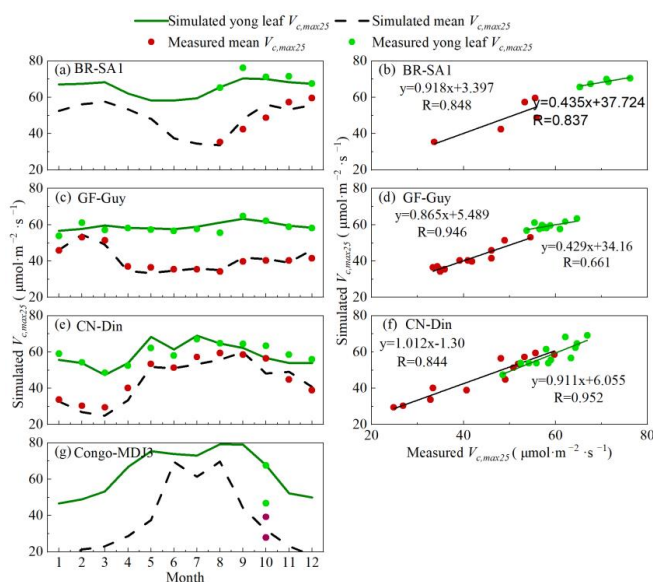

347

348 3. Results

349 3.1 Validation of the gridded $V_{c,max25}$ seasonality of young leaves using in situ observations

350 The seasonality of simulated mean $V_{c,max25}$ of all canopy leaves and $V_{c,max25}$ of young leaves was
351 evaluated with in situ measurements at 4 sites: CN-Din site in southern China (Latitude: 23.170°N; Longitude:
352 112.540°E), MDJ-03 site in Congo (Latitude: 5.984° S; Longitude: 12.869° E), and BR-Sa1 (Latitude:
353 2.8567°S; Longitude: 54.958°W) and GF-Guy (Latitude: 5.278°N ; Longitude: 52.925°W) sites in southern
354 America. Overall, the estimated mean $V_{c,max25}$ of all canopy leaves (black line) ranged from 20 $\mu\text{mol m}^{-2} \text{s}^{-1}$
355 to 60 $\mu\text{mol m}^{-2} \text{s}^{-1}$, and their seasonal fluctuations agreed well with the in situ mean $V_{c,max25}$ (red dots) (**Fig.**
356 **3**). In contrast, $V_{c,max25}$ (green line) of the young leaf cohorts (green line) exhibited higher values compared
357 with those of all canopy leaves, ranging from between 40 $\mu\text{mol m}^{-2} \text{s}^{-1}$ and 80 $\mu\text{mol m}^{-2} \text{s}^{-1}$. This finding is
358 consistent with previous studies that young leaves were more photosynthetically effective than old leaves
359 (Urban et al., 2008; Albert et al., 2018; Menezes et al., 2022). Specifically, our simulations can capture well
360 the various seasonal patterns of $V_{c,max25}$ across different sites. At the BR-Sa1 site, the estimates were
361 correlated well with the observed mean $V_{c,max25}$ for all ($R=0.85$) and young leaves ($R=0.84$), which both
362 increased during the dry season (approximately between June December) (**Fig. 3a, 3b**). At the GF-Guy site,
363 in situ mean $V_{c,max25}$ of all canopy leaves showed considerable seasonality, while $V_{c,max25}$ of young leaves
364 remain much stable (**Fig. 3c**). Our estimates also performed well in simulating the $V_{c,max25}$ of all canopy leaves
365 ($R=0.95$) and that of young leaves ($R=0.66$) (**Fig. 3d**). In contrast, at the Din site in subtropical Asia, both
366 $V_{c,max25}$ for all canopy leaves and young leaves increased during the wet-season period, with the highest
367 precipitation occurring in June or July (**Fig. 3e**). This is similar in the Congo-MDJ3 site, where both $V_{c,max,25}$
368 for all canopy leaves and young leaves also increased during the wet-season period but with larger seasonal
369 variations. Our model showed the best simulations of $V_{c,max25}$ of young leaves in Din site (all canopy leaves:
370 $R=0.84$; young leaves: 0.95). Nevertheless, many more long-term in situ measurements are needed to
371 determine the reliability of these time series fluctuations.

372 Then, we analyzed the spatial patterns of $V_{c,max25}$ across TEFs using the K-means clustering analysis.
373 Results showed that $V_{c,max25}$ for young leaf cohorts in tropical forests had evident seasonal dynamics, bringing
374 influences on canopy photosynthesis. **Fig. S3** shows the seasonal fluctuations in $V_{c,max25}$ for the young leaves
375 in ten individual regions, as clustered using K-means analysis. In the middle and southern regions of the
376 Amazon, the young leaf $V_{c,max25}$ decreased with the onset of the wet season (approximately February) and
377 conversely increased with the onset of the rainy season (approximately June). In contrast, in subtropical Asia,
378 the young leaf $V_{c,max25}$ increased during the wet season, peaking in June or July when rainfall was highest.
379 Near the equator, the young $V_{c,max25}$ showed a bimodal seasonality with very slight variations.

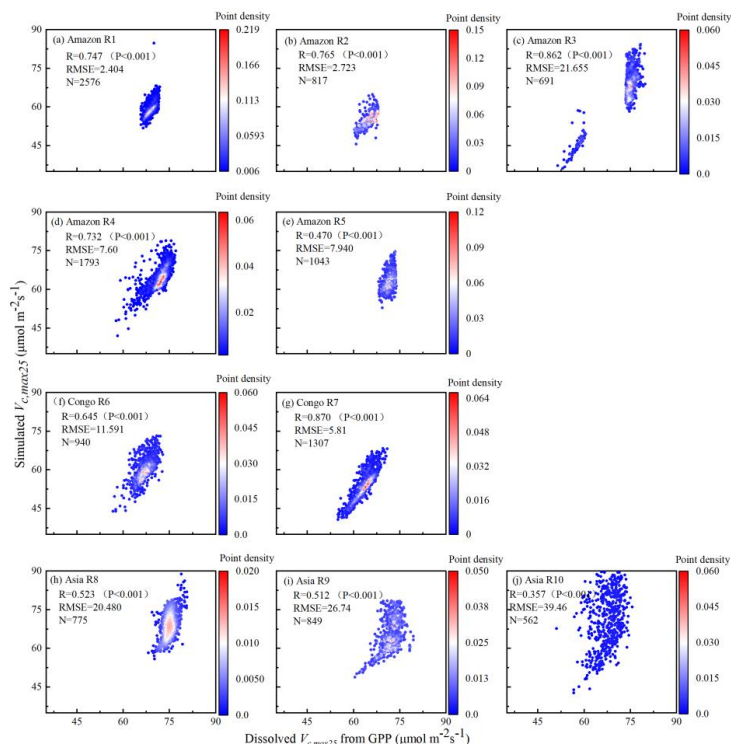

380

381 **Figure 3.** Validations of simulated seasonal $V_{c,max25}$ for all canopy leaves and young leaves with in situ
 382 observations. The green lines and green dots are the seasonal young leaf $V_{c,max25}$ simulated from RTSIF
 383 derived GPP by the proposed method. The black line and red dots are the mean leaf age $V_{c,max25}$ values from
 384 the simulations and in situ observations, respectively. Simulated $V_{c,max25}$ denoted as the young leaf $V_{c,max25}$
 385 simulated from RTSIF-derived GPP by using the new proposed method. Mean $V_{c,max25}$ denoted as the mean
 386 leaves age $V_{c,max25}$.

387

388 3.2 Validation of the young leaves $V_{c,max25}$ simulated from RTSIF-derived GPP against that 389 dissolved from GOSIF-derived GPP

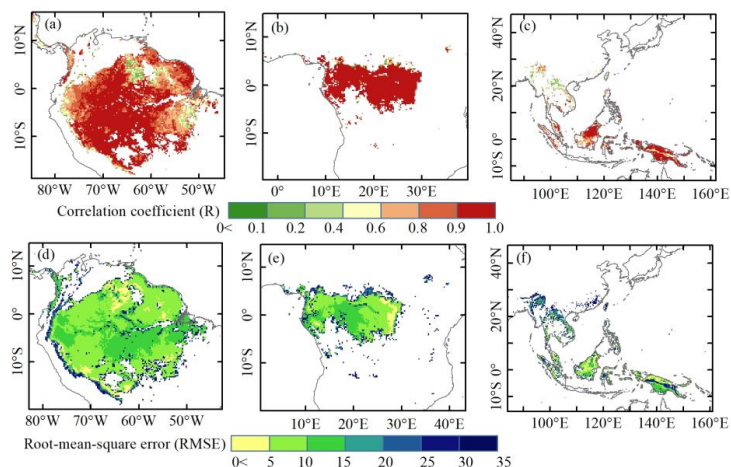

390 The $V_{c,max25}$ of young leaves simulated from RTSIF-derived GPP demonstrated significant correlations
 391 (R ranges from 0.512 to 0.870) with those dissolved from GOSIF-derived GPP (**Fig. 4a-j**). However, notable
 392 discrepancies remained between these two independent $V_{c,max25}$ estimates (**Fig. 5**). Statistically, the seasonally
 393 young leaf $V_{c,max25}$ simulated from RTSIF-derived GPP exhibited strong correlations with those dissolved
 394 from the GOSIF-derived GPP ($R > 0.80$) across 86.34% of the entire TEFs area, with a mean correlation
 395 coefficient of 0.87 (**Fig. 5a-c**). And the RMSE remained below 11.591 for 91.68% of the TEFs (**Fig. 4d-f**).
 396 Nevertheless, this correlation varies across sub-regions. The K-means spatial clustering analysis showed that
 397 $V_{c,max25}$ of young leaves simulated from RTSIF-derived GPP was more strongly correlated with the those
 398 estimated from the GOSIF-derived GPP in the low-latitudes (Amazon R1 $R=0.903$; Amazon R2 $R=0.935$;
 399 Amazon R4 $R=0.869$; Amazon R5 $R=0.767$; Congo R6 $R=0.905$; Congo R7 $R=0.965$; Asia R8 $R=0.860$;
 400 Asia R9 $R=0.841$) in comparison to those in the higher latitudes (Amazon R3 $R=0.602$; Amazon R10
 401 $R=0.499$). The RMSE results also showed better performance in capturing the seasonality of $V_{c,max25}$ in the
 402 low-latitude regions (Amazon R1 RMSE=1.779; Amazon R2 RMSE=2.169; Amazon R4 RMSE=4.668;
 403 Congo R6 RMSE=3.262; Congo R7 RMSE=4.726; Asia R8 RMSE=3.378; Asia R9 RMSE=5.861; **Fig. S4**)
 404 compared to those in the regions further from the equator at higher latitudes (Amazon R5 RMSE = 14.845;
 405 Amazon R10 RMSE = 6.918; **Fig. S5**). However, more in situ measurements are needed to refine and validate
 406 the simulated $V_{c,max25}$ product. Despite these obstacles, the present product provides an improvement from
 407 the current state of the art and can be immediately applied in parameterizing terrestrial ecosystem models.

408

409 **Figure 4.** Comparisons of the young leaves $V_{c,max25}$ simulated from RTSIF-derived GPP against that dissolved
 410 from GOSIF-derived GPP

411

412

413 **Figure 5.** The root mean square error (RMSE) and correlation coefficient (R) between the young leaves
 414 $V_{c,max25}$ derived from RTSIF-derived GPP and that dissolved from GOSIF-derived GPP.

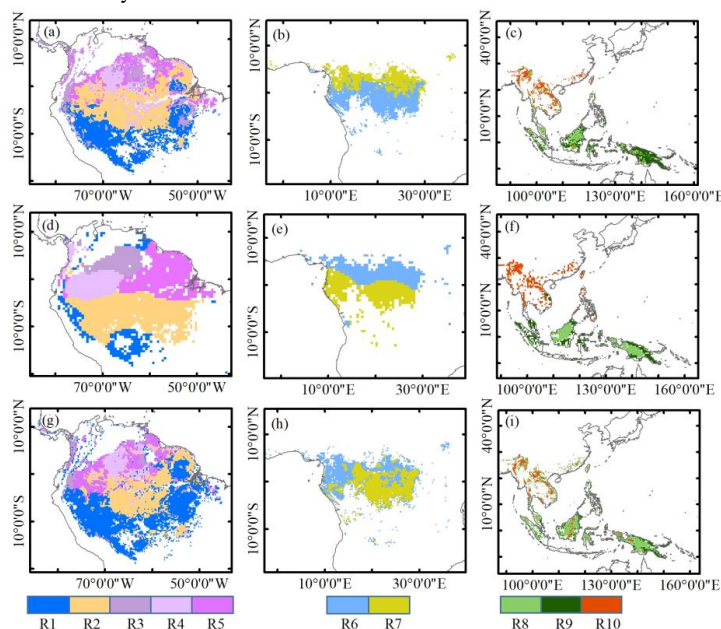

415

416 3.3 Comparison of the seasonal $V_{c,max25}$ of young leaves with the leaf age product

417 Field measurements revealed different seasonal patterns of young leaf $V_{c,max25}$ across the TEFs. However,
 418 due to the low spatial coverage of in situ observation sites, it still remains challenging to comprehensively
 419 and directly assess the their variations. Here, the K-means clustering analysis was performed on the simulated
 420 $V_{c,max25}$ maps to investigate its geospatial coherency in comparison with a gridded leaf age product developed
 421 by Yang et al. (2023).

422 The geospatial distribution of the young leaf $V_{c,max25}$ products clustered based on the satellite vegetation
 423 signals (Fig. 6a-c) was closely matched those of climatic factors classified by the K-means clustering analysis
 424 (Fig. 6d-f) analyzed by Chen et al. (2021). These distributions were generally comparable to the spatial
 425 patterns of the Lad-LAI products clustered based on the endogenous climate variables presented earlier in
 426 the maps from Yang et al. (2021) (Fig. 6g-i). All these results exhibit similar spatial clustering patterns. In
 427 the middle (sub-region R2) and northern (sub-region R3) Amazon (Fig. 7a), the seasonal variation in the
 428 young leaf $V_{c,max25}$ (Fig. 8b, c) was consistent with that of the BR-Sa1 and GF-Guy sites, where young leaves
 429 increase during the dry seasons. Moreover, the seasonality of the young leaf $V_{c,max25}$ in subtropical Asia (Fig.
 430 8f) was similar to that of Din, where young leaves conversely increase during the wet seasons. The young
 431 leaf $V_{c,max25}$ peaked in July in sub-region R10, which was located between sub-regions R8 and R9, where the
 432 young leaf $V_{c,max25}$ exhibited a bidirectional phenology (Fig. 8j). The other four sub-regions (R1, R2, R7 and
 433 R8) were located near the equator. Unlike sub-regions R1, R2, R7 and R8 that were far from the equator, the
 434 young leaf $V_{c,max25}$ clustered near the equator showed less seasonal variations. In particular, in these sub-
 435 regions close to the equator, the seasonal pattern of the young leaf $V_{c,max25}$ was bidirectional. The first peak
 436 occurred in approximately March, while the second peak occurred in August (Fig. 8a, d, e, g). These results
 437 were in good agreement with previous studies (Li et al., 2021) that reported a single peak at high latitudes
 438 and bidirectional seasonality at low latitudes.

439
 440 **Figure 6.** Comparison of sub-regions of the young leaf $V_{c,max25}$ (a-c) with those of climatic factors classified
 441 by the K-means clustering analysis (d-f) analyzed by Chen et al. (2021), and those of the Leaf-age-dependent
 442 leaf area index seasonality product (Lad-LAI) (g-i) developed by Yang et al. (2023).

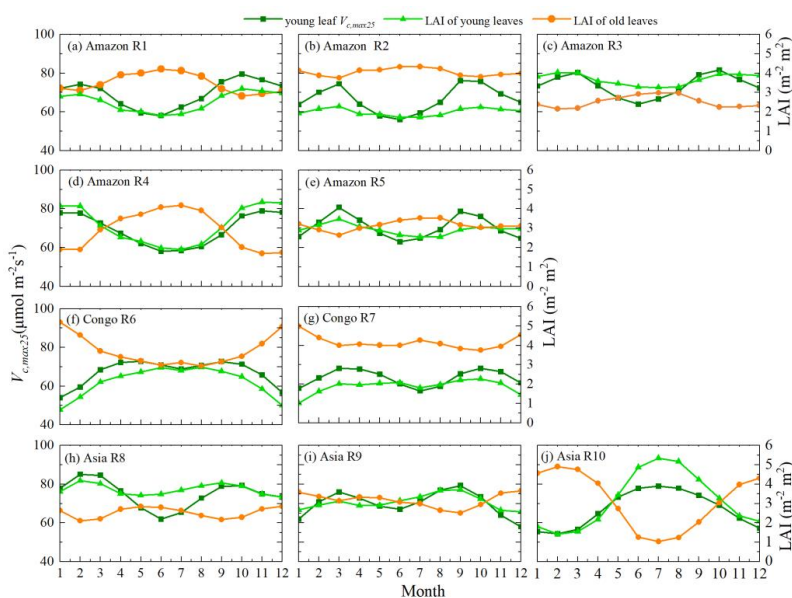

443

444

445 **Figure 7.** Spatial maps of the correlation coefficient (R) between the monthly simulated $V_{c,max25}$ and the Leaf-
 446 age-dependent leaf area index seasonality product (Lad-LAI) developed by Yang et al. (2023).
 447

448

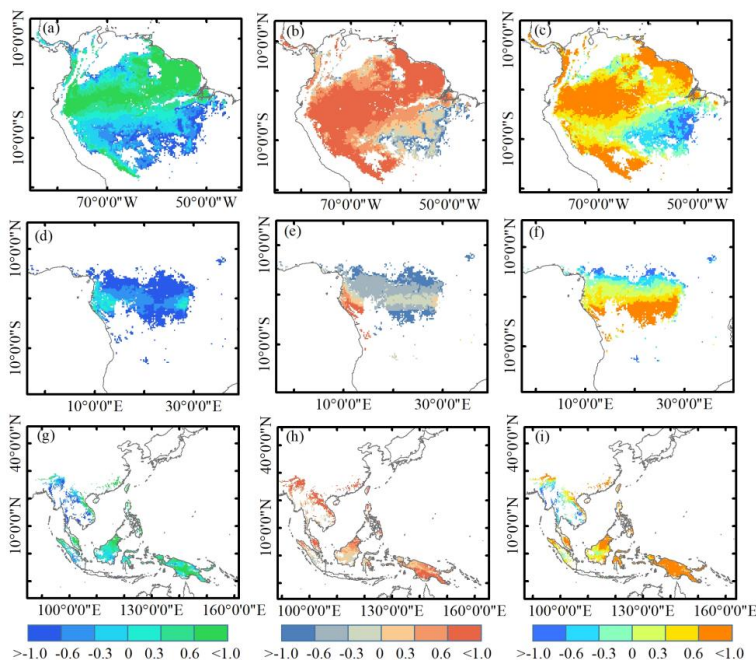

449 **Figure 8.** Seasonality of the simulated $V_{c,max25}$ of young leaves in comparison with the Leaf-age-dependent
 450 leaf area index seasonality product (Lad-LAI) developed by Yang et al. (2023).
 451

452 3.4 Partial correlations between the seasonal $V_{c,max25}$ of young leaves and individual 453 climatic factors

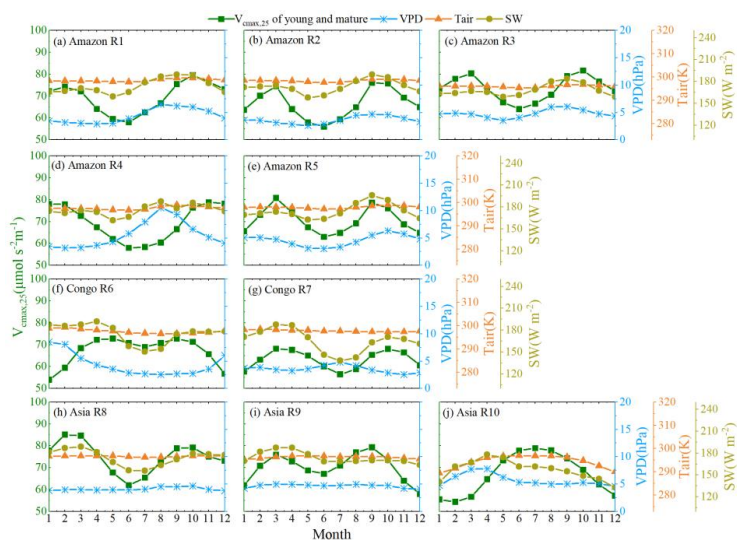

454 To assess potential impacts of the climatic seasonality on $V_{c,max25}$ of young leaves, we also conducted
 455 spatial clustering analyses on climate factors such as vapor pressure deficit (VPD), air temperature (T_{air}), and
 456 downward shortwave solar radiation (SW) (Fig. 8d-f), which were found to be key drivers of leaf phenology
 457 in TEFs (Li et al. 2021; Yang et al., 2021; 2023). Notably, the spatial patterns of the young leaf $V_{c,max25}$
 458 generated from satellite-derived vegetation signals (Fig. 8a-c), closely matched the patterns derived from
 459 independent climate variables such as T_{air} , VPD and SW (see Fig. 8). There was a notable positive correlation
 460 between the SW and $V_{c,max25}$ across most parts of TEFs (Fig. 9). The correlation coefficients exceeded 0.34
 461 in all cases except in the Amazon sub-region R4, where the correlation coefficient was only 0.167. These
 462 results highlight the significant role of SW in influencing the canopy photosynthesis in TEF. Although the
 463 seasonal fluctuations in temperature were less distinct (Fig. 10), possibly due to minor variations in

464 temperature gradients, a substantial positive correlation was observed between the temperature and young
 465 leaf $V_{c,max25}$ (**Fig. 9**). This correlation surpassed 0.608 in the Amazon sub-regions R1-R3 and R5 and the Asia
 466 sub-regions R9 and R10 (**Fig. S6**). Conversely, a negative correlation, with a mean correlation coefficient of
 467 -0.64, was noted in the sub-region R6 of the Congo (**Fig. S6**). These findings were in agreement with earlier
 468 investigations and indicated that air temperature significantly impacted the seasonal dynamics of $V_{c,max25}$
 469 (Zhou et al., 2015). The relationship between the young leaf $V_{c,max25}$ and VPD considerably varied across the
 470 different sub-regions (**Fig. 8**), indicating complex influences of the VPD on canopy photosynthesis in TEFs.
 471 This variability was mainly due to the seasonal variations in canopy leaf age, which aged during the rainy
 472 season and became rejuvenated during dry seasons (Li et al., 2021; Yang et al., 2021; 2023). As a result, the
 473 seasonality of leaf photosynthetic capacity tended to show an inverse trend to the seasonality of the leaf age,
 474 as expected (Chen et al., 2020).

475
 476 **Figure 9.** Spatial maps of correlation coefficient (R) between the SIF-simulated monthly $V_{c,max25}$ and climatic
 477 and phenological patterns. a, d and g are the spatial maps of correlation coefficient between $V_{c,max25}$ and vapor
 478 pressure deficit(VPD); b, e and h are the spatial maps of correlation coefficient between $V_{c,max25}$ and air
 479 temperature(T_{air}); c, f and i are the spatial maps of correlation coefficient between $V_{c,max25}$ and downward
 480 shortwave solar radiation(SW)
 481

482
 483 **Figure 10.** Seasonality of $V_{c,max25}$ of young leaves, air temperature (T_{air}), vapor pressure deficit (VPD) and
 484 downward shortwave solar radiation (SW) in the ten sub-regions classified using the K-means clustering
 485 analysis method.

486

487 3.5 Testing potential uncertainties in the young leaves $V_{c,max25}$

488 The seasonal variations in the young leaf $V_{c,max25}$ using 4×4 neighboring pixels were closely aligned
 489 with those observed in the 0.25° products utilizing a grid of 2×2 pixels (**Fig. S7**). Results showed a highly
 490 linear correlation between the simulated 0.25° resolution and 0.5° resolution consistent ($R > 0.995$), with the
 491 root mean square error (RMSE) being maintained below 0.66 (**Fig. 11**). This evidence supported the concept
 492 that the neighbor-based decomposition approach was both robust and dependable for producing the $V_{c,max25}$
 493 products at various spatial resolutions.

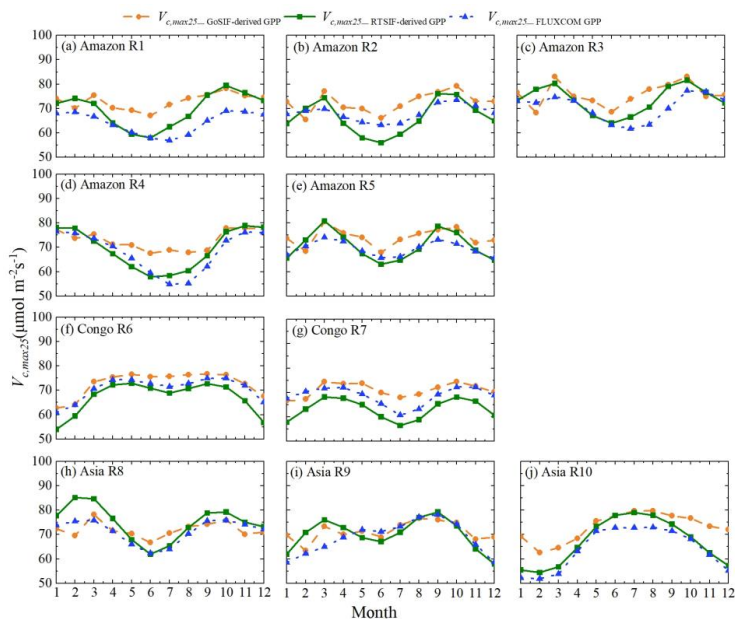

494 Three differentiated versions of the young leaves $V_{c,max25}$ products were produced from RTSIF-, GOSIF-
 495 and FLUXCOM-derived GPP at various spatial resolutions (**Figs. S8-10**). Despite minor differences, all these
 496 $V_{c,max25}$ products exhibited high spatial correlations (**Fig. 12**). Notably, all three products demonstrated
 497 remarkable similarities in the overall geographic patterns (R ranged from 0.87 to 0.963, $P < 0.001$) (**Fig. 13**).
 498 The seasonality of the simulated $V_{c,max25}$ from various GPP products aligned well across all the ten sub-
 499 regions (**Fig. 12**). By comparing these datasets with the in situ observation sites, we found that the $V_{c,max25}$
 500 generated from RTSIF-derived GPP had the highest correlation and a minimal deviation against the in situ
 501 measurements, with R equal to 0.85 and RMSE equal to 13.69 (**Fig. 13**). Overall, all three versions of the
 502 young leaf $V_{c,max25}$ products demonstrated consistent seasonal variability and effectively performed across
 503 the ten sub-regions.

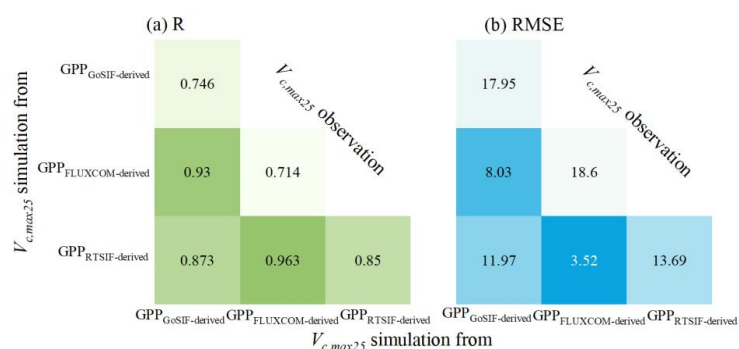

504

505 **Figure 11.** Scatter plots between the simulated $V_{c,max25}$ of young leaves simulated using the 2×2 (0.25°
 506 resolution) and 4×4 (0.5° resolution) neighboring pixels in the above-mentioned ten clustered sub-regions.

 517

518 4. Discussion

519 Tropical forests, marked by no obvious seasonal shifts in greenness but distant variations in leaf age
 520 cohorts (Luo et al., 2021; Zhao et al., 2019; Walther et al., 2019), show distinct leaf phenology compared
 521 with temperate and boreal forests. The young leaves are the main leaf cohort to influence photosynthesis

522 (Oliveira et al., 2023; Sharma et al., 2017; Antwi-Boasiako et al., 2011), as previous studies showed that the
523 photosynthesis rates decrease with leaf aging (Menezes et al., 2022; Wang et al., 2020). Thus, understanding
524 the mechanism by which the leaf age influences photosynthesis is crucial for assessing plant growth,
525 ecosystem primary productivity, and the carbon cycle in evergreen forests. (Albert et al., 2018). The leaf
526 carboxylation capacity ($V_{c,max25}$) is crucial for estimating the photosynthetic CO₂ absorption in tropical forests
527 within ESMs. However, most ESMs currently adopt either a single static or an average annual value to
528 represent the $V_{c,max25}$ for each plant functional type (Stocker et al., 2020; Spafford et al., 2023). This empirical
529 practice causes uncertainties in tropical forest biomes, which are characterized by their extensive plant
530 functional diversity (Echeverría-Londoño et al., 2018; Spicer et al., 2022) and variable photosynthetic
531 capacity (Piao et al., 2019; Pinheiro et al., 2023). Additionally, $V_{c,max25}$ for a certain plant species can also
532 vary significantly with leaf aging, ambient growth temperatures, and the availability of water and nutrients
533 (Stefanski et al., 2022; Lu et al., 2022; Crous et al., 2022;). Thus, seasonal variations in the photosynthesis in
534 tropical evergreen forests are impacted by the turnover of old leaves with low $V_{c,max25}$ values and their
535 replacement by new leaves with higher $V_{c,max25}$ values (Wang et al., 2021; Murphy et al., 2020; Abdul et al.,
536 2016). These findings highlight the importance of accurately quantifying the leaf age and integrating the leaf
537 age information when estimating $V_{c,max25}$ to improve the modeling of the leaf CO₂ assimilation in tropical
538 forests. However, to the best of our knowledge, to date, no comprehensive continental-scale data are available
539 on the leaf age-dependent $V_{c,max25}$ variations throughout tropical evergreen forests. This data gap remains
540 because these variations cannot be adequately mapped by the limited field observations (Hakala et al., 2019)
541 or reliably modeled by ESMs that depend on uncertain climatic variables (Brunner et al., 2021). These
542 challenges prevent researchers worldwide from using remote sensing techniques and land surface models
543 (LSMs) to accurately model the seasonality of large-scale photosynthesis (GPP) (Krause et al., 2022).

544 In this study, we for the first time to provide the continental-scale monthly gridded $V_{c,max25}$ of young
545 leaves. Based on the newly developed $V_{c,max25}$ product. Additionally, the seasonality of the young leaf $V_{c,max25}$
546 has been effectively evaluated at four locations—CN-Din site in southern China, MDJ-03 site in Congo, and
547 BR-Sa1 and GF-Guy sites in southern America—using the precise, detailed records of the young leaf $V_{c,max25}$.
548 To evaluate the reliability of the gridded young leaf $V_{c,max25}$ across the entire TEFs, the seasonality of the
549 young leaf $V_{c,max25}$ was also validated pixel by pixel using the dissolved method from the gridded GPP and
550 the leaf age product developed by Yang et al. (2021). The results demonstrated a substantial variation in the
551 $V_{c,max25}$ with leaf age, with observed fluctuations (ranging from 40 $\mu\text{mol m}^{-2} \text{s}^{-1}$ to 90 $\mu\text{mol m}^{-2} \text{s}^{-1}$) closely
552 aligning with variations outlined for tropical and subtropical regions in current ESMs, as described by Rogers
553 (2014). These results show the critical need for including age-dependent variations of the $V_{c,max25}$ in future
554 ESM designs. Additionally, the $V_{c,max25}$ values derived from the combined leaves of these updated
555 photosynthesis products can effectively capture the widespread greening of the canopy leaves during the dry
556 season north of the equator. This represents a significant improvement in our capacity to promptly assess and
557 potentially map the $V_{c,max25}$ with high spatial and temporal accuracy in tropical forests. The robustness of
558 these new photosynthesis products has been supported through both direct and indirect assessments.

559 Importantly, in equatorial regions characterized by high annual rainfall, no marked dry seasons typically
560 occur. As a result, variations in the tree canopy phenology are subtler than those observed at higher latitudes
561 (Yang et al., 2021). In these areas, $V_{c,max25}$ of the leaf cohorts display a bimodal phenology pattern with
562 minimal seasonal fluctuation, a phenomenon that is effectively captured by the newly developed
563 photosynthesis product. To convert the SIF data into GPP, a constant coefficient was used, and $V_{c,max25}$ was
564 assumed to be uniformly distributed across all tropical evergreen forests, potentially introducing further
565 uncertainties. This assumption was reflected in the MSD assessment, where the bias component was

566 predominant, especially near the equator. Nevertheless, the impact of this on the seasonality of photosynthesis
567 was minima; because the phase-dependent component of the RMSE remained relatively insignificant.

568 The “leaf demographic-identical (LDO)” hypothesis categorizes the leaf cohorts into three distinct age
569 classes: new leaves (from 1 to 60 days), mature leaves (from 60 to 180 days), and old leaves (larger than 180
570 days), with corresponding mean $V_{c,max25}$ values as reported by Wu et al. (2016). To facilitate a more effective
571 comparison between the observations and models, we categorized the leaves into two age groups. Leaf ages
572 greater than 6 months are classified as a distinct old leaf class, as per Harris et al. (2007), while leaf ages less
573 than 6 months are combined into a single young leaf class. Juliane et al. (2021) reported that the average
574 $V_{c,max25}$ of mature plants (60-180 days) was the highest. However, the older age classes had values of $30.4 \pm$
575 1.2 (234–612 days). The $V_{c,max25}$ of the young leaves was 23% greater than that of old leaves, with minimal
576 fluctuations observed in the latter group. The link between the older leaves and $V_{c,max25}$ is less understood in
577 TEFs due to limited field data (Chen et al., 2020). To address these simulation challenges, we defined $V_{c,max25}$
578 for old leaves as a consistent static value; however, this could lead to inaccuracies in predicting
579 photosynthetic performance. This approach affects the accurate depiction of $V_{c,max25}$ and GPP seasonality in
580 ESMs (De Weirdt et al., 2012). Moreover, additional uncertainties stem from assumptions that neglect the
581 spatial and temporal variations influenced by the plant functional type variability, which shifts with seasonal
582 climate anomalies and varies within close proximity in diverse forest ecosystems. These generalizations
583 could also contribute to inaccuracies in simulating seasonal variations in $V_{c,max25}$. Reflecting the inherent
584 variability in photosynthetic behavior across ages, the data revealed two distinct responses: (1) some species,
585 such as *P. tomentosa* and *P. caimito*, showed marked reductions in $V_{c,max25}$ as they aged, whereas (2) others,
586 such as *M. angularis* and *V. parviflora*, maintained consistent $V_{c,max25}$ values after peaking. Juliane et al. (2021)
587 reported a modest yet significant correlation between the $V_{c,max25}$ and leaf age due to these contrasting patterns.
588 Variations in the photosynthetic capacity at the ecosystem level could be influenced by factors such as the
589 composition of species and the presence and proportion of different functional groups of plants in the forest.

590 In summary, we have presented a novel approach to develop a gridded dataset that incorporates leaf age
591 sensitivity into the photosynthesis products for TEFs on a continental scale. Although some uncertainties
592 remain, a monthly gridded young leaf $V_{c,max25}$ dataset is provided. This innovation facilitates the development
593 of a comprehensive phenological modeling approach for all TEFs within ESMs, which are traditionally
594 operated at coarser resolutions. These improvements substantially enhance our ability to monitor and
595 mechanistically interpret the variations in the $V_{c,max25}$ of young leaf across various regions and periods,
596 providing essential data for the parameterization and assessment of ESMs. Additionally, as remote sensing
597 technologies continue to advance, we anticipate that the enhanced temporal and spatial resolution of RTSIF-
598 derived GPP will facilitate more accurate mapping of the photosynthesis products in the future.

599

600 5. Data availability

601 The 0.25 degree time-series $V_{c,max25}$ data from 2001-2018 is presented in this paper as the main dataset.
602 We also provided another two versions of $V_{c,max25}$ generated from GOSIF-derived GPP and FLUXCOM GPP,
603 respectively. The three datasets are available at <https://doi.org/10.5281/zenodo.14807414> (Yang et al., 2025).
604 These datasets are compressed in a GeoTiff format, with a spatial reference of WGS84. Each file in these
605 datasets is named as follows: “ $V_{c,max25}_{\{GPP\ source\}}derived_{\{YYYYMM\}}.tif$ ”.

606

607 6. Conclusions

608 This study for the first time to develop a monthly gridded dataset of $V_{c,max25}$ of young leaves from 2001
609 to 2018 based on RTSIF data. The $V_{c,max25}$ of young leaves simulated from RTSIF-derived GPP was assessed
610 against in situ observations of the monthly $V_{c,max25}$ records, the $V_{c,max25}$ product dissolved from the GOSIF-

611 derived GPP, and the leaf age product L_{ad} -LAI (Yang et al., 2023). Evaluations from these independent leaf-
612 age-related data demonstrated the reliability of the seasonal $V_{c,max25}$ simulations for the young leaf cohorts.
613 Additionally, the $V_{c,max25}$ of young leaves varied across TEFs. In the middle and southern regions of the
614 Amazon, the young leaf $V_{c,max25}$ decreased with the onset of the wet season (approximately February) and
615 conversely increased with the onset of the rainy season (approximately June). In contrast, in subtropical Asia,
616 the young leaf $V_{c,max25}$ increased during the wet season, peaking in June or July when rainfall was highest.
617 Near the equator, the young $V_{c,max25}$ showed a bimodal seasonality with very slight variations. The $V_{c,max25}$
618 products of young leaves can provide useful information to improve our understanding of how tropical and
619 subtropical forests are adapting to ongoing climate change. and can be used to refine the phenology models
620 incorporated into LSMs.
